(C) Fig. 15.35A is a further variation in which R and C form a potential divider across the output from V_2 . At increasing frequencies a larger negative feedback voltage is applied, the amount being limited by the variable resistance R . C_1 is a blocking condenser (Ref. 63).

(D) For feedback over more than one stage, see Sect. 9.

SECTION 7 : COMBINED TREBLE TONE CONTROLS

Treble controls giving a choice of treble boosting or treble attenuation without also incorporating bass boosting or attenuation are comparatively rare. Attention is directed to Sect. 8 and Figs. 15.37A, 15.37B, 15.39, 15.40, 15.46.

One example in this class is Fig. 15.35B which provides continuously-variable tone control from treble boost to treble attenuation by means of a resistor-capacitor network in the feedback circuit (Ref. 67).

SECTION 8 : COMBINED BASS AND TREBLE TONE CONTROLS

(i) Stepped controls—general (ii) Quality switch (iii) Universal step-type tone control not using inductors (iv) Universal step-type tone control using inductors (v) Fixed bass and treble boosting (vi) Step-type tone control using negative feedback (vii) Continuously-variable controls—general (viii) Single control continuously-variable tone controls (ix) Ganged continuously-variable tone controls (x) Dual control continuously-variable tone controls.

(i) Stepped controls—general

Stepped controls are capable of better performance than continuously variable controls, partly because it is possible to vary two or more component values simultaneously and partly because the attenuation at middle frequencies may be adjusted so as to avoid an apparent change in volume as the control is moved. For most radio purposes it is sufficient to have two control knobs, one controlling the bass and the other the treble, with five positions on each—one “flat,” two boosting and two attenuating with alternative degrees of each.

(ii) Quality switch

An alternative arrangement which is very effective with the non-technical public is to select suitable values for each type of listening conditions. For example, one manufacturer* has brought out a model with an 11 position tone control as under :

1. for distant stations, extremely noisy—maximum sensitivity (10% feedback), bass normal, treble attenuation severe to counteract static and noise.
2. for distant stations, noisy—maximum sensitivity, bass normal, treble attenuation less severe.
3. for distant stations, less noisy—maximum sensitivity, bass normal, treble attenuation still less.
4. for distant stations, still less noisy—maximum sensitivity, bass normal, treble attenuation slight.
5. for distant stations, slight noise—maximum sensitivity, bass normal, no treble attenuation.
6. for local stations with good fidelity at low volume—reduced sensitivity (25% feedback), bass boost, treble boost.
7. for fidelity at medium volume—slight treble boost, less bass boost.
8. for fidelity at normal volume—no treble boost, no bass boost.
9. for fidelity at normal volume but reducing needle scratch—slight treble attenuation, no bass boost.
10. as (9) but increased treble attenuation.
11. as (10) but increased treble attenuation.

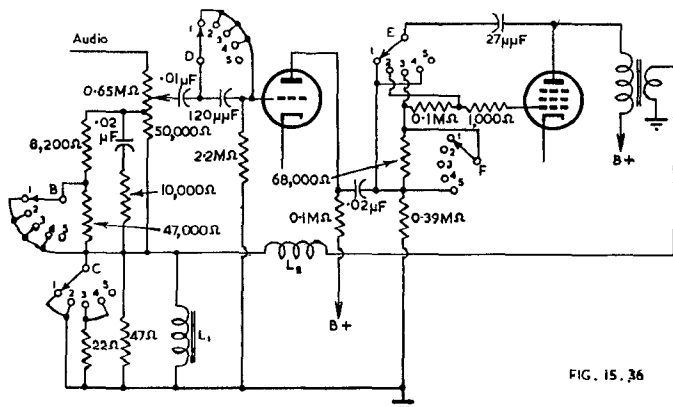

Fig. 15.36. One form of Quality Switch (Ref. 33).

An alternative form using a 5 position switch is shown in Fig. 15.36 (Ref. 33). The switch positions are

1. heavy bass attenuation and very limited treble attenuation for very distant reception, no feedback.
2. normal bass, heavy treble attenuation, no feedback.
3. bass attenuation, medium treble attenuation, half feedback.
4. normal bass, slight treble attenuation, half feedback.

Note : Positions 1 to 4 inclusive are for use with narrow i-f bandwidth.

5. normal bass, no treble attenuation, maximum feedback, wide i-f bandwidth, for fidelity reception of local stations.

At low settings of the tapped volume control the capacitance in series with the inductance provide a dip at middle high frequencies, thus effectively giving bass and treble boost.

*Columbus Radio (Radio Corporation of New Zealand Limited).

(iii) Universal step-type tone control not using inductors

A simple form is shown in Fig. 15.37A where treble boost is obtained by by-passing (C_1), treble attenuation by shunt capacitance (C_4), bass attenuation by grid coupling condenser (C_3), and bass boosting by the conventional method (C_2). Each of these may have two or three values— C_1 may be 0.01, 0.02, 0.03 μF ; C_2 may be 0.0025, 0.006 μF ; C_4 may be 0.002, 0.005 μF ; C_3 may be 0.02, 0.05, 0.1 μF .

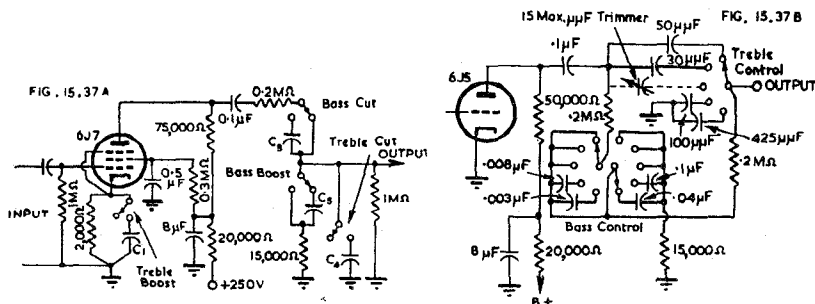

Fig. 15.37A. Simple universal tone control not using inductors.

Fig. 15.37B. Step-type tone control not using inductors (Ref. 70).

An improved form is given in Fig. 15.37B and its frequency characteristics in Fig. 15.37C (Ref. 70). The 15 μF max. trimmer capacitor is for the purpose of compensating in the "flat" position for the loss of high audio frequencies caused by stray shunt and Miller Effect capacitances when the following stage is a triode.

(iv) Universal step-type tone control using inductors

The treble boosting circuit of Fig. 15.30 may be used, combined with treble attenuation by shunt capacitance and conventional bass boosting and attenuation.

A typical example is Fig. 15.40 (Ref. 64; see also Refs. 17, 54, 55). The nominal slope is 6 db/octave for all positions, but the capacitances and inductances may be selected to give any desired frequencies for the commencement of attenuation or

FIG. 15.40

Fig. 15.40. Universal step-type tone control using inductors.

boosting. The inductor may be wound with an air-core as under : Former diameter $\frac{3}{4}$ in. Length between cheeks $\frac{1}{2}$ in. Winding wire 40 S.W.G. (or 36 A.W.G) SSE. Total turns 6740, tapped at 4520 turns. Layer wound. Total radial depth of winding say 0.6 in.

One defect of this method of treble boosting is the tendency for the inductor to pick up hum.

(v) Fixed bass and treble boosting

When it is desired to incorporate a fixed amount of bass and treble boosting, as for example equalizing the response of a pair of headphones, the circuit of Fig. 15.41 may be used. For headphone equalizing (Ref. 7) suitable values are $C_1 = 0.0003$, $C_2 = 0.015 \mu\text{F}$, $R_1 = R_4 = 0.1 \text{ M}\Omega$, $R_5 = 0$. For bass and treble boost for tone control suitable values are (Ref. 25) :— $C_1 = 0.0002 \mu\text{F}$, $R_1 = 0.2 \text{ M}\Omega$, $R_4 = 0.3 \text{ M}\Omega$, $R_5 = 0$, giving 16 db bass boost (20 c/s) and 7 db treble boost (10 000 c/s) relative to 1000 c/s. If $R_5 = 50\,000$ ohms, other values being unchanged, the bass boost is 16 db and treble boost 12 db.

(vi) Step type tone control using negative feedback

Circuits providing universal step-type tone control using negative feedback are described in Sect. 9 (Fig. 15.58A).

(vii) Continuously-variable controls—general

Continuously-variable controls are in two groups, those which have one control knob and those which have two or more. A single control knob is obviously limited in its capabilities—for example it may be used to provide bass boosting when turned in one direction from the centre point, or treble boosting in the other direction, with flat response at the centre point. On the other hand, with two control knobs it is possible to make any desired combination of bass and treble characteristics.

FIG. 15.41

Fig. 15.41. Circuit giving fixed bass and treble boosting (Ref. 7).

FIG. 15.42

Fig. 15.42. Single control continuously variable tone control (Ref. 22).

(viii) Single-control continuously variable tone controls

(A) A typical example is Fig. 15.42 (Ref. 22). When C_1 goes to the grid end of potentiometer R_2 , the bass is attenuated by the grid coupling condenser C_1 , limited by R_1 . When C_1 goes to the earthed end of R_2 , the treble is attenuated by the shunt capacitance of C_1 .

two twin triodes form the "cross-coupled phase inverter"—see Chapter 12 Sect. 6(viii)—which is here used to amplify the difference between the input voltages to the 6SN7 grids. The frequency response curves are shown in Fig. 15.43B for different values of R_1 . The maximum output and the point of zero phase shift occur at $f/f_0 = 1$, where $f_0 = 1/2\pi RC$. The frequency of the peak in the curve may be determined by choice of R and C ; in the circuit shown, this frequency is adjustable from 360 to 4000 c/s by means of a dual 1 M Ω potentiometer. A choice of $f_0 = 600$ to 800 c/s is pleasing in many cases.

(ix) Ganged continuously-variable tone controls

Two or more controls may be ganged and operated by a single knob. One control may be the tone control and the other a control of gain so that the apparent output level is held approximately constant at all settings.

(x) Dual control continuously-variable tone controls

(A) Simple duo-control circuit, Fig. 15.44A (Ref. 22)

This filter incorporates resistors and condensers only, and R_3 controls the bass and R_4 the treble. A filter having a similar function is also described in Ref. 31.

A slight modification of this circuit is Fig. 15.44B which gives either bass or treble boosting (Ref. 41).

Fig. 15.44A. Simple duo-control circuit giving individual control of bass and treble. Typical values are: $R_1 = 0.25$ M Ω ; $R_2 = R_3 = 0.5$ M Ω ; $R_4 = 0.25$ M Ω ; $R_5 = R_6 = 0.5$ M Ω ; $C_1 = 0.01$ μ F; $C_2 = 0.001$ μ F (Ref. 22).

Fig. 15.44B. Simple tone control giving bass and treble boosting (Ref. 41).

(B) Duo-control circuit incorporating L and C (Fig. 15.45, Ref. 26)

In this filter, R_1 controls the bass and R_3 the treble. Hum may be troublesome on account of L .

(C) Cutler duo-control circuit (Fig. 15.46, Ref. 26)

This filter may only be used to feed into the grid of an amplifier valve; R_4 controls the bass boost and R_3 the treble boost. The maximum boost is 17 db at 40 c/s and 15 db at 10 000 c/s, relative to 1000 c/s, with the values shown.

Fig. 15.45. Duo-control circuit incorporating L and C (Ref. 26).

Fig. 15.46. Cutler duo-control circuit (Ref. 26).

(D) Paraphase bass-treble tone control (Figs. 15.47A, Ref. 56)

This is an outstandingly flexible circuit which may be designed for any cross-over frequency—400 c/s in Fig. 15.47A and the curves in Fig. 15.47B. The design procedure is :

1. Choose a cross-over frequency f_c .
2. Choose $R \geq 10R_L$ where R_L = generator impedance.
3. Make $C = 1/(2\pi f_c R)$.
4. Make $K = 10$; then $KR = 10R$ and $C/K = C/10$.

Example : Choose $f_c = 400$ c/s. Say generator impedance = 1000 ohms, then select

$R = 82\,000$ ohms, from which

$C = 1/(2\pi \times 400 \times 82\,000) = 0.005\ \mu\text{F}$; $C/K = 0.0005\ \mu\text{F}$.

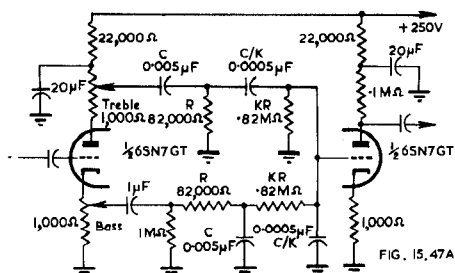

FIG. 15.47A

Fig. 15.47A. Paraphase bass-treble tone control (Ref. 56).

FIG. 15.47B

Fig. 15.47B. Frequency characteristics of paraphase bass-treble tone control (Fig. 15.47A) (Ref. 56).

(E) Two-stage bass and treble tone control (Fig. 15.48, Ref. 41)

This employs a twin triode with the treble boost control in the coupling from V_1 to V_2 and the bass boost control in the coupling from the plate of V_2 to the following stage.

(F) Simple two channel amplifier (Fig. 15.49, Ref. 22)

Owing to the separate amplifier valves, this circuit does not require the series resistors R_3 and R_4 used in Fig. 15.44 and has thereby less attenuation in the filter network.

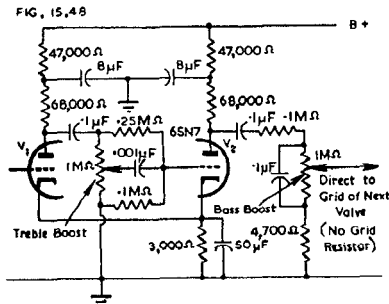

Fig. 15.48. Two-stage bass and treble tone control (Ref. 41).

Fig. 15.49. Simple two channel amplifier (Ref. 22).

(G) Wide-range two-channel amplifier (Fig. 15.50, Ref. 31)

In this circuit V_1 is an amplifying valve common to both channels, V_2 is a bass amplifier only, while V_3 is a twin triode having one grid fed from the bass amplifier and the other from V_1 through a filter network which only passes the higher frequencies. However two plates of V_3 are approximately equal in amplitude for all frequencies, owing to the common cathode coupling, and opposite in phase, so that the output may be applied directly to a push-pull power output stage. The bass amplifier V_2 is a true bass booster, so that it is not necessary to attenuate all except bass frequencies. The two controls provide (1) flat response (2) independent treble boost (3) independent bass boost equal to the gain of V_2 . If it is desired to add treble attenuation, the filter circuit of Fig. 15.51 may be used. This gives a flat response when the moving arm of the potentiometer is at the centre tap.

Fig. 15.50. Wide-range two-channel amplifier (Ref. 31).

(H) Resonant plate loading (Fig. 15.52, Refs. 26, 54)

Two parallel tuned circuits, one of which may be tuned to 50-80 c/s and the other to 6000-8000 c/s (or any other desired frequencies) are connected in series with the

Fig. 15.51. Modification to Fig. 15.50 to provide treble attenuation (Ref. 31).

Fig. 15.52. Resonant plate loading to provide bass and treble boost (Refs. 26, 54).

plate load resistance R_3 . Control of the bass is given by R_1 and of the treble by R_2 . The Q of each of these circuits should not exceed 1—see Sect. 1(ix).

(I) Negative feedback incorporating L and C in cathode circuit (Fig. 15.53, Ref. 26)

Feedback provides degeneration across R_1 and R_2 , which determines the gain at middle frequencies. With L and C connected directly across R_1 and R_2 , the feedback is decreased at low and high frequencies respectively and the stage gain is consequently greater at these frequencies. L may require shielding to reduce hum pickup.

Fig. 15.53. Bass and treble boosting due to negative feedback incorporating L and C in cathode circuit (Ref. 26).

Fig. 15.54. Bass and treble boosting due to negative feedback incorporating L and C (Ref. 15).

(J) Negative feedback incorporating L and C (Fig. 15.54, Ref. 15)

V_1 is a power amplifier valve with L_1 and C_2 and their control potentiometers in the feedback network. L_1 may have an inductance of about 10 henrys and C_2 may be $0.002 \mu\text{F}$; $R_3 = R_4$ may be 0.1 megohm.

(K) Patchett tone control (Fig. 15.55, Ref. 9)

This circuit has been developed to provide continuously-variable independent bass and treble boost without variation of the middle frequencies and at the same time with frequency characteristics which are close to the ideal for tone control purposes. V_1 is a phase splitter and develops equal voltages across its plate and cathode load resistances. The former feeds directly through an isolating resistor to the output; the latter feeds the bass and treble filters and potentiometers which in turn feed the grids of the twin triode V_2 whose plates are connected to the output. The output voltage at middle frequencies is about one third of the input voltage. An input of 2.5 volts r.m.s. may be applied with negligible distortion. V_1 may be type 6C5 or 6J5; V_2 may be type 6N7 or other twin triode.

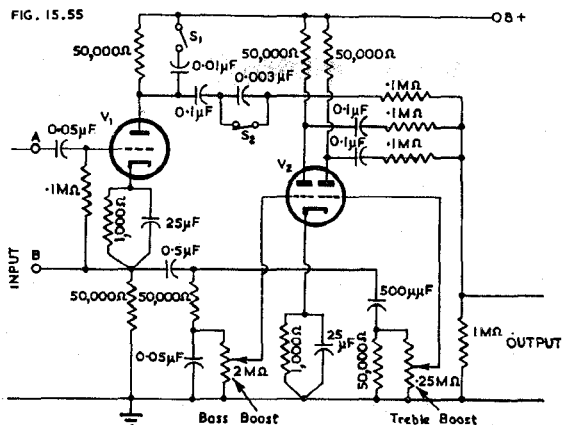

Fig. 15.55. Patchett tone control circuit (Ref. 9).

Fig. 15.56A. Response characteristics of Patchett tone control circuit with S_1 open and S_2 closed, and other control at minimum (Ref. 9).Fig. 15.56B. Response characteristics of Patchett tone control circuit with S_1 closed and S_2 open (Ref. 9).

Fig. 15.56A shows the response characteristics without provision for bass or treble attenuation; Fig. 15.56B shows the response with bass and treble attenuation.

If desired, step switches may be arranged to give a wider choice of frequency characteristics by changing the values of the filter condensers.

(L) Two-stage universal tone control (Fig. 15.57A, Ref. 77)

This is a very effective arrangement incorporating a twin triode, which gives entirely independent control of both bass and treble with control extending over a wide range of boosting and attenuation in each case (Fig. 15.57B). The overall gain of the amplifier of Fig. 15.57A at 800 c/s is only slight.

Fig. 15.57A. Two stage universal tone control (Ref. 77).

Fig. 15.57B. Response characteristics of Fig. 15.57A (Ref. 77).

SECTION 9: FEEDBACK TO PROVIDE TONE CONTROL

(i) *Introduction* (ii) *Amplifiers with feedback providing tone control* (iii) *Whistle filters using feedback.*

(i) Introduction

Simple feedback circuits to give tone control have been described above (Figs. 15.11, 13, 14A, 14B, 15, 35B). See also Ref. 80. Tone control may be achieved by incorporating a suitable frequency selective network in the feedback loop, but this involves the question of stability if the feedback is over 2 or more stages—in this case the design should be based on Chapter 7 Sect. 3.

The general principles have been covered very fully in the literature e.g. Refs. 16, 19 (see also References Chapter 7).

In any amplifier in which negative feedback tone control is to be used, maximum freedom in other aspects of the design is desirable. For example it should be possible to alter the feedback factor, and a variation in the feedback over the a-f range should be acceptable. It is also desirable not to be limited to a specified value of output resistance. The feedback should preferably be applied over a small number of stages.

In the case of fidelity amplifiers, there should be sufficient negative feedback at the bass resonant frequency of the loudspeaker to give adequate damping.

Most tone-control amplifiers are only stable for values of β up to a limiting value. One good experimental test is to determine the maximum of β before instability occurs. The working value of β should be less than this limiting value by a comfortable margin (say 8 to 10 db) to allow for all variable factors and for tolerances in the various components.

(ii) Amplifiers with feedback providing tone control

(A) Dual Control continuously variable bass and treble tone control

A simple but effective circuit is shown in Fig. 15.57C and its frequency characteristics in Fig. 15.57D (Ref. 91). Figs. 15.57C and 15.57D will be found on page 1483. The mid-frequency gain is approximately unity, and the output is 4 V r.m.s. (or 1 V r.m.s. with low gain valve) with not more than 0.1% total harmonic distortion up to 5000 c/s. An Americanized form is given in Ref. 98.

A more elaborate circuit is given in Ref. 84.

(D) The use of feedback to provide special attenuation characteristics at low or high frequencies

If an amplifier is designed with a falling low frequency characteristic, possibly due (in part) to economy in the output transformer design, and negative feedback is applied over the amplifier, its response can readily be made flat or, owing to a phase shift caused by coupling capacitors and by the inductance of the output transformer, the response may rise at those frequencies where it fell without feedback.

If in such an amplifier one of the grid coupling capacitors (included in portion of the amplifier covered by the feedback loop) is replaced by one of smaller capacitance, the feedback will tend to counteract the attenuation produced by this capacitor. The response will be more or less flat down to a certain frequency below which the attenuation will be rapid.

Fig. 15.58B. Use of feedback to provide special attenuation characteristics at low frequencies. The total effective resistance across T_1 primary is taken as 1000 ohms. Switch S_1 normal; S_2 tone control (low frequency attenuation). Switch S' controls feedback.

Some practical response characteristics are described below, based on a theoretical analysis of Fig. 15.58B (after E. Watkinson) :

(a) To provide rapid low frequency attenuation below a specified frequency f_0 . (Curves are in Fig. 15.58C)

1. Design the amplifier so that the response without feedback and without tone control is only slightly down at f_0 , say -6 db (100 c/s in Curve A).

2. Design the tone control to provide a total attenuation, without feedback, of about 3 db at $10 f_0$ (Curve D).

3. Apply sufficient negative feedback to flatten the response over the desired frequency range (Curve C). In the example, 20 db of feedback is used, and the combined effect is to give an attenuation of 18 db in the octave from 100 to 50 c/s.

(b) To provide optional bass boosting

If now the tone control is switched out of circuit, there will be bass boosting as the result of phase shift in the amplifier (Curve B).

Thus by a single switch S it is possible to change from curve C to curve B, using only one additional component.

Fig. 15.58C. Frequency characteristics of circuit of Fig. 15.58B. (A) No feedback, no tone control; (B) feedback without tone control; (C) feedback with tone control; (D) no feedback, with tone control.

A more satisfactory result over a wider range of volume levels can be obtained by using a volume control with two tappings (e.g. at one sixth and one third of the resistance) as in Ref. 88.

A more elaborate type of continuously-variable control has been described (Ref. 79) but requires a special volume control.

Another more elaborate type (Ref. 82) uses three ganged volume controls which are not tapped.

Fig. 15.60. Step-type tone-compensated volume control for bass correction only (Ref. 43).

(iii) Methods incorporating step-type controls

All the simpler systems with step-type controls neglect the treble boosting, which is only of secondary importance, but they are capable of a fairly close approach to the ideal for the lower frequencies. One design is shown in Fig. 15.60 (Ref. 43) which uses five 6 db filter sections each divided into two parts, thus giving 11 steps with a total range of 30 db. This is for use with an amplifier having low output resistance (less than 10 000 ohms). The numerical values shown in the figure are for $R_1 = 50\ 000$ ohms.

See also Ref. 78 for a design mounted on a single switch assembly, with a greater number of positions.

(iv) **Method incorporating inverse volume expansion with multi-channel amplifier** (Ref. 21)

In Fig. 15.61 there are three amplifier channels. The centre one is essentially flat over the whole a-f range. The upper (high-pass) and lower (low-pass) amplifiers may be adjusted to give zero output at any selected output level (generally the maximum) and at any lower level there will be bass and treble boosting which is a function of the output level. Each of the boosting amplifiers is brought to zero output at the desired output level by adjusting three potentiometers (R_1 , R_2 , R_3 in the bass-boost amplifier). Under these conditions the output voltages of V_1 and V_2 are equal but opposite in phase, hence giving a combined output which is zero.

SECTION 11 : WHISTLE FILTERS

- (i) Resonant circuit filters (ii) Narrow band rejection filter (iii) Crystal filters
(iv) Parallel-T network (v) Filters incorporating L and C.

A whistle filter is one which is sharply tuned to eliminate a particular frequency, usually 9 or 10 Kc/s, with the least possible effect on adjacent frequencies.

The same principles may also be applied to the elimination of scratch from a pickup when this is peaked, but in this case the maximum attenuation is adjusted to occur at the frequency of pickup resonance.

(i) Resonant circuit filters (Ref. 15 62)

The ratio of normal gain (A_n) to gain (A_r) at the resonant frequency of L_1C_1 is

least 8 db over a frequency range from approximately 8000 to 12 000 c/s when $f_r = 10\,000$ c/s. Thus the filter cuts such a serious hole in the amplifier frequency characteristics that it is not a satisfactory solution. It is reasonably satisfactory for a maximum attenuation of 6 db, but this may not be sufficient to eliminate the whistle.

For theory and curves see Refs. 17, 51, pp. 52-54.

(ii) Narrow band rejection filter

A more complicated and more effective circuit is Fig. 15.62A (Ref. 81) which, when tuned to 9000 c/s, gives an attenuation of 2 db at 8000 c/s, over 40 db at 9000 c/s, 8 db at 10 000 c/s and 5 db at 20 000 c/s relatively to the level at low frequencies. The frequency of resonance may be changed either by adjusting the inductance of L_1 , or by varying the capacitance of both C_1 and C_2 . The attenuation at low frequencies (insertion loss) is 2 db.

Fig. 15.62A. Narrow-band rejection filter (Ref. 81).

A narrow band rejection filter is described in Ref. 75 which has the disadvantage of reducing the maximum a-f power output. An improved form for application to a linear reflex detector is Fig. 15.63 in which an attenuation of more than 40 db is obtained at 9000 c/s while the attenuation is only 3 db at 8400 c/s. The principle may also be applied to a cathode-loaded amplifier by omitting C_1 and providing the correct bias for amplification.

The resonant circuit LC_3 is tuned approximately to the whistle frequency, a vernier control for C_3 being desirable. The value of C_1 should be such that its reactance is very much smaller than R_1 at the lowest signal frequency and should be very much larger than R_1 at 9000 c/s. The value of C_2 should be such that its reactance is approximately equal to $R_2 + R_3$ at the low frequency limit of the amplifier, say 50 c/s. If its reactance is higher, a slight amount of bass boosting will occur. The potentiometer R_2R_3 is adjusted to give zero output at the whistle frequency (Ref. 74).

An elaboration of this principle, using two valves, is given in Ref. 83.

(iii) Crystal filters

A crystal filter is one of the few really satisfactory methods of eliminating a whistle, but the cost precludes its use in all except the most expensive communication receivers.

(iv) Parallel-T network

See also Sect. 6(iii)C.

The circuit of Fig. 4.40 may be inserted between two r.c.c. stages with a load resistance of say 0.25 megohm and following grid resistor say 1 megohm. Suitable values for a 10 000 c/s whistle filter are:— $C_1 = C_2 = 0.0001 \mu\text{F}$, $C_3 = 0.0002 \mu\text{F}$, $R_1 = R_2 = 160\,000$ ohms, $R_0 = 80\,000$ ohms.

Fig. 15.63. Narrow-band rejection filter for 9 Kc/s (Ref. 74).

A special application of the parallel-T network is described in Chapter 17 Sect. 5 and Figs. 17.24B and 24C where an attenuation of 34 db at 10 000 c/s with almost flat response up to 6 Kc/s is obtained by means of a parallel-T feedback loop which gives minimum feedback at 6 Kc/s, together with a parallel-T filter across the output of the amplifier to give the desired attenuation at 10 Kc/s (Ref. 57).

The parallel-T network is also used in the equalizer circuit of Fig. 17.35B and in the filter unit of Fig. 17.35C.

SECTION 13 : THE LISTENER AND TONE CONTROL

Tone control is a controversial subject with very strong conflicting views held by many competent authorities. It is the author's opinion that, in view of the differences of opinion, it is only reasonable to provide the listener with some degree of tone control to permit him to derive the maximum degree of satisfaction while listening. This freedom of choice should not be unlimited, otherwise some listeners will become lost in the possible variations.

1. The cheapest type of set will probably be fitted with a fixed shunt capacitance tone control.
2. Sets which are somewhat higher-priced will be fitted with a single control. This may cover any one of the following :
 - (a) Variable resistance and fixed shunt capacitance (this has obvious shortcomings).
 - (b) Bass boosting only (this is quite satisfactory in its class provided that the bass boosting is limited to about 6 db total).
 - (c) Continuously-variable control giving, say, bass boosting in one direction and treble boosting in the other.
 - (d) Step-type control in the form of a "quality switch."
3. The most elaborate radio receivers and amplifiers may be fitted with two controls, one for bass and the other for treble. In addition, many equipments in this class will be fitted with automatic frequency-compensated volume control, thereby limiting the degree of manual bass boosting which is necessary (say 6 db maximum).

Anything which can be done to assist the listener to obtain the best results with the least trouble is to be commended.

SECTION 14 : EQUALIZER NETWORKS

Equalizer networks for pickups are covered in Chapter 17 Sect. 5 while those for microphones are covered in Chapter 18 Sect. 1(xii).

An example of a universal equalizer is given in Ref. 49

A helpful general article on design is Ref. 92. See also Ref. 102.

SECTION 1: GENERAL PRINCIPLES

(i) *Introduction* (ii) *An ideal system* (iii) *Practical problems in volume expansion*
(iv) *Distortion* (v) *General comments.*

(i) Introduction

The maximum volume range of any sound reproducer is the difference in decibels between the maximum sound output and the level of masking by background noise which latter may include hum, random noise, needle scratch or microphone noise.

The volume range transmitted by a broadcast station may vary from a low value up to at least 60 db for a F-M transmitter (F.C.C.), the value depending on the type of programme. In the case of an A-M transmitter the maximum volume range is about 50 db—see Chapter 14 Sect. 7(iv).

If the original sound has a volume range greater than the maximum volume range of the transmitter, it is usual to compress it in some way. The compression may be accomplished manually by the control engineer, or automatically by a device known as a peak limiter or a volume compressor.

A similar case arises with recorded music, where the maximum volume range may be as low as 35 db for shellac lateral-cut disc records.

Many types of programme have a maximum volume range less than 35 db, and therefore do not require compression. However, most broadcast transmitters have an automatic peak limiter permanently operating, while it has even been found beneficial to use volume compression in F-M broadcasting (Ref. 29).

If reproduced music is to have the same volume range as in its original form, some kind of volume expander is required. But, as will be shown later, volume expansion cannot be applied indiscriminately and cannot be perfect.

One advantage of the use of volume expansion is that it reduces the background noise, other than room noise. This is a considerable advantage when the source is a disc record.

A serious shortcoming of automatic volume expansion is that the circuit can never duplicate the original volume range because it has no way of knowing what these

original levels were—it will make the loud portions louder and the soft portions softer, but always by the same amount for a given input level. Thus the expander circuit might increase every signal that is 10 db above the average volume level to 15 db above the average, but the level in the studio might have been higher or lower than this.

The amplitude ratios of a soft and a loud note when rendered simultaneously cannot be compressed or expanded by any system. If the loud note causes a certain compression in the transmitter, the soft note will be compressed in the same ratio and may fall below the noise level (Ref. 33).

(ii) An ideal system

In an ideal system the transmitter would broadcast two separate carrier frequencies, one modulated with the music and the other modulated with some signal indicating the degree of compression being used at each instant. In the case of disc recorded music it would be necessary to have two grooves and two pickups. In each case the reproducer would incorporate a volume expander in which the degree of expansion is controlled by the second (indicating) signal.

Alternatively, only a single modulated carrier may be used provided that the expander characteristic in the receiver is the inverse of the compression characteristic in the transmitter. In addition, the time lags of the compressor and the expander should be equal. This is an ideal which cannot be reached at the present time owing to the lack of standardization and the use of manual controls.

There are serious technical problems both in the compression and expansion operation, but these are considered in Sections 2 and 4 respectively.

(iii) Practical problems in volume expansion

At the present time most broadcast stations employ some form of automatic volume compression, while compression is also used in recording on discs. The problem facing the receiver and amplifier designer is how to make the best use of volume expansion under conditions where it is impossible to reach the ideal.

(A) Orchestral reproduction

This subject is dealt with in a general manner in Chapter 14 Sect. 7(iv) and (v).

It is in orchestral reproduction that volume expansion can be employed to its full advantage. Experience indicates that the operation of the volume expander in the upwards direction should be as rapid as practicable (see Sect. 4) but that the fall should be very gradual—up to 1 or 2 seconds or even more, the optimum rate varying with the type of music and with the listener's choice.

Most competent audio-frequency engineers agree that automatic volume expansion is capable of giving more realistic reproduction of recorded orchestral music when used under the best possible conditions, even though it is known to have many technical defects. The usual amount of volume expansion used in such cases is 12 to 20 db maximum, with the maximum expansion variable at the desire of the listener.

(B) Average home listening

The average home radio receiver, used for a variety of purposes including speech, background music, drama and miscellaneous programmes, is usually better without expansion. Expansion might beneficially be used on orchestral programmes provided that the audience is prepared to listen intently, the room noise level is sufficiently low, and the neighbours do not object. These conditions are the exception rather than the rule.

On the other hand, volume expansion with manual control is well worth incorporation into a home gramophone amplifier.

(C) Background music

Music which is intended to form a background should be compressed and not expanded. The maximum dynamic range may be from 25 db down to possibly 10 db (Ref. 45).

(D) Factory music

Factory music must be heard above a very high noise level without becoming inaudible for any appreciable period. It should be compressed and not expanded, with a maximum dynamic range from 20 db down to possibly 5 db in exceptionally noisy locations.

References to General Principles : 3, 20, 29, 33, 34, 45, 48, 59.

(iv) Distortion

Apart from the harmonic and intermodulation distortion and extraneous noises produced by the compressor and expander, which may be kept low by good design, there are some special features which require consideration. Some of these are described in Sect. 2(iv) in connection with volume compression.

(v) General comments

There is an extraordinarily wide variety of devices for both volume compression and volume expansion, but in many cases the information published is too meagre to permit comparisons between the different methods. There is the additional problem that some of the designs may not be suitable for quantity production, on account of unduly critical adjustments and/or critical selection of valves.

The subject is a very complicated one, and the present unsatisfactory state of the "published art" has forced the author to refrain deliberately from giving much comment. The methods and circuits described in the following sections have been compiled mainly from very limited sources, often from a single article, and the information and claims based solely on the articles, to which full references have been given.

SECTION 2 : VOLUME COMPRESSION

(i) Introduction (ii) Peak limiters (iii) Volume limiters (iv) Distortion caused by peak limiters or volume limiters (v) Volume compression (vi) Volume compression plus limiting (vii) Compression of commercial speech.

(i) Introduction

In this Section it is intended to approach the subject from the point of view of the radio receiver or amplifier designer.

Volume compressors may be divided into three groups :

(A) Peak limiters

A peak limiter is an amplifier whose gain will be quickly reduced and slowly restored when the instantaneous peak power of the input exceeds a predetermined value. The output for all inputs in excess of this value is substantially constant.

(B) Volume limiters

A volume limiter is an amplifier whose gain is automatically reduced when the average input volume to the amplifier exceeds a predetermined value, so that the output for all inputs in excess of this value is substantially constant. A volume limiter differs from a peak limiter in that it is controlled by the average volume instead of by the instantaneous peaks.

(C) Volume compressors

These are used for the purpose of compression over a substantial part of the entire operating range.

(ii) Peak limiters

Peak limiters are used principally in broadcast transmitters. They are intended to prevent overmodulation and to increase the average level of the programme. The latter result follows automatically if the input is increased and the peak limiter left to look after the peaks.

Fig. 16.1. Compression characteristics (B, C, D) of typical peak limiter or volume limiter.

Some static limiter characteristics are shown in Fig. 16.1. Curve OA is the curve of a linear amplifier. Curve OTD is that of an "ideal" limiter, with point T as the threshold of limiting. It will be seen that the output does not rise above a level of 12 db, no matter how great the input may become.

Curve OTB is that of a practical peak limiter, the curve TB indicating by its slope a compression ratio of 10 to 1 (both being measured in db). The compression in db at any point is as indicated by the arrows.

Curve OC is that of a peak limiter having "over-control" (Refs. 36, 40, 44) which does not exceed 100% modulation (line TD) until the compression reaches 12 db.

With peak limiters a volume expander cannot be used to give correct compensation for the compression.

Most of the earlier and simpler forms of peak limiters have a comparatively slow "attack" time, that is the time taken for the limiter to operate on a sudden increase in input level—usual times are 1 or 2 milliseconds. A slow attack time results in overmodulation and distortion for short intervals following each transient. More recent examples of good design (Refs. 36, 38, 40, 44, 63) claim to have "attack" times less than 100 microseconds, while some (Refs. 36, 40, 44) incorporate a time delay filter in the signal circuit which is claimed to permit almost instantaneous operation. Tests have been carried out under dynamic conditions to demonstrate the performance of various types of limiters (Refs. 4, 40, 63). It is good practice for the "attack" time of a peak limiter to be less than 200 microseconds, while still shorter times (e.g. 100 microseconds or less) are desirable.

The recovery times in most cases are manually controlled, with times up to 2 or even 3 seconds, but automatic control has also been used to lengthen the recovery time so as to avoid "pumping" when several programme peaks occur in rapid succession (Ref. 36). The recovery time is not made longer than necessary, since it causes reduced modulation percentage.

One design (Ref. 86) has a subsidiary series CR circuit that has only a slight effect with a single sharp peak, thereby giving a fairly short recovery time (0.33 sec.) but with a sustained peak the recovery time increases to 2 seconds.

If a fixed value of recovery time is used, the most suitable range is from 0.5 to 1.5 seconds, and "pumping" may be avoided by restricting the limiting action to 4 or

6 db. A preferable arrangement incorporates a double value of recovery time, in which a longer recovery time occurs on sustained or repetitive peaks, and a short recovery time on brief, non-repetitive peaks (e.g. Ref. 72).

Careful listening tests with modern peak limiters having very short "attack" time, indicate that differences in quality can only be discerned when the limiting action (compression) reaches 5 db with a good modern type (Ref. 63) or 8 to 10 db with the nearly instantaneous type (Ref. 44).

Some broadcast stations unfortunately abuse the limiter by increasing the percentage modulation to such an extent that the distortion is distinctly audible in any good receiver.

References to peak limiters : 4, 36, 37, 38, 40, 44, 63.

(iii) Volume limiters

These are very similar in most respects to peak limiters, and the same general remarks hold for both. Examples of volume limiters are Refs. 12, 29.

(iv) Distortion caused by peak limiters or volume limiters

(A) Distortion caused by slow attack time

This is definitely audible in some types of programmes when the attack time is greater than 100 microseconds.

(B) Transient waveform distortion

This occurs in some types of limiters during limiting (Ref. 40). It may only affect part of one cycle, or it may continue over many cycles.

(C) Thump

Control current surges caused by rapid changes in input level may or may not be audible as a thump. Careful design is necessary to reduce the trouble. One design is claimed to have a very high signal/thump ratio (Refs. 36, 40, 44).

(D) Non-linear distortion

In the best designs the total harmonic distortion is below 1% and the intermodulation distortion below 3% under all conditions, over the whole a-f range.

(E) "Pumping"

This has already been described above.

(F) Sibilant speech sounds

The high frequency components in speech (sibilant sounds) are normally at a much lower level than the low frequency components. When volume compression is applied to speech, the control voltage derived from sibilants alone is much less than that from vowel sounds. Consequently the amplifier gain is higher for sibilants alone than for other speech sounds, leading to accentuation and distortion of the sibilants. This trouble may be avoided by incorporating a suitable equalizer in the control circuit (Ref. 9).

(G) Effect of pre-emphasis

Pre-emphasis, as used in certain recording systems and in F-M broadcasting, sometimes tends to give overmodulation with high frequency peaks. It is therefore advisable to place the pre-emphasis network ahead of the limiting amplifier. In such cases the limiting should be held to low values such as 2 or 3 db (Refs. 4, 44).

(v) Volume compression

Volume compression is distinguished from limiting in that it extends over the whole, or a substantial part of, the entire operating range. The compression characteristic may either be a straight line (A) or a smooth curve (B) shown typically in Fig. 16.2 ; in both examples an input range of 60 db is compressed to an output range of 40 db.

Either type of compression characteristic may be used satisfactorily in conjunction with an expander provided that the expansion characteristic is the inverse of the compression characteristic.

Some examples of volume compressors are Refs. 2, 31, 66—see also the a.g.c. circuit of Ref. 39. The attack time of a volume compressor should be fairly slow—this will permit the attack time of the expander to be made the same value. A compressor for use with recording is described in Ref. 69.

Fig. 16.2. Compression characteristics of volume compressors.

(vi) Volume compression plus limiting

In broadcast transmitters it is desirable to adopt both volume compression and limiting—volume compression for use with discretion depending on the type of programme; limiting for all programmes to permit a high percentage modulation to be used without peaks exceeding 100%.

One combined equipment has been designed (Ref. 39) incorporating a memory circuit which holds the gain constant for a predetermined time to preserve the dynamic range of the programme.

References to Section 2 (Volume compression, general): 2, 4, 5, 9, 12, 29, 31, 32, 36, 37, 38, 39, 40, 44, 63, 66, 69, 85, 89.

(vii) Compression of commercial speech

The comments above apply to good fidelity systems. For commercial speech, some form of "level governing amplifier" (W.E. Co.) or "constant volume amplifier" (British Post Office) is commonly used in complex systems. However, for simple systems, it is difficult to improve on an efficient speech clipper (see Sect. 6).

SECTION 3: GAIN CONTROL DEVICES

(i) Remote cut-off pentodes (ii) Pentagrids and triode-hexodes (iii) Plate resistance control (iv) Negative feedback (v) Lamps (vi) Suppressor-grid control.

Gain control devices are used in both volume compressors and expanders to provide a gain which is a function of the input signal.

(i) Remote cut-off pentodes

This is an application of audio a.v.c., and remote cut-off pentodes are capable of being used in both applications. The predominant (second) harmonic distortion does not exceed 1% with valve type 78 having a load resistance of 50 000 ohms, with an input of 0.15 volt (Ref. 62). The distortion may be reduced by push-pull operation and by limiting the input voltage to a low level.

A method of testing valves for the preselection of remote cut-off pentodes is described in Ref. 70.

It is the author's opinion that, despite all the troublesome features, the push-pull circuit using suitable selected remote cut-off pentodes, gives the most satisfactory control performance. This control stage must be followed by a "combining circuit" such as a push-pull transformer or centre-tapped-choke, either in the plate circuit or in the following grid circuit—the latter being preferable. See also remarks in Sect. 4(iv).

(ii) Pentagrids and triode-hexodes

Type 6L7 pentagrids are capable of handling higher input voltages than pentodes for the same distortion. The predominant (second) harmonic distortion does not exceed 1% with valve type 6L7 having a load resistance of 50 000 ohms, with an input of 0.5 volt (Ref. 62). The input signal is applied to the remote cut-off grid (No. 1) here operated at fixed bias, and the control voltage is applied to the sharp cut-off grid (No. 3). See Refs. 14, 35.

Type 6A8 pentagrids may also be used, with the signal applied to the oscillator grid (No. 1) and the control voltage applied to the signal grid (No. 4). See Ref. 14.

Type 6K8 triode-hexodes may be used, with the signal applied to No. 1 grid and the control voltage applied to No. 3 grid. See Ref. 14.

Many other types of multi-grid valves may also be used.

(iii) Plate resistance control

The plate resistance of a valve is a function of the grid bias voltage. A triode has a sharp change from a fairly low value at normal bias voltages to a high value when approaching cut-off, and infinity beyond cut-off. This effect has been applied in a volume compressor (Ref. 12).

(iv) Negative feedback

The gain of an amplifier may be controlled by means of a negative feedback network in which one element is the plate resistance of a valve whose grid is connected to the control voltage. One application (Ref. 31) gives less than 1.8% total harmonic distortion under all conditions, with an output of 12 volts.

Another application of negative feedback is Fig. 16.3 which employs a remote cut-off pentode with negative feedback provided by capacitance C_2 from plate to grid. By this means the effective plate resistance with feedback becomes approximately $1/g_m$. Thus a valve with a range of mutual conductance from 2000 to 2 micromhos may be used as a resistance varying from 500 to 500 000 ohms. The ratio between output and input voltages is given by

$$R_L / (g_m R_1 R_L + R_1 + R_L).$$

Fig. 16.3. Pentode with negative feedback used as shunt resistance in an attenuator to provide gain control.

Fig. 16.4. Resistance characteristic of typical 4-6 volt 0.04 A metal filament lamp used in volume expanders (Ref. 45).

With the values given in Fig. 16.3, a variation approaching 33 db is obtainable when V_1 has a maximum g_m of 2000 micromhos (Ref. 62). The dominant (second) harmonic distortion is less than 0.2% for an input voltage of 2 volts.

(v) Lamps

Metal filament (dial) lamps may be used as control devices in volume expanders. A typical tungsten filament lamp has a resistance at maximum brilliancy of about 10 times that at room temperature (Fig. 16.4). See Sect. 4(ii) for applications of metal filament lamps in expanders.

Note: Carbon filament lamps have a resistance which is less when at maximum brilliancy than at room temperature.

(vi) Suppressor-grid control

The control voltage may be applied to the suppressor grid of a suitable pentode valve. This is used in Figs. 16.11 and 16.12.

References to suppressor-grid control : 7, 10, 16, 27, 33, 46.

SECTION 4 : VOLUME EXPANSION

(i) Introduction (ii) Expanders incorporating lamps (iii) Expanders utilizing feedback (iv) Expanders incorporating remote cut-off pentodes (v) Expanders incorporating remote cut-off triodes (vi) Expanders incorporating suppressor-grid controlled pentodes (vii) Expanders incorporating valves with five grids (viii) Expanders incorporating plate resistance control.

(i) Introduction

Volume expansion is very similar to volume compression, and the same control methods are used for both, but the control voltage is of opposite polarity. In fact, an expander/compressor may be designed with a switch to change from one to the other (Fig. 16.14).

The desirable characteristics which a volume expander should have are :

1. Negligible non-linear distortion.
2. The degree of expansion should be under control.
3. The degree and control of expansion should be independent of the volume level at which the amplifier is operated.
4. The expansion should result in the upwards expansion of loud passages and the downwards expansion of soft passages.
5. The attack time should be short—times from 0.2 to 200 milliseconds are in common use, but the shorter times are preferable (say not exceeding 20 milliseconds).
6. The recovery time should be adjustable from a fraction of a second to 1 or 2 seconds.
7. There should be no audible thump or transient distortion with sudden large transients.
8. There should be no appreciable reduction in maximum power output.
9. The overall gain should not be reduced seriously by the expander.
10. The shape of the expansion characteristic should provide some expansion at low output levels, the amount of expansion steadily increasing all the way to maximum power output.

For most purposes an expansion of 10 or 12 db is satisfactory, although some prefer up to 15 or even 20 db.

It is preferable to introduce the expander into the amplifying chain so that minimum amplification follows it. It is therefore desirable to select a type of expander which is capable of a fairly high output voltage. It is preferable for tone controls to precede the expansion unit.

Electronic methods of volume expansion may be divided into two groups, those in which the control voltage is derived from the output voltage, and those in which it is derived from the input voltage, suitably amplified. The former method is cheaper and employs fewer valves, but it has a less desirable shape of expansion characteristic and may be unstable. The latter method is used in Figs. 16.10 to 16.15 inclusive, and is preferable in order to avoid thumps and blocking effects.

When the control voltage is derived from the input voltage, a "side-chain" amplifier is used (e.g. Fig. 16.10) with the final stage transformer-coupled to a suitable full-wave rectifier and load network.

(ii) Expanders incorporating lamps

Small metal filament lamps are sometimes used in volume expanders, the variation of about 10 to 1 in resistance (see Fig. 16.4) giving sufficient range of control. The simplicity and cheapness of some of these volume expanders make a strong appeal, although there are many shortcomings. If the lamps are placed in the voice coil circuit there is a loss of something like 50% of the power output. It is difficult to find lamps with characteristics suitable for all applications. It is not possible for the listener to control either the amount of expansion or the time constant. The degree of expansion falls rapidly as the operating level is reduced, and an appreciable amount of expansion can only be achieved at maximum power output. The more complicated designs overcome a few of these defects.

A lamp with a 40 mA current has an attack time of about 30 milliseconds and a recovery time of about 150 milliseconds (Ref. 45).

(A) Lamps in voice coil circuit

The simplest form is Fig. 16.5 in which the lamp is shunted across the voice coil, but this is only effective with a pentode valve without voltage feedback, and the distortion due to mismatching is severe except at one level. It is not used in practice.

FIG. 16.5

Fig. 16.5. Simplest form of volume expander using a lamp

FIG. 16.6

Fig. 16.6. Bridge type of volume expander using lamps.

FIG. 16.7

Fig. 16.7. Bridge type of volume expander using lamps which provides bass boosting at low levels.

The bridge circuit of Fig. 16.6 is quite practical, and may be used with any type of output valve. At maximum volume this may possibly have an efficiency of 66%. With the addition of two inductors L_1 and L_2 and two capacitors C_1 and C_2 (Fig. 16.7) it may be used to provide bass boosting at low output levels only (Refs. 50, 51, 52, 61). Correct load matching is arranged for maximum output, leaving the low level condition to look after itself.

A suggested application of both carbon and metal filament lamps is Ref. 53.

(B) Volume expander in stage preceding loudspeaker

The loss of power caused by lamps in the voice coil circuit may be avoided by incorporating the expander in an earlier stage. This necessitates a low power amplifier (driver) stage which provides enough power to operate the expander, say 3 watts, followed by a step-up transformer to the output stage, which may be a high-power push-pull amplifier. The volume control should follow the expander, or else two volume controls should be used (Ref. 54).

(C) Lamp-controlled feedback

This is undoubtedly the best form of expander using lamps, although it suffers from most of the limitations of the lamp. An expansion of about 10 db is practicable and Fig. 16.8 shows one form which it may take. Refs. 22, 34, 45.

References to expanders incorporating lamps : 22, 33, 34, 45, 50, 51, 52, 53, 54, 55, 61.

Fig. 16.8. Lamp-operated negative feedback volume expander (Ref. 22).

(iii) Expanders utilizing feedback

Two designs have been developed by Stevens (Ref. 58) and subsequently received attention (Ref. 22) but have certain limitations.

An improved form is shown in Fig. 16.9 which gives an expansion of 29 db, with minimum gain of 200 times. The distortion is not visible on a C.R.O. with an output of 30 volts r.m.s. The attack time is 50 milliseconds and the recovery time about 1 second; the latter may be adjusted by varying R_{10} . For further details see Refs. 22, 24 and 68.

(iv) Expanders incorporating remote cut-off pentodes

This is the oldest type of volume expander and a very satisfactory one, the valves being types suitable for use as i-f amplifiers or audio a.v.c. stages in receivers. It is possible to obtain a good control characteristic and any reasonable degree of expansion, to provide independent volume and expansion controls, and to arrange the time constants of the circuit to give the desired attack and recovery times. In order to avoid non-linear distortion, the controlled stages should operate with input voltages not greater than 0.15 volt, with a load resistance of 50 000 ohms. The controlled stages are nearly always arranged in push-pull—this eliminates even harmonic distortion and reduces intermodulation distortion. Push-pull operation is particularly valuable in reducing "thump" with large transients; it also reduces any residual ripple that may come through from the rectifier. A further advantage of push-pull operation is that cathode and screen by-pass capacitors

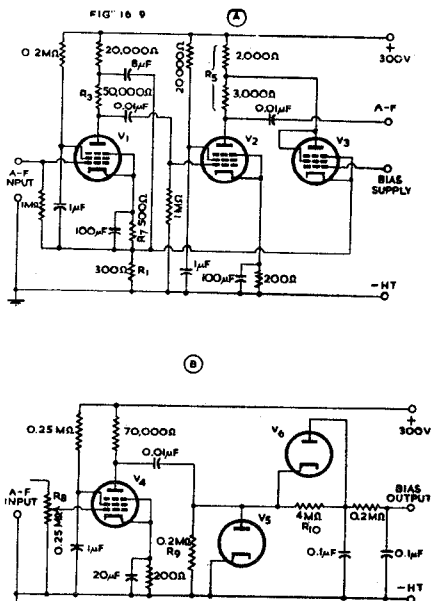

Fig. 16.9. Volume expander using negative feedback; (A) amplifier (B) circuit for supplying control bias to the amplifier (Refs. 22, 24). $V_1 = V_2 = V_3 = V_4 = 6H6$; V_5 and V_6 together = 6H6.

16.4(iv) EXPANDERS INCORPORATING REMOTE CUT-OFF PENTODES 689

FIG. 16.10.

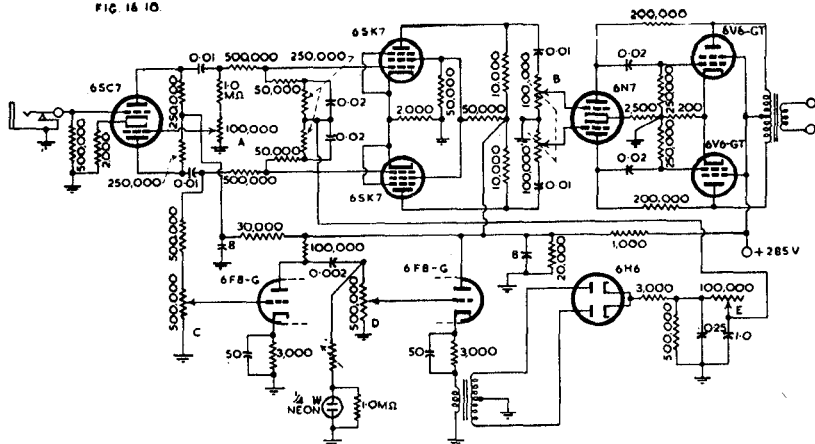

Fig. 16.10. Volume expander incorporating remote cut-off pentodes (Ref. 23). Controls A = balance, B = volume, C = input level, D = expansion, E = time constant.

may be omitted, thus eliminating time delay in the adjustment of electrode voltages. Valves used in each push-pull pair must be very carefully matched for plate current and mutual conductance at several points over the operating range of grid bias voltages. Owing to the limited input-voltage which may be used, there should be one voltage amplifier stage between the controlled stage and the power amplifier.

An example of good design is Fig. 16.10 (Ref. 23). The minimum attack time is about 10 milliseconds and the recovery time of the order of 1 second. The expansion curve (db versus voltage) is approximately linear up to a d.c. control voltage of 20 volts, which gives 10 db expansion. The 6SC7 stage is common to both sections. The 6SK7 push-pull stage is the controlled stage; this is followed by the 6N7 voltage amplifier stage which is coupled to the 6V6-GT power amplifier. The signal to feed the rectifier is taken from the plate circuit of the 6SC7 stage, amplified in two stages (6F8-G), the second being a cathode follower, and rectified by the 6H6. The direct voltage from the 6H6 filter circuit is applied to the signal grids of the 6SK7 valves.

In any expander of this general type, whatever may be the method of controlling the gain, it is necessary to prevent the transients in the output of the individual expander valves from becoming so large as to cut off the following stage. This can be accomplished by transformer coupling, by a direct-coupled phase inverter (as in Fig. 16.13) or by the use of low values of load resistances and coupling capacitances (as Fig. 16.10). With the third method it is necessary to incorporate an equalizing network to give a flat overall frequency response.

Refs. 22 (Part 1), 23.

(v) Expanders incorporating remote cut-off triodes

Any remote cut-off pentode may be connected as a triode (screen, suppressor and plate tied together) to form a triode which may be used in a similar manner to a pentode, except that the gain will be lower. It has been stated that a single valve has 0.37% total harmonic distortion unexpanded, 0.64% expanded, predominately second harmonic, when the output level is -25 db (i.e. 0.056 volt). For further details see Refs. 1, 42.

(vi) Expanders incorporating suppressor-grid controlled pentodes

A sharp cut-off pentode of suitable design may be used for controlling the gain—the English Mazda AC/SP1 and the American 6SJ7 are typical examples. One example of this application is Fig. 16.11 (Refs. 7, 10) which has an attack time of about 1 millisecond, and a variable recovery time of about 1 second maximum. Resistors

FIG 16 II

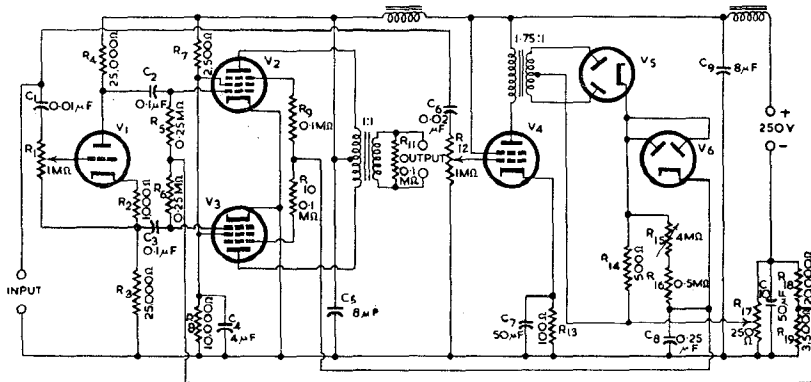

Fig. 16.11. Volume expander incorporating push-pull suppressor-controlled pentodes (Ref. 7). $V_1 = 6H4$, $V_2 = V_3 = 6X4$, $V_4 = 6K4$, $V_5 = V_6 = 6Z3$.

R_9 and R_{10} prevent the suppressor grids from being driven positive. With the moving contacts of R_{12} and R_{11} at the chassis ends, R_1 should be adjusted in conjunction with the volume control of the main amplifier so that the latter will just be fully loaded with the loudest signal. R_{11} is then adjusted to give the desired expansion. R_{12} is advanced until the loudest signal just causes the suppressors to be at cathode potential. Any further alteration in volume level should be made by R_1 . Some suggested modifications are given in Refs. 10, 16.

A second example is Fig. 16.12 (Ref. 27) in which the need for push-pull operation and for a transformer is avoided by an ingenious device. V_1 is the suppressor-controlled stage while V_2 is a "dummy" designed to balance the plate and screen currents of V_1 so that the current passing through each load resistor is constant. The maximum signal input to the expander stage is about 0.25 volt, and the maximum signal output of the expander is of the order of several volts, for low distortion. The controlled range is about 15 db. The diode rectifier incorporated in the suppressor circuit prevents the suppressor from being driven positive. The time constants are such that 75% of final gain is achieved in the fast position in approximately 20 milliseconds, and in the slow position 60 milliseconds. The recovery times are about 0.5 and 1.2 seconds.

FIG. 16.12

Fig. 16.12. Single-ended surgeless volume expander incorporating suppressor-grid control (Ref. 27).

(vii) Expanders incorporating valves with five grids**(A) Incorporating type 6L7**

This valve type has two signal input grids, grid No. 1 having a remote cut-off characteristic, and grid No. 3 having a sharp cut-off characteristic. Normally the signal is applied to No. 1 grid which operates at a fixed bias of about -10 volts, grid No. 3 is operated with a static bias of approximately -18 volts, the screen is maintained at 100 volts and the static plate current is from 0.12 to 0.15 mA. The expansion available is about 20 db, and the maximum input is 1 volt, or say 0.5 volt for reasonably low distortion. There may be difficulty with hum, owing to the low signal amplification with small input voltages. There must be a careful compromise between time of "attack" and suppression of the ripple voltage produced by the bias rectifier. Particularly when the input level is low, the transient voltages on No. 3 grid become audible as clicks or thumps. These remarks apply to the old form of single valve design (Refs. 13, 35, 55, 64).

An improved form is shown in Fig. 16.13 (Ref. 21) which makes use of push-pull 6L7 control valves and direct-coupling to the following 6SJ7 phase inverter. The attack time is 12 milliseconds and the recovery time adjustable from 0.07 to 0.9 second.

FIG. 16.13.

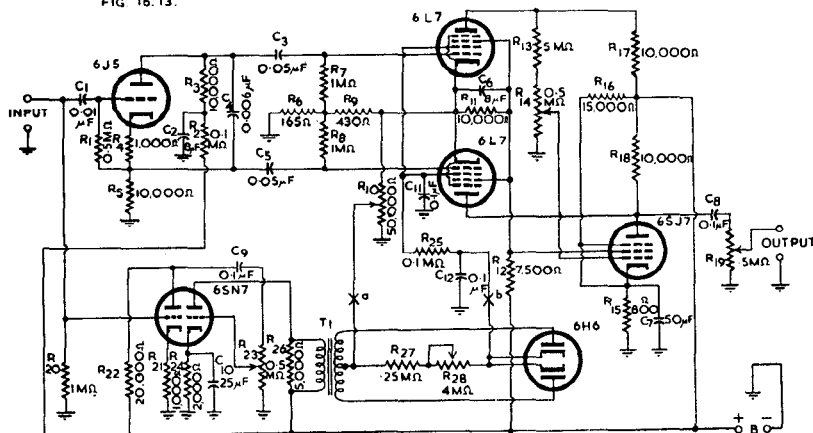

Fig. 16.13. Volume expander incorporating push-pull 6L7 control valves (Ref. 21).

(B) Incorporating 6A8

The input signal is applied to Grid No. 1 (oscillator grid) and the amplified voltage for control purposes is taken from a volume control in the plate circuit of Grid No. 2 (anode grid), rectified by a separate rectifier and then applied to Grid No. 4 (control grid). Ref. 14; also Ref. 56 (incorporating MX40).

(C) Incorporating triode-hexode (6K8)

The input signal is applied both to Grid No. 1 of the hexode and to the grid of the triode, and the amplified voltage for control purposes is taken from a volume control in the triode plate circuit, rectified by a separate rectifier and then applied to Grid No. 3 of the hexode. Ref. 14.

(D) Incorporating type 6SA7, 6BE6, or 7Q7

One possible application is Fig. 16.14 (Ref. 25) in which push-pull 7Q7 valves form the controlled stage. The maximum expansion is 18 db, attack time 3 milliseconds and recovery time 0.5 second. The push-pull signal is applied from the phase splitter to the No. 3 grids of the 7Q7 valves, while the control voltage is applied to the No. 1 grids in parallel. In the original article this expansion circuit is incorporated

FIG 16.15

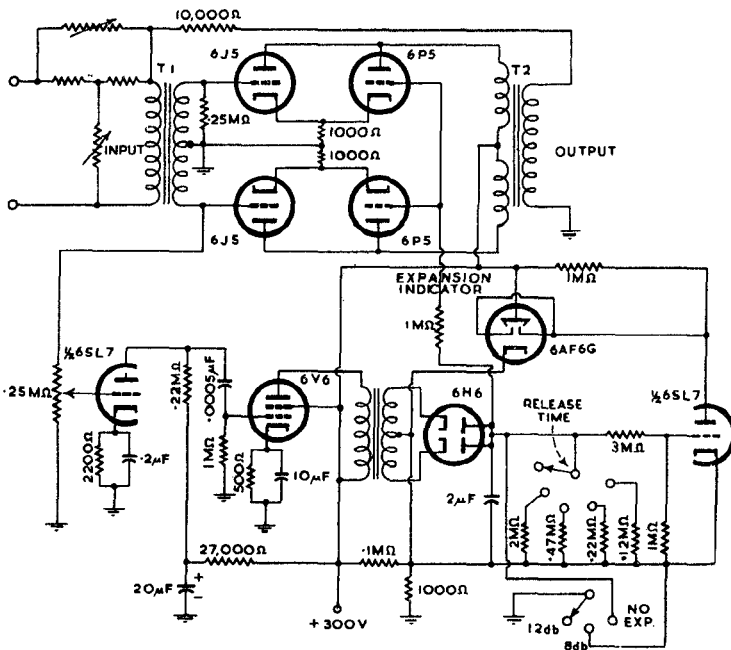

Fig. 16.15. *Volume expander incorporating plate resistance control (Ref. 43).*

SECTION 5 : PUBLIC ADDRESS A.V.C.

Audio a.v.c. may be applied to an a-f amplifier so as to permit the speaker to move his head without causing a serious drop in sound output level from the loudspeaker. The usual method is to incorporate into the amplifier a control valve, at such a level that the input voltage to the control valve is about 0.5 volt for type 6L7 or 0.15 volt for a remote cut-off pentode. Other methods of control can, of course, be used. The control voltage may be derived from a suitable point on the main amplifier, preferably through an isolating stage, with a full wave rectifier and filter in the usual way. A typical example is Ref. 65.

References to public address a.v.c. : 39, 65, 92.

SECTION 6 : SPEECH CLIPPERS

In the case of speech it is practicable to clip the peaks without seriously affecting the tonal qualities of the voice, and with a bearable degree of distortion. With a suitably designed speech clipper it is possible to operate at a higher average level than with a limiter, owing to the long recovery time which is necessary with the latter. A speech clipper is practically instantaneous in its action.

When peaks have been clipped there should be a minimum of phase distortion in the remainder of the amplifier, at least up to 8000 c/s. The response should be flat from 200 to 4000 c/s, but there must be treble attenuation above 4000 c/s—at least 25 db at 10 000 c/s. The treble attenuation may be provided by a single constant k section filter, since the harmonics are attenuated sufficiently before they are shifted

far enough in phase to increase appreciably the peak amplitude of the wave. At the bass end, satisfactory results are obtained if the response following the clipper stage is attenuated 3 db or less.

The Plex amplifier (Ref. 37, Fig. 3) is capable of 20 db peak clipping before the distortion becomes serious. The average increase in power level is about 12 db.

An alternative design of speech clipper incorporated in a speech amplifier is given in Fig. 2 of Ref. 28.

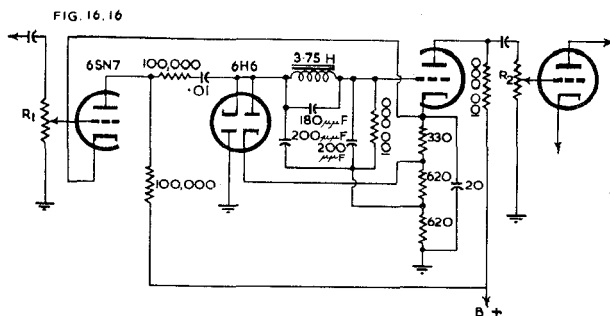

Fig. 16.16. Simple form of speech clipper suitable for an amateur transmitter. The 3.75 H choke must have low d.c. resistance and good a-f characteristics (Ref. 28).

A much simpler form of speech clipper, but one good enough for use with amateur transmitters, is shown in Fig. 16.16 (Ref. 28).

"Infinite" peak clipping has been used successfully, giving articulation from 50 to 90%. If preceded and followed by suitable frequency-tilting filters, the articulation may reach 97% with a quality sounding very much like normal speech. See Chapter 14 Sect. 11(ii), also Ref. 71 of this chapter.

References to speech clippers: 28, 37, 63, 71.

SECTION 7: NOISE PEAK AND OUTPUT LIMITERS

(i) Introduction (ii) Instantaneous noise peak limiters (iii) Output limiters (iv) General remarks.

(i) Introduction

Limiters are restrictive devices to mitigate the effects of undesired electrical disturbances of an impulsive nature such as static and ignition noise on the output of an A-M receiver.

(ii) Instantaneous noise-peak limiters

(A) Series noise-peak limiters

These are highly effective in radio receivers. Fig. 16.17 is a simple series limiter which only requires four additional components as shown inside the dash-dash rectangle. Threshold bias is derived from the rectified carrier.

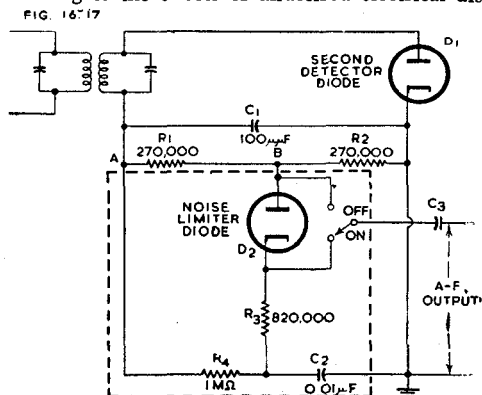

Fig. 16.17. Simple series limiter (Ref. 30).

When a 6H6 valve is used for both diodes, the hum may be reduced by earthing the end of the heater which is closer to the diode D_2 . The hum may still be troublesome even with this precaution.

A circuit giving lower hum is Fig. 16.18; if a limiter on/off switch is used, two different values of C_5 will be required.

(B) Series-type noise limiter with threshold adjustment

In this form the limiter threshold can be varied from about 65% modulation down to substantially zero, on half of the modulation cycle (Fig. 16.19). Diode D_3 may be added to buck the thermionic potential of the limiter diode and thereby improve the effectiveness at low carrier levels; this is at the cost of increased distortion.

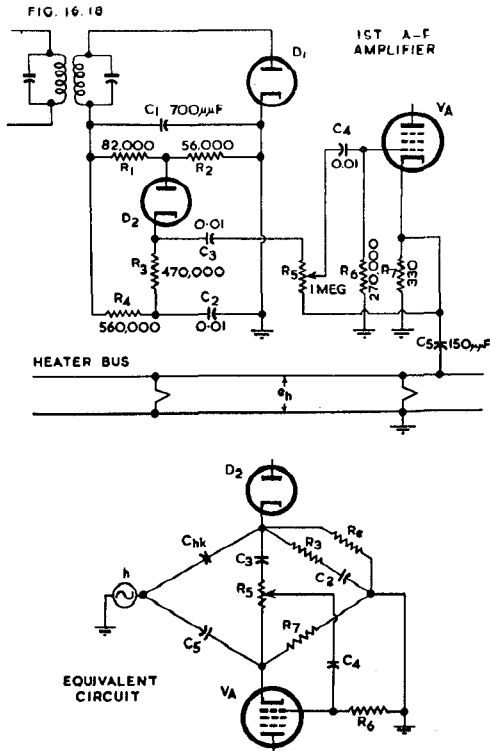

Fig. 16.18. Hum-reduction version of simple series limiter with equivalent circuit to show bridge configuration (Ref. 30).

(C) Low-loss series-type noise limiter (Fig. 16.20)

This provides the a-f amplifier with a higher percentage of the a-f voltage across the detector diode load (2 or 3 db improvement).

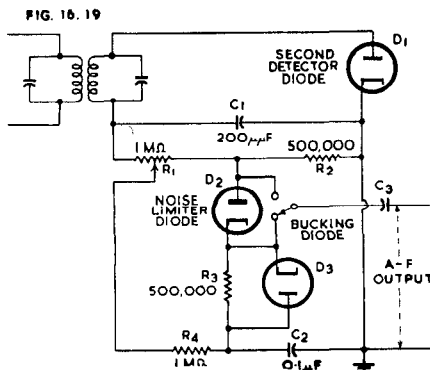

Fig. 16.19. Series-type noise limiter with threshold adjustment (Ref. 30).

Fig. 16.20. Low-loss series limiter. (Ref. 30).

(D) Balanced-detector noise limiter (Fig. 16.21)

This functions as a balanced bridge arrangement for detector voltages above the limiting threshold, with unbalance at all other times. It must be adjusted manually for each carrier level. This is not a very satisfactory form of limiter.

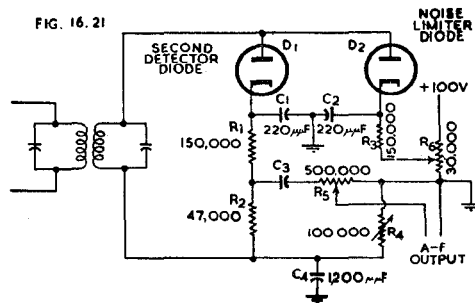

Fig. 16.21. Balanced-detector noise limiter (Ref. 30).

(E) Automatic balanced-detector noise limiter (Fig. 16.22)

The additional diode is operated from a tertiary winding on the final i-f transformer. Limiting does not take place at modulation depths below 100%. This is an improvement on Fig. 16.21 but it also is limited in performance.

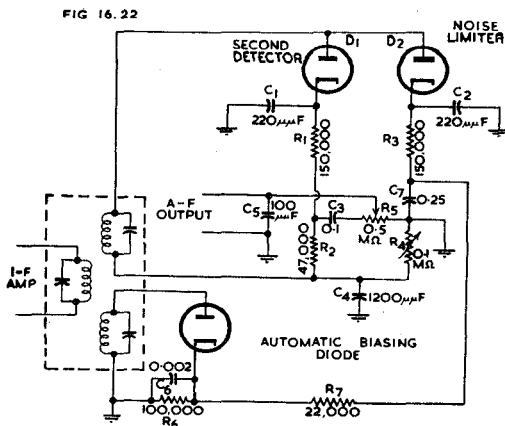

Fig. 16.22. Automatic balanced-detector noise limiter. (Ref. 30).

Fig. 16.23. Balancing-type noise limiter (Ref. 30).

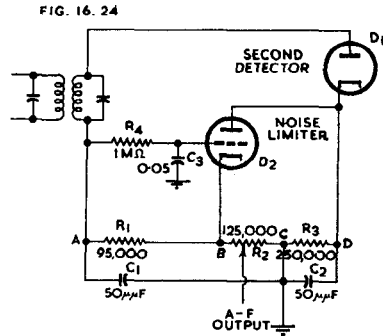

Fig. 16.24. Triode shunt-type noise limiter (Ref. 30).

(F) Balancing-type noise limiter (Fig. 16.23)

This uses a limiter diode with reversed polarity, shunted across the detector diode. The modulation distortion is quite high, even on relatively low modulation depths. This circuit gives effective limiting of noise peaks. It provides about twice the normally obtainable a.v.c. voltage when the direct potential across R_2 is utilized.

(G) Triode shunt-type noise limiter (Fig. 16.24)

This circuit employs the plate resistance of a triode shunted across a portion of detector diode load, the magnitude of the shunt resistance being controlled by the grid and plate voltages, which act in conjunction with differential time-constants.

The percentage of modulation at which distortion begins depends on the triode used, the values of R_1 , R_2 and R_3 , the time-constants involved, and the absolute carrier level. The higher carrier levels produce no distortion and no limiting. Serious distortion has been observed with 10% modulation at low signal levels. Effective limiting action is restricted to a narrow range of carrier input levels, generally above 10 Mc/s in carrier frequency.

Fig. 16.25. Diode shunt-type noise limiter (Ref. 30).

(H) Simple diode shunt-type noise limiter (Fig. 16.25)

This is the simplest form of limiter, but the performance is not very good; some improvement is evident on pulse type interference on signals above 10 Mc/s.

(I) Modified shunt-type noise limiter (Fig. 16.26)

This limiter begins to cause distortion at about 100% modulation for the values shown. This form is much more effective than the simple shunt limiter, although not so good as the simple series-type limiter at the lower carrier frequencies.

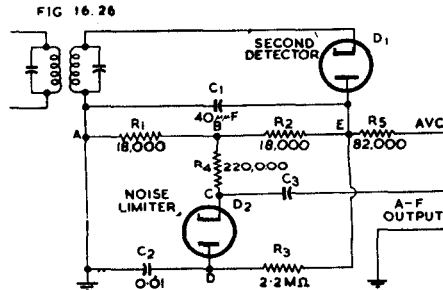

Fig. 16.26. Modified shunt noise limiter (Ref. 30).

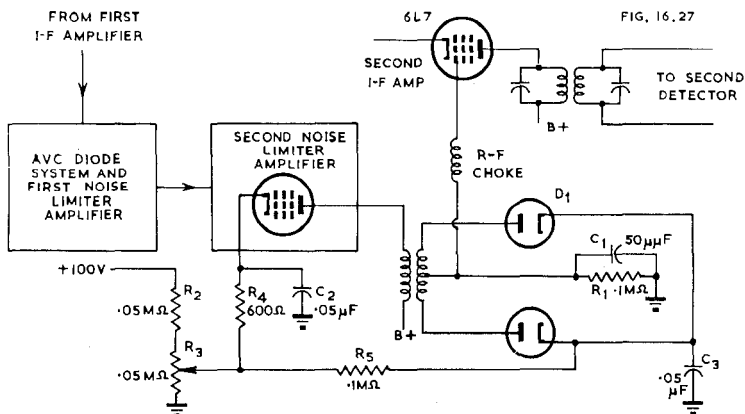

Fig. 16.27. Degenerative noise limiter, acting between first and second i-f stages (Ref. 30).

(J) Degenerative noise-limiter (Fig. 16.27)

Degenerative feed to the i-f amplifier prior to final detection is used in this circuit. A portion of the output from the first i-f amplifier is amplified in the first and second noise-limiter amplifiers, and the resulting i-f output is coupled into a full-wave rectifier having R_1 as a load resistance. The direct voltage developed across R_1 provides the bias for the grid of a 6L7 serving as second i-f amplifier. Front panel control R_3 provides a positive delay voltage for the diode cathodes, to prevent rectification until the signal or noise peaks exceed this bias. This limiter requires manual adjustment of the threshold of operation, and is useless on fading signals. Modulation distortion is determined by the delay bias obtained from R_3 or by an accessory a.v.c bias if provision is made for automatic biasing.

(iii) Output limiters

(A) R-F output limiter

This method, using low voltages on r-f amplifier plates and screens, is mainly used for telegraphy (Ref. 30).

(B) A-F saturation-type output limiter

This method gives control of the maximum output of the a-f power amplifier by suitably adjusting the plate, screen and grid voltages. A low-pass filter filters out distortion produced in the output stage. A similar result may also be achieved in an a-f voltage amplifier by controlling the screen voltage of a pentode valve. These are mainly used for modulated c-w (Ref. 30).

(C) Logarithmic compressor (Fig. 16.28)

This circuit is a two-stage a-f amplifier with negative feedback, having two diodes connected in series with the feedback path in such a way as to provide a path for both positive and negative half-cycles of the feedback voltage. Potentiometer R_{10} provides bias to the diodes for setting the limiting level.

Using the diodes in this manner is equivalent to varying the feedback percentage from a low value to a maximum as the instantaneous feedback voltage rises, with the reverse effect as the instantaneous feedback voltage falls. This circuit produces considerable distortion on speech or music but does not destroy intelligibility. Noise interference is reduced substantially, and almost as effectively in some cases as with a series noise-peak limiter.

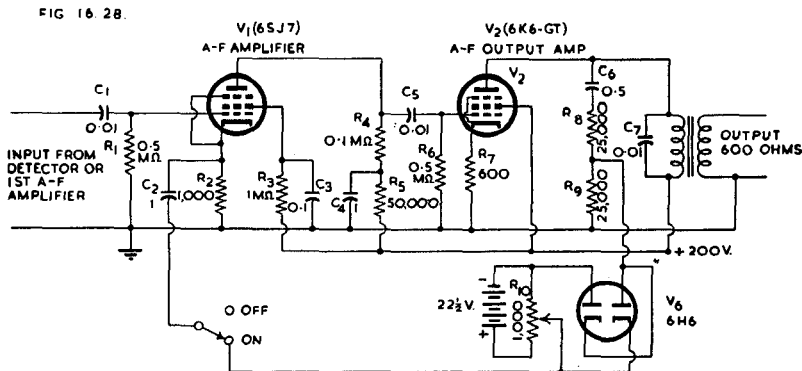

Fig. 16.28. Logarithmic compressor (Ref. 30).

(iv) General remarks

Satisfactory protection against blocking may be provided by arranging for the stage preceding the final i-f amplifier to overload before the final i-f amplifier, then for each preceding stage to overload in turn.

A linear detector (or second detector) is desirable when handling a high noise level.

It is desirable to have control of the a-f gain of the stage following an instantaneous limiter—shunt limiters operate better with low following a-f gain. Ref. 30.

SECTION 1: INTRODUCTION TO DISC RECORDING

(i) Methods used in sound recording (ii) Principles of lateral recording (iii) Frequency range (iv) Surface noise and dynamic range (v) Processing (vi) Turntables and driving mechanism (vii) Automatic record changers.

(i) Methods used in sound recording

There are many methods which have been used for sound recording, but these may be arranged in the following principal groups :

1. **Magnetic recording** includes magnetic wire and magnetic tape. See Refs. 258 (Chapter 29), 272, 316, 318.

2. **Sound on film** finds its principal application in cinema films. The Philips-Miller engraved film system is used to a limited extent for broadcast transcription. Film is also used for embossed lateral recording for some special applications. The high cost of the film precludes the use of this medium in most other fields. See Ref. 258.

3. **Mechanical groove recording** is used in various forms including

(a) the cylinder (e.g. dictaphone)

(b) the disc, which is the only type of recording considered in this chapter.

Two methods of recording are used with discs :

1. **Vertical recording** ("hill and dale"), which has had only a limited field of application, and appears unlikely to be used extensively in the future.

2. **Lateral recording** which is the method used most generally, and is the subject of this chapter.

Lateral recording is used with five types of discs—

(a) The 78 r.p.m. "shellac" pressings,

(b) The 33-1/3 r.p.m. fine groove, otherwise known as microgroove or long-playing (LP) records,

(c) The 45 r.p.m. fine groove records,

(d) Lacquer discs used for direct playback—see Sect. 8,

(e) Discs used principally for broadcast transcription recording, usually operated at 33-1/3 r.p.m.—see Sect. 9.

The nominal speed of rotation is interpreted for recording as follows :

Supply frequency	50 c/s	60 c/s (R.M.A.)
78 r.p.m. nominal	77.92	78.26 r.p.m. (R.M.A.)
33-1/3 r.p.m. nominal	33-1/3	33-1/3 r.p.m. (R.M.A.)
Tolerance in speed of rotation	$\pm 0.5\%$	$\pm 0.3\%$ (N.A.B.)

The speed is usually checked by means of a **stroboscope** illuminated by a lamp supplied from a.c. mains. The usual arrangement is :

Supply frequency	50 c/s	60 c/s (N.A.B.)
Number of bars on stroboscope	77	92 for 78 r.p.m.
	180	216 for 33-1/3 r.p.m.

At either 78.26 or 33-1/3 r.p.m. not more than 21 dots per minute in either direction may drift past a reference point (N.A.B. for recording).

See Reference 89 for a "Glossary of disk-recording terms." See Reference 105 for a "Bibliography of disc recording" (1921 to 1947).

See References 2, 87, 237 and 260 for American Recording Standards. See Sect. 2 for current English and American practice.

(ii) Principles of lateral recording

In lateral recording the groove forms a spiral either from the outside to the inside (as with all commercial "home" recordings) or from the inside to the outside (as with some transcription discs). The groove undulates horizontally from side to side of the mean path so as to deflect the stylus (needle) and armature of the pickup in accordance with the recorded sound (Fig. 17.1). The undulation of the groove is called "modulation" and the movement to one side of the mean path at any instant is called the amplitude of the modulation. The stylus is wedged in the groove by the effective vertical pressure due to the weight of the pickup, and moves radially about the pivot of the armature (Fig. 17.2).

FIG. 17. 1

FIG. 17. 2

Fig. 17.1. Unmodulated (left) and modulated (right) groove of lateral recording.

Fig. 17.2. Motion of stylus tip with lateral recording.

If the recorded sound is of sine-wave form, the maximum transverse velocity of the stylus tip will occur at O and zero velocity will occur at B and B', the two extremities of travel. This is an example of simple harmonic motion (see Chapter 6 Sect. 4). The maximum transverse velocity is $2\pi fA$ where f is the frequency in c/s and A is the peak amplitude. The r.m.s. transverse velocity is given by $1.41 \pi fA$.

The recorded level may be specified in terms of r.m.s. velocities at 1000 c/s, or in decibels with a reference level 0 db = 1 cm/sec. lateral r.m.s. stylus velocity. The following tables are based on this usage.

(A) 78 r.p.m.—Cross-over frequency = 500 c/s

Level	Velocity		Comments
	r.m.s.	Peak amplitude*	
+ 10 db	3.16 cm/sec	0.56 mil	R.M.A. Frequency Test Record No. 1(A) R.M.A. Frequency Test Record No. 1(B) max. velocity (1000 c/s).
+ 16 db	6.31 cm/sec	1.1 mils	
+ 18 db	7.94 cm/sec	1.4 mils	
+ 22 db	12.6 cm/sec	2.2 mils	
+ 26.8 db	22 cm/sec	3.8 mils	Max. instantaneous programme peak.

* Over constant amplitude portion.

(B) 78 r.p.m.—Cross-over frequency = 250 c/s

Level	Velocity r.m.s.	Peak amplitude*	Comments
+ 10 db	3.16 cm/sec	1.1 mils	Normal maximum level
+ 12 db	3.98 cm/sec	1.4 mils	
+ 15 db	5.62 cm/sec	2.0 mils	
+ 18 db	7.94 cm/sec	2.8 mils	

N.B. 1 mil = 0.001 inch.

(C) 45 r.p.m.

Level	Velocity r.m.s.	Comments
+ 14.3 db	5.2 cm/sec	RCA Test record 12-5-31 (1000 c/s)
+ 22.9 db	14.0 cm/sec	Max. instantaneous programme peak.
+ 25.1 db	18.0 cm/sec	Max. level on R.C.A. Test Record 12-5-37.

(D) 33-1/3 r.p.m. (LP)

Level	Velocity r.m.s.	Comments
+ 7.5 db	2.4 cm/sec	Columbia Test record RD-103 (1000 c/s).
+ 22.9 db	14.0 cm/sec	Max. instantaneous programme peak.

There are two basic methods of recording sounds of different frequencies—constant velocity and constant amplitude. “Constant velocity” refers to the maximum transverse velocity of the stylus tip at the zero axis, this being held constant as the frequency changes. A diagrammatic representation of constant velocity recording for two frequencies is given in Fig. 17.3.

FIG. 17.3

FIG. 17.4

Fig. 17.3. Diagram of constant velocity recording for two frequencies f and $2f$.

Fig. 17.4. Diagram of constant amplitude recording for two frequencies f and $2f$.

It may be shown that constant velocity recording has the following characteristics for constant power at all frequencies—

1. The peak amplitude is inversely proportional to the frequency.
2. The maximum slope of the curve is the same for all frequencies.

In the general case when the power is changing, the maximum velocity at any frequency is proportional to the peak amplitude. With an “ideal” electro-magnetic pickup, which inherently follows a constant velocity characteristic, the output voltage for sine waveform is proportional to the maximum velocity at all frequencies.

Constant velocity recording is not suitable for use over a very wide frequency ratio, owing to the large variation in peak amplitudes. For example, over a range of 8 octaves the ratio of maximum to minimum amplitude is 256 to 1.

“Constant amplitude” recording indicates that the maximum amplitude is held constant when the frequency changes, for constant power output (Fig. 17.4). It may be shown that the maximum slope is proportional to the frequency.

Constant amplitude recording is very suitable for low frequencies, but is not satisfactory with large amplitudes at the highest audio frequencies because the transverse velocity of the needle tip becomes excessive, leading to distortion in recording and in reproducing. On the other hand, constant velocity recording is satisfactory over a

*Over constant amplitude portion.

limited frequency range of medium or high frequencies. Therefore most recording systems employ an approximation to constant amplitude recording at low frequencies and an approximation to constant velocity recording for at least part of the medium and higher frequency range (see Sect. 5).

It may be shown (Ref. 146) that the minimum radius of curvature at the peak of the curve is given by

$$\rho = 0.025 \lambda^2 / A \quad (1)$$

where ρ = radius of curvature in inches

λ = wavelength of sine-wave curve in inches

and A = peak amplitude of curve in inches.

Equation (1) may also be put into the form

$$A = 0.025 \lambda^2 / \rho \quad (2)$$

Any stylus is unable to fit accurately an undulation in the groove with a radius of curvature at the point of contact less than its own radius of curvature. We may therefore apply eqn. (2), taking ρ as the radius of curvature of the stylus, to give the maximum amplitude (called the **critical amplitude**) for correct operation,

$$A_{crit} = 0.025 \lambda^2 / \rho \quad (3)$$

where ρ = radius of curvature of stylus, in inches.

But since the r.m.s. transverse velocity is equal to $1.41 \pi f A$ we can determine the critical velocity in cm/sec,

$$\text{Critical velocity r.m.s.} = 11.3 f A_{crit} \text{ cm/sec} \quad (4)$$

where A_{crit} = critical amplitude in inches.

(iii) Frequency range

The maximum recorded frequency in commercial shellac records manufactured prior to 1940 was of the order of 6000 c/s. At the present time most new recordings are recorded up to at least 8000 c/s, while many manufacturers record up to 10 000 or 15 000 c/s. Recordings up to ultrasonic frequencies (20 000 c/s) have been made, and are claimed to provide improved fidelity even though the higher frequencies are inaudible (Refs. 195, 271).

The lowest recorded frequency is of the order of 30 c/s, although some record manufacturers do not publish their recording characteristics below 50 c/s.

(iv) Surface noise and dynamic range

Surface noise (needle scratch) is unavoidable with any method of disc recording, but the maximum signal-to-noise ratio may be made quite high. The maximum dynamic range will be greater than the measured signal-to-noise ratio on account of the nature of the noise, which approaches the characteristics of random noise if there are no resonances anywhere in the equipment—see Chapter 14 Sect. 7(v).

Surface noise is not really objectionable if it is reasonably low in level and if it can be described as "silky." This latter criterion can only be attained when the pickup and loudspeaker both have smooth response throughout the whole frequency range. If the pickup has a prominent resonance within the audible frequency range—even if correctly equalized—the noise will not be "silky" and will tend to become objectionable.

In all cases the high frequency range of the equipment should be limited by a suitable filter giving a choice of cut-off frequencies. Filters with very rapid cut-off characteristics are undesirable on account of distortion effects, but a combination of a "roll-off" characteristic and a filter with an ultimate attenuation of at least 12 db/octave appears to be satisfactory. Any other method of achieving a "rounded" cut-off characteristic would probably also be satisfactory.

The maximum signal to noise ratio of **shellac pressings** varies considerably. The older shellac pressings had a maximum signal to noise ratio* of the order of 30 or 35 db. The most recent English shellac pressings have a maximum signal to noise ratio* of 50 db (Ref. 88) for a new record. The best of recent American 78 r.p.m. shellac recordings have a maximum signal to noise ratio* of 45 or 46 db when new

*Measured with flat frequency response.

(Refs. 255, 254). The average post-war shellac record, taking into account all the various types of records on the market, both English and American, has a maximum signal to noise ratio* of about 38 db (Ref. 256).

A new vinyl fine groove record can have an average surface noise, measured on a system whose response is flat on a velocity basis from 500 to 10 000 c/s, about 56 db below the peak recording level; if measured on a system whose response is the inverse of the recording characteristic, the surface noise is approximately 62 db below peak recording level. The B.B.C. "D Channel" recording has a weighted signal to noise ratio greater than 60 db (Ref. 297).

The surface noise increases with the use of the record. After 100 playings with a 2 ounce pickup some shellac records showed negligible increase in noise level while others showed 5 db increase, the average being about 2.5 db (Ref. 181). After 200 playings of a fine groove vinyl record (LP) the surface noise increased by 2 db (Ref. 308).

The cost factor limits the use of **polyethylene** (Ref. 181) which has a scratch level even lower than that of vinyl. See also Sect. 9(ii) for the measurement of noise in accordance with NAB standards for transcription records.

(v) Processing

The processing of shellac pressings is described in Refs. 7, 10 and 25. The processing of vinyl (LP) records is described in Ref. 308.

(vi) Turntables and driving mechanism

Turntables should be strongly constructed, free from flexing, and should run true. The typical home-type turntable and motor is unsatisfactory for good fidelity on account of insufficient motor power, insufficient flywheel action and insufficient mechanical rigidity; it suffers from rumble, wow and (with some pickups) hum due to the proximity of the motor. The motor should be as far as possible from an electromagnetic pickup. Motor and turntable vibrations are transmitted through the mounting board and pickup arm to the pickup head and are finally reproduced in the loudspeaker as rumble. Steel turntables may be used without bad effects with crystal pickups and high level moving iron types, except that in the latter case the turntable should be solid, without perforations. Steel turntables are unsatisfactory with some low-level pickups, particularly moving coil types.

Either rim or centre drive may be used, and first class products using both methods are available. In the moderate price class, it seems that (for the same price) the rim drive is generally the more satisfactory arrangement.

The specification for a motor and turntable unit should include—

1. Type of motor.
2. Voltage and frequency range.
3. Power consumption.
4. Torque to brake the turntable from the nominal speed to a lower speed (e.g. 78 to 77 r.p.m.), the torque being expressed in oz-ins and the applied voltage and frequency to be stated.
5. Turntable diameter.
6. Form of automatic stop.

(vii) Automatic record changers

With most record changers it is important to adjust the vertical angle between the stylus and the record so that the deviation from normal is the same (although opposite in direction) at both the top and bottom of a stack of records.

Care should be taken to minimize the impact of the stylus on to the record surface when the arm is released by the changer mechanism.

There are three types of trip mechanisms, one being the velocity trip in which the changer mechanism is triggered by a sudden change in groove pitch. This system has

*Measured with flat frequency response.

the advantage of not requiring adjustments for different inside diameters. It has the disadvantage of requiring, in most designs, that the stylus, cartridge and arm operate a spring tension as they move inwards. This presses the stylus against the outside wall of the grooves and tends to produce differential wear as well as other undesirable effects.

The second type of trip mechanism operates when the stylus reaches a specific inside diameter, and the eccentricity of the inside groove has no effect. The disadvantage of this arrangement is that there are large differences in the inside diameters of the various types of records, so that an adjustable (preferably continuously-variable) control is required. This method is used in 45 r.p.m. record changers, where there is no eccentric inside groove.

The third type is the eccentric groove.

Difficulty is often experienced in an attempt to incorporate automatic record changers in high fidelity equipment owing to rumble and, in some cases, hum pickup. In addition, some high fidelity pickups are unsuitable for use on any automatic record changers. The choice of a pickup for use with an automatic record changer is necessarily a compromise, and many high fidelity enthusiasts prefer to use a good quality turntable with manual operation.

Automatic record changers for 45 r.p.m.

The R.C.A. record changer is described in Ref. 263. The tripping mechanism requires an extremely small lateral force from the pickup arm, since the work of putting the mechanism into cycle is supplied by the moving turntable.

SECTION 2 : DISCS AND STYLI

- (i) *General information on discs* (ii) *Dimensions of records and grooves* (iii) *Styli*
(iv) *Pinch effect* (v) *Radius compensation* (vi) *Record and stylus wear.*

(i) General information on discs

Shellac discs are used only with 78 r.p.m. standard groove records. The material is hard, and has no appreciable elastic deformation under pressure.

Vinyl* is used for all forms of fine groove discs, and has appreciable elastic deformation under pressure. As a consequence, high peak accelerations are reduced as compared with the same recording in shellac. For the effects of elastic deformation see Ref. 212. Vinyl has the defect that it becomes electrified and collects a considerable amount of dust. The effect of dust collection on vinyl records through electrostatic attraction may be avoided by the use of a liquid anti-static agent which may be sprayed or wiped on to the surface of the record.

(ii) Dimensions of records and grooves

(A) 78 r.p.m.

The usual nominal sizes of shellac pressings are 10 in. and 12 in. diameter. Dimensions and tolerances as recommended by the American Radio Manufacturers' Association and as used by English and American manufacturers are tabulated opposite.

European continental records do not differ in any significant respect from English practice. The outside diameters are 25 cm (9.85 in.) and 30 cm. (11.8 in.) and the hole diameter is 0.284 inch.

On the basis of these dimensions, the ratio of maximum to minimum R.M.A. groove diameter is 3.07 to 1 for a 12 inch record, providing a groove speed from approximately 3.9 to 1.3 feet per second (47 to 15.3 inches per second).

*The name vinyl is a general name covering unfilled vinyl co-polymer resins, which may vary somewhat in their physical characteristics.

DIMENSIONS OF RECORDS AND GROOVES (78 r.p.m.).

	U.S.A. (in inches)	English*	
		Present range	Recommended
Outer diameter : 12 in.	$11\frac{1}{8} \pm 1/32^\dagger$	11-15/16 — 11-27/32	$11\frac{1}{8} - 11-27/32$
10 in.	$9\frac{1}{8} \pm 1/32^\dagger$	9-15/16 — 9-27/32	$9\frac{1}{8} - 9-27/32$
Thickness : 12 in.	$0.090 \pm 0.010^\dagger$	0.092 — .082	0.090 — .080
10 in.	$0.080 \pm 0.010^\dagger$	0.080 — .070	0.080 — .070
Centre hole diameter	$0.286 \pm 0.001^\dagger$ — 0.002	0.292 — 0.284	0.2845 — .2835
Centre pin diameter	$.02835 \pm .0005$	0.282 — 0.280	0.2825 — .2820
Outermost groove diameter : 12 in.	$11\frac{1}{2} \pm 0.02^\dagger$	11.500 — 11.395	11.500 ± 0.015
10 in.	$9\frac{1}{2} \pm 0.02^\dagger$	9.515 — 9.485	9.500 ± 0.015
Innermost groove diameter	not less than $3\frac{1}{4}^\dagger$	3.875 — 3.750	3.875
Grooves per inch	88, 96, 104, 112, 120 †	103 — 72 (84 to 96 usual on classical recordings)	104 — 72
Width of groove at top	6.5 — 8 mils †	6.5 — 8 mils	6.5 — 6.7 mils
Depth of groove	not standardized	—	2.9 mils
Radius at bottom of groove	2.2 max. mils †	0.8 — 2.5 mils	1.5 — 1.8 mils
Angle of groove	$87^\circ - 97^\circ^\dagger$	$82^\circ - 98^\circ$	$85^\circ - 90^\circ$

N.B. 1 mil = 0.001 inch.

*Based on Ref. 235 for most dimensions ; Refs. 131, 174 for recommended groove cross-sectional dimensions.

 † R.M.A. REC-103 (Ref. 260). ‡ R.C.A. Victor practice**Additional data (REC-103)**Eccentric stopping groove diameter $3\frac{3}{8}$ in. ; run-out relative centre hole 0.250 ± 0.015 in. ; groove minimum depth 0.003 in.

Lead-in spiral : at least 1 complete turn between outer edge of record and recording pitch.

Lead-out spiral : Nominal pitch $\frac{1}{8}$ in. minimum.

The wavelength for 78 r.p.m. is given by

$$\lambda = (1.3\pi d)/f \quad (5)$$

where λ = wavelength in inches for 78 r.p.m.

d = groove diameter in inches

and f = frequency in c/s.

Equation (5) gives the following values—

Frequency	50	250	500	10 000 c/s
Wavelength—outermost groove	0.94	0.19	0.094	0.0047 in.
Wavelength—innermost groove	0.31	0.061	0.031	0.0015 in.

The effective width of the stylus with dimensions as in Fig. 17.5B is about 4 mils, giving a radius of curvature of 2 mils. Using eqn. (3) of Sect. 1,

$$A_{crit} = 0.025 \lambda^2/0.002$$

and for 10 000 c/s the critical amplitude is—

$$A_{crit} = 0.00028 \text{ in. for outermost groove}$$

$$A_{crit} = 0.000028 \text{ in. for innermost groove.}$$

The critical velocity is given by eqn. (4) of Sect. 1,

$$\text{Critical velocity r.m.s.} = 31.6 \text{ cm/sec at outermost groove}$$

$$= 3.16 \text{ cm/sec at innermost groove.}$$

The critical velocity at the outermost groove is more than sufficient for the highest level of recording, but as the groove diameter decreases a point will be reached where the peak recorded velocity is greater than the critical velocity—thus leading to distortion and loss of high frequency response.

A slightly higher critical velocity could be obtained by the use of a somewhat smaller stylus radius, since the two values are inversely proportional.

The maximum instantaneous peak recorded velocity is about 15 cm/sec (American practice) so that there is every likelihood that the critical velocity will sometimes be exceeded on the smaller diameter grooves. The saving feature in practice is that maximum amplitude does not normally occur at 10 000 c/s with either speech or music, except when cymbals are recorded at maximum amplitude.

(B) 45 r.p.m.*

The R.C.A. Victor 45 r.p.m. fine groove records are only made with a nominal diameter of 7 inches, and are primarily intended for ready use in record changers. The inner portion of the record forms a collar which is thicker than the playing area, thus preventing the playing surfaces from touching. The groove dimensions are

Width across shoulders 3.0 mils + 0 – 0.5

Angle $92^\circ \pm 3^\circ$

Radius at bottom of groove not greater than 0.25 mil.

The recommended vertical stylus force is 5 ± 1 grams.

The grooves per inch vary from 178 to 274. The maximum instantaneous programme peak recording velocity is 14 cm/second (about 4 db below 78 r.p.m. records).

Fig. 17.5A. Cross-sectional view of R.C.A. 7 inch 45 r.p.m. record (Ref. 254).

FIG. 17.5A

The cross-sectional view of a record is shown in Fig. 17.5A. The outermost music groove is 6½ inch diameter, while the innermost music groove is 4.875 inches minimum diameter—the latter gives 10% intermodulation distortion and a groove velocity of 11.5 inches per second.

The maximum playing time is 5½ minutes. A lead-in groove extends from the edge of the record and makes from 1 to 1½ turns before entering the first music pitch. There are from 1 to 1½ turns of unmodulated music pitch before the start of music. There is from 0 to ¼ turn of unmodulated music pitch at the end of music. The

*For R.C.A. 45 r.p.m. Extended Play records see Supplement.

lead-out groove makes from $\frac{3}{4}$ to $1\frac{1}{4}$ turns from the music pitch to 1-15/16 inch radius, beyond which it makes from 1 to 2 turns to the concentric circle (3-13/16 inch diameter).

The central hole is 1.504 ± 0.002 inches in diameter.

(iii) Styli

(A) Styli used with shellac pressings are in five principal groups :

(1) **Ordinary steel needles** which are ground to shape by the abrasive in the record. The exact shape of the needle point when new is not so important as with permanent or semi-permanent styli. For examples of record wear see Ref. 10 Part 4.

(2) **Semi-permanent needles** such as chromium plated steel. The needle shape is important and "shadow-graph" needles are recommended. For the best results these should not be used for more than one playing of a 12 inch shellac record (for photograph of wear see Ref. 274). Alloys such as osmium are also used.

*Columbia only.

(3) "**Permanent**" styli employ a jewel such as a diamond, sapphire or ruby, usually in the form of a jewel tip. The tips of permanent needles should be accurately ground to shape, and highly polished. Diamond tipped needles have a life of several thousands of playings of shellac records for good fidelity. Tungsten carbide is also used. For stylus wear see Sect. 2(vi).

(4) **Fibre needles** are used by some enthusiasts in the belief that they reduce scratch and record wear. While it is true that they reduce scratch they do so by attenuating all the higher frequencies, and they do this no more efficiently than an electrical attenuator. The attenuation of a fibre needle at 4000 c/s is 19 db down as compared with a loud tone steel needle in a typical pickup (Ref. 7). After the first few grooves they wear sufficiently to occupy the whole of the groove and thereby spread the weight of a heavy, stiff pickup of old design. If such pickups are used, contrary to all good advice, then fibre needles are possibly the best compromise because a soft needle damps down the pronounced high-frequency resonance of the pickup. There is evidence to indicate that abrasive particles from the record become embedded in the fibre and thereby cause wear, even though the fibre itself is softer than the record. With modern pickups having light weight and high lateral and vertical compliance the wear from a well polished sapphire point is undoubtedly less than that from a fibre needle.

For photographs of new and worn fibre needles see Ref. 274.

(5) **Thorn needles** are very much harder than fibre, but the amount of needle wear is very much dependent upon the pickup compliance and stylus force. With suitable lightweight pickups, the needle wear is reasonable up to 6 playings (Ref. 309), but some loss of high frequency response is inevitable. If sharpened with the use of very fine glasspaper, there is risk of glass dust becoming embedded in the needle—this danger may be avoided by the use of a very fine rotary cutting wheel (Ref. 309, April 1951).

Since thorn needles are normally in contact with the whole of the bottom of the groove, they will tend to remove all dust from the groove. It therefore seems probable that the noise from a record which has been played exclusively with thorn needles will be no greater at the bottom of the groove than on the sides.

Fine point thorn needles have also been used with fine groove (LP) records (Ref. 309).

The shape of the stylus tip to give optimum results with most English and American recordings may be taken as (RTMA Standard REC-126-A, Ref. 260) :

	Radius of tip	Angle
Metal point	2.7 (+ 0.2 - 0.3) mils	40° to 50°
Sapphire	3.0 (+ 0.2 - 0.3) mils	40° to 50°

A cross-sectional view of a correct size of sapphire stylus point in a typical groove is given in Fig. 17.5B. It will be seen that the stylus does not reach to the bottom of the groove; this is very important because the abrasive dust collects at the bottom of the groove. In addition, there should be some allowance for the stylus to wear on the sides without the bottom of the stylus coming too close to the bottom of the groove.

FIG. 17.5B

Fig. 17.5B. Cross-sectional view of typical record groove and needle tip.

In some modern records, as well as in transcription discs, a tip radius of 2 mils may be used, but in other (and particularly older) recordings it is likely to scrape the groove bottom and suffer from "groove skating" and single point contact.

One interesting suggestion is to combine a 2 mil radius with a "flattened" extremity (actually a 3.5 mil radius). Although more expensive to produce it seems to have distinct advantages (Ref. 244).

Oval sapphire styli are available with a minor axis of 1.5 to 2.0 mils and a major axis of 2.5 to 3.5 mils. These should be used with the major axis

at right angles to the centre-line of the groove, and will permit better response to high-amplitude high-frequency recordings.

The N.A.B. "secondary standard" stylus (permanent point) has an angle of 40° to 55° and a bottom radius of 2.5 ± 0.1 mils. It provides a compromise suitable for the reproduction of both transcriptions and shellac discs.

The use of larger styli (radius 4 mils) is advocated by some engineers (Refs. 223, 225) but it does not appear to be the best all-round compromise.

Needles are made in various sizes. The ordinary steel needles used in mechanical reproducers are used in the stiff heavy weight pickups whose frequency response does not exceed about 6000 c/s; they are also used in some "needle armature" pickups. For the best high frequency response the "loud tone" or "full tone" needles should be used, because of their smaller size and weight. "Soft tone" and "trailing" needles (as used with acetate discs) cause severe treble attenuation when used with typical pickups. Most light weight pickups with a frequency response extending to 10 000 c/s or over use miniature needles to enable the armature resonance to be at a high frequency. A typical example is the H.M.V. Silent Stylus or Columbia 99 (chromium-plated long-playing). Thorn needles are also made of similar size.

Efforts have been made to develop a stylus tip suitable for both 78 r.p.m. and fine groove (see Refs. 279, 281) but a considerable degree of compromise is necessary and the best results are not obtainable from either type of recording.

(B) Styli for fine groove records

With a few exceptions, all styli for fine groove records are permanent types—usually jewels. Diamond tips are the only really satisfactory ones for long life, although expensive to purchase in the first case. Sapphire tips are very common, but wear rather rapidly—see Sect. 2(vi) for stylus wear. Other materials used are tungsten carbide, osmium and other metal alloys.

Dimensions of styli for fine groove records

(RTMA Standard REC-126-A, Ref. 260, for home phonographs)

Radius of tip $0.001 + 0.0001 - 0.0002$ inch

Included angle of tip 40° to 50° .

Note: With a 90° groove angle, a tip with a radius of 0.001 inch has an effective radius of 0.0007 at the point of contact.

(C) Colour codes for styli

1. RTMA REC-126-A for home phonographs (Ref. 260). Needles with a 0.001 inch radius shall be colour coded red.

2. English Gramophone Equipment Panel of the Radio and Electronic Component Manufacturers' Federation (Jan. 1951). Red—0.0010 in.; lemon—0.0020 in.; green—0.0025 in.; french blue—0.0030 in.; orange—0.0035 in.; violet—universal; sky blue—oval tip. Material (marked by band on shaft) black—hard metal; white—diamond; no colour—sapphire.

(iv) Pinch effect

Owing to the fact that the cutting is done by a stylus having an effectively flat cutting face, the width of the groove measured at right angles to the groove is narrower at two places in each cycle (see Sect. 6). As a result of this effect, the stylus tip should rise and fall twice in each cycle—only a limited number of pickups, however, make adequate provision for this movement.

The flexibility of the stylus, if mounted at an acute angle to the record, together with that of the record itself, tends to prevent the needle from riding merely the peaks of the vertical undulations. The pinch effect undoubtedly increases needle wear and possibly also record wear (Ref. 212).

Various forms of "bent shank" needles have been developed to provide some vertical compliance. All "bent shank" needles tend to give a drooping high-frequency response the amount of which varies considerably from one make to another; it may, of course, be compensated if desired.

(v) Radius compensation

Radius compensation does not appear to be used with shellac discs, although it is used with LP discs (R.C.A. Victor) and in transcription discs.

(vi) Record and stylus wear

Record wear is a complicated effect depending upon many conditions of operation including :

1. Vertical stylus force.
2. Lateral mechanical compliance at stylus tip.
3. Vertical mechanical compliance at stylus tip.
4. Lateral and vertical pivot friction in pickup arm, or lateral spring tension.
5. Mechanical resonances of pickup and arm.
6. Tracking error.
7. Shape, material and polish of stylus tip.
8. Maximum transverse velocity of record grooves.
9. Record material.
10. Dust.

It is understood that the turntable is free from vibration and wobble and that the record is neither eccentric nor warped ; if not, these are additional causes of record and stylus wear.

The **vertical stylus force** for use on shellac records should preferably not exceed about 1 ounce weight (28.35 grams) and it should be as light as possible to reduce record and stylus wear to the minimum. However care should be taken to provide sufficient force to ensure satisfactory tracking, otherwise the wear will increase. Increased force, say up to 2 ounces (about 60 grams), causes very little additional record wear provided that a well-polished jewel point is used and the pickup has high lateral compliance.

The stylus force with fine groove records is quite critical, but is a function of the pickup. Forces approximating 6 grams weight are common, but it is safer to err slightly on the high side than on the low side. Some manufacturers give a "minimum tracking weight" and a "normal" value—the latter is the correct one to use.

If the required vertical pressure is not known, it may be determined by using an intermodulation test record, decreasing the pressure until the distortion commences to rise—and then increasing by a margin of, say, 50%.

High lateral compliance at the stylus tip is one of the most important requirements for low record and stylus wear. In general, high lateral compliance and light weight go together.

Vertical compliance at the stylus tip permits the tip to maintain contact with the groove in spite of the "pinch effect." Bent shank styli reduce record wear in cases where the pickup has insufficient vertical compliance.

Mechanical resonances of the pickup are serious causes of record and stylus wear. Both the "arm resonance" (if it comes within the recorded frequency range) and the "armature resonance" affect the record and stylus wear, even if electrically equalized.

Tracking error is discussed in Sect. 4 ; if reduced to the usual low values, record and stylus wear from this cause are very slight.

The **shape and polish** of a jewel stylus tip are of the utmost importance in regard to record wear.

Wear of shellac records

One example is a record which had been played 1000 times with a 1.35 ounce (38 grams) pickup and a sapphire stylus and was then demonstrated as giving fidelity virtually unaffected (Refs. 128, 131). It may be stated as a rough guide that the limit of life of an average shellac record is about 4000 playings under good conditions.

Unmodulated grooves on shellac records will wear indefinitely with a jewel stylus on which the vertical force does not exceed 1 ounce (30 grams). By far the most significant cause of wear is the dynamic action of the stylus in the grooves. If the dynamic force at any moment exceeds the elastic limit of the record material, the shellac crumbles. This permits the stylus to drop down a little deeper in the groove, eventually increasing the bearing area of the needle by contact with the bottom of

the groove. At this point with a pickup having low stylus force, the wear apparently stops. This wear does not produce any apparent change in quality of the reproduced sound, although it can be seen as a light streak on the surface of the record. Both lateral and vertical forces must be considered in producing the wear (Ref. 155). Wherever there is excessive stylus wear, it is always accompanied by excessive record wear.

It is important to distinguish between visible wear and audible wear. Visible wear does not necessarily cause any audible defect. It is possible that visible wear may occur earlier with a diamond tip, but audible wear, which is caused by actual widening of the groove at corners, will occur far more rapidly with a worn sapphire or metal tip. The flats on the sides act as scrapers in attempting to negotiate sharp bends in the record groove. A well polished spherical diamond or sapphire tip is believed to cause less record wear than a metal alloy tip.

Wear of vinyl records

Wear of vinyl fine groove records is very slight, provided that the stylus force does not exceed about 7 grams, that a pickup of ample lateral and vertical compliance is used, that the jewel tip is well polished, that there are no marked mechanical resonances, and that dust is excluded. **Dust** is the most important cause of record and stylus wear with vinyl records in the home, and care should be taken to reduce it to a minimum—see Sect. 2(i). Wear in vinyl records shows itself principally in widening of the groove thus leading eventually to distortion and rattles (Ref. 155).

Wear of sapphire styli

The wear of sapphire styli is a function of the material of which the pressings are made, the lateral and vertical compliance of the pickup at the stylus tip, the dynamic mass of the pickup at the stylus tip, the characteristics of the armature (high frequency) resonance and the pickup arm (low frequency) resonance, and the stylus force. Additional wear may be caused by "skating" (due to the use of a tip radius which is too small for the groove), by insufficient vertical force to maintain the stylus always in contact with the groove, and by warped or eccentric records or turntables. When using a pickup with high lateral and vertical compliance and low dynamic mass at the stylus tip, an increase of stylus force has only a minor effect in increasing the wear on the stylus tip. It has been shown (Ref. 282) that with such a pickup (GP20) on a heavily modulated **shellac record**, an increase from 7.5 to 14.5 grams in stylus force causes increased flats on the stylus tip resulting in a drop of only 3 db at 10 000 c/s on a test record. Such a stylus and pickup may be used for 800 playings of a 12 inch shellac record with reasonably good fidelity, or 2000 playings with fair fidelity (— 5 db at 10 000 c/s on a test record).

On the other hand a typical light-weight pickup with a stylus force of 1 ounce (28 grams) has been shown to produce wear on sapphire styli on shellac records as follows (Ref. 59).

Wear just noticeable after 50 playings of 12 inch disc.

1 mil flats after 200 playings	} The effect of flats on distortion is covered in Sect. 6(iv).
2 mil flats after 750 playings	
2.5 mil flats after 1500 playings	

It is obvious that this pickup produces much greater wear than the one with high lateral and vertical compliance (GP20) described earlier. It is probable that the greater wear is due principally to the lower lateral and vertical compliance, although the increased stylus force would also be a contributing factor.

Some excellent photographs of stylus wear are given in Refs. 274 and 290.

The use of a test record at, say, 10 000 c/s to indicate wear of the stylus tip requires careful interpretation of the results. The level of recording of the test record is lower than that which may be reached with music, while the effect of wear of the stylus tip is shown less prominently towards the outer diameter of the record than it would be with a smaller groove diameter.

It is wise to avoid using sapphire or other permanent stylus tips on records which have been played previously with steel needles. For a photograph of wear after 20 playings under such conditions see Ref. 274.

Stylus wear with fine groove records

Apparently stylus wear is far more rapid on microgroove than on standard groove vinyl records; a rough estimate is about three times faster (Ref. 290). For this reason, diamond styli are much to be preferred to sapphire or osmium, even for home use, where high fidelity is required.

In one case, when tested on 12 inch long playing records, with a GE RPX-041 pickup having 8 grams pressure, a diamond stylus showed a slight flat after 37 hours playing time, whereas a sapphire under similar conditions was badly worn after 5½ hours (15 playings)—see photographs Ref. 290.

There appear to be considerable variations on the hardness of the sapphires, which are practically all made of synthetic sapphire (Ref. 302), so that it is impossible to quote any figures of stylus wear which can be regarded as typical. In all cases the stylus life is very much affected by the pickup.

Osmium tipped styli have a life only two fifths (Ref. 290) or one sixth (Shure) that of sapphire. This makes the effective life with an osmium tipped stylus, for high fidelity, extremely short.

Method for giving positive indication of stylus condition

Obtain a lacquer disc with unmodulated grooves cut on both sides of it—one side for a 3 mil stylus and the other for a 1 mil stylus. Both types of grooves may be on the one side of the disc. Whenever in doubt, play two or three grooves on this disc. If the stylus leaves the grooves unchanged in lustre and smoothness, it is in good condition. If, however, the groove walls show score marks or any other difference when compared with the unplayed grooves, the stylus needs replacement. An ordinary magnifying glass will be of assistance (Ref. 298).

SECTION 3 : PICKUPS

(i) *General survey* (ii) *Electro-magnetic (moving iron) pickups* (iii) *Dynamic (moving coil) pickups* (iv) *Piezo-electric (crystal) pickups* (v) *Magnetostriction pickups* (vi) *Strain-sensitive pickups* (vii) *Ribbon pickups* (viii) *Capacitance pickups* (ix) *Eddy-current pickups*.

(i) General survey

The performance expected from good quality pickups includes—

1. Wide frequency response with the minimum of equalizing. No sharp peaks over + 2 db. For most applications a slight droop in the high frequency response is not undesirable as it may be used to compensate for the pre-emphasis in most recordings.

2. Low stylus pressure.

3. High lateral compliance.

4. High vertical compliance at stylus tip.

5. Low effective vibrating mass of armature at high frequencies.

6. Fairly high output level.

7. Low distortion.

8. Freedom from major resonances over the useful frequency range (see below). The low frequency (arm) resonance should be below 30 c/s so that it will have a negligible effect on record wear. The high frequency (armature) resonance should be as high as possible—certainly over 8000 c/s—and preferably above the useful frequency range. Even so, the resonance should be effectively damped.

9. Minimum "needle talk" (direct acoustical radiation).

10. High signal to hum ratio.

11. Negligibly small voltage generation from vertical movement of the stylus tip.

12. General ruggedness.

13. Freedom from the effects of excessive humidity. Pickups having a restricted frequency range (say from 70 to 6000 c/s) should meet the same requirements as good quality pickups, apart from frequency.

Pickups which have sufficient vertical compliance are sometimes fitted with needle guards to reduce or prevent damage to the pickup from accidentally dropping it.

Pickup manufacturers sometimes quote the minimum vertical stylus force to provide perfect tracking. It is generally regarded as sound practice to adopt a stylus force at least 1.5 times this minimum value, thus making some provision for warped and eccentric records.

For styli, see Sect. 2(iii).

Single purpose pickups for home use often incorporate a fixed spring counterbalance. Dual purpose pickups usually apply a higher stylus pressure for 78 r.p.m. than for fine groove records. In some cases the pickup head (or cartridge) includes the additional weight for 78 r.p.m., in other cases this is provided by an adjustment of spring tension or by a counterbalancing weight.

It is desirable in all cases to keep the moment of inertia about both vertical and horizontal pivots to a minimum.

Where a spring counterbalance is used, it should be checked periodically for pressure; during weighing, the height of the stylus from the baseboard must be exactly the same as the top of the record.

Up and down movements of the stylus tip, due to the pinch effect and small record surface irregularities should be absorbed by the vertical compliance of the stylus, without generating any output noise.

Pickups for 78 r.p.m.

A stylus force not more than 1 ounce (say 30 grams) is desirable, with 2 ounces as the upper limit.

One of the difficult problems with permanent tipped styli is provision for changing needles without adding seriously to the armature mass. Certain pickups are designed for use with miniature needles pushed into place and gripped by a wedge against which they are held by the pressure from the record. There are two troubles which may occur. The first is that the needle may rotate about its axis, thus placing its "flats" at some unknown angle to the groove—such a case is known to the author. This may be eliminated by tightening the clutch or by using a little cement. The second trouble is "buzz," which is more serious because there appears to be no cure; however it only seems to occur on deeply modulated recordings of complex waveform, and is only apparent when the frequency range is extended.

Nearly all high fidelity pickups have the stylus permanently fixed to the armature—this appears to be essential for the high frequency resonance to occur above 10 000 c/s.

Pickups for fine groove records

The maximum desirable needle pressure is 6 grams (0.21 ounce) and high lateral compliance is essential. Pickups have been produced by many manufacturers, mainly using diamond, sapphire or osmium tips.

Careful pickup arm design, specifically for fine groove recording, is of paramount importance. It is inadvisable to use a fine groove pickup head or cartridge on an arm other than that designed for it.

A very simple and effective test for the tracking efficiency of a pickup and arm for fine groove records is known as the **McProud Test** (Ref. 314). A 45 r.p.m. record is placed on a standard turntable running at 45 r.p.m. with the maximum possible eccentricity (1½ inches swing), and the pickup is required to track the record satisfactorily.

Dual purpose pickups have been designed which have two opposed needles 180° apart, suitable for playing either standard 78 r.p.m. or fine groove records.

Pickups employ many principles of operation, but most types are basically either constant velocity or constant amplitude. For example both electro-magnetic (moving iron) and dynamic (moving coil) pickups are basically constant velocity, while piezo-electric (crystal) types are basically constant amplitude. Since the recording characteristic includes both constant velocity and constant amplitude sections, either group is satisfactory although requiring different equalization.

Resonances in pickups

Most pickups have two major resonances. The **arm resonance** occurs at some frequency below 100 c/s, while the **armature resonance** occurs at some frequency about 3000 c/s. Both resonances have deleterious effects in increasing record wear. The arm resonance tends to cause the pickup to jump out of the groove when a high amplitude is recorded at the frequency of resonance—the frequency of resonance (if undamped) should be well below the lowest frequency for which acceptable tracking is required; say from 15 to 25 c/s.

A recent development is the use of pickup arms with high viscosity oil or other viscous fluid to damp arm resonance. The damping may be applied as a viscous film in a ball and socket (hemispherical) joint between the pickup arm and the mounting socket, and gives damping in both horizontal and vertical directions. The arm is pivoted at a point which is the centre of both ball and socket, and above the centre of gravity of the arm. The clearance between the two surfaces is about 0.006 inch. By this means the resonant force is greatly reduced, improved resistance to external shock is obtained and protection against damage from accidental dropping of the pickup head is achieved. The amount of mechanical resistance is not a critical value—the upper limit is reached when it interferes with the tracking of records having reasonably small values of eccentricity or warpage. With the usual values of suspension compliance and mass, this would occur at several times the amount of resistance necessary to give critical damping of the arm resonance. Even if the damping is considerably below critical, it still has quite a beneficial effect. The viscosity of the fluid is a function of temperature, but the variation does not seriously affect the performance over a reasonable temperature range. Ref. 311.

The **armature resonance** has a serious effect on needle scratch (see Sect. 1). "During operation the needle is subjected to a continuous shower of blows, and although highly damped by rubber buffers, it is in a state of perpetual oscillation at its own resonance frequency" (Ref. 229). In any quality pickup, the armature resonance with the recommended needle should be over 8000 c/s; many light-weight pickups have the resonance at a frequency over 12 000 c/s—in some cases over 18 000 c/s.

Pickups tend to be rich in harmonics at frequencies in the region of half the armature resonance frequency. In all cases the armature resonance should be effectively damped. Damping material used to obtain smooth response characteristics may adversely affect the tracking capabilities of the pickup, and therefore should be investigated carefully and used judiciously (Ref. 285).

The frequency of the armature resonance is affected by the record material—for example, a change from a lacquer disc to a shellac pressing causes in one case an increase in the resonant frequency in the ratio 1:2 approximately (Ref. 276). A pickup with an armature resonance well outside the a-f range on shellac discs, shows a much lower resonance frequency on vinyl—usually inside the a-f range. This is an unfortunate characteristic of vinyl. The only pickups known to the author with armature resonances above 15 000 c/s on vinyl fine groove recordings are of the ribbon armature type.

There is a third resonance caused by the pickup head and arm rotating about the arm. With heavy pickups this resonance occurs at frequencies between 100 and 400 c/s, but with light-weight pickups the frequency would be higher. This resonance does not have any effect on the general tonal balance, and in any case should be very slight with good mechanical design.

Crystal pickups have a fourth resonance which occurs at a high frequency—the resonance of the crystal itself.

References to resonances in pickups: 10 (Part 2), 17 (second letter), 276, 283, 285, 311, 331.

The testing of pickups

The testing of pickups for frequency response characteristics is covered by R.M.A. REC-125-A which states that the test record shall be R.M.A. Frequency Test Record

No. 1 when available. This is recorded on side A at a r.m.s. velocity of 3.16 cm/sec (+ 10 db). Crystal pickups are terminated by a load resistance of 1 megohm (or 5 megohms for ammonium phosphate crystals) shunted by a capacitance of 100 μ F. Other types of pickups should be terminated as required. The response should be stated in decibels (0 db = 1 volt).

Pickups should be tested under the same conditions with which they will operate in normal service. Pickups intended to be used on shellac records should be tested on shellac discs; pickups intended for use on vinyl records should be tested on vinyl discs, while those intended for use on either type of disc should be tested separately on each. Pickups which are satisfactory on vinyl discs give, in some cases, quite poor results on shellac discs owing to the increased stiffness of the material and the reduction in damping by the record. This also applies to pickups with very limited vertical compliance—while passable on vinyl, they are poor on shellac.

The variable speed turntable is sometimes used as an alternative to the standard frequency records for the calibration of pickups—see Refs. 273, 295.

In the design and production of pickups it is usual to supply some form of electro-mechanical calibrator such as in Ref. 284.

For distortion in pickups and the procedure for determining the “tracking” capabilities of a pickup see Sect. 6(vi).

(ii) Electro-magnetic (moving iron) pickups

All “moving iron” pickups have a steady field supplied by a permanent magnet, a coil wound over the magnetic circuit, and an iron armature in the magnet gap. The old type of heavy pickup of this type used with shellac records weighed about 3½ ounces (say 100 grams) and had low lateral compliance. It will not be further described.

The more recent light-weight models are capable of good fidelity, and some models are among the best pickups available. The increased fidelity and higher compliance are obtained at the cost of lower output level—very much lower in some cases.

Electro-magnetic pickups may arbitrarily be divided into three groups, based on the output voltage developed across the pickup with recorded velocity 3.16 cm/sec (+ 10 db).

- (a) High level—output voltage above 100 millivolts.
- (b) Medium level—output voltage from 20 to 100 millivolts.
- (c) Low level—output voltage below 20 millivolts.

Some typical representatives in each group are described below. In most cases the descriptions are based on published information supplied by the manufacturer. The inclusion of certain models should not be taken as indicating their superiority over types not included.

(a) High level pickups

Decca ffr pickup type D (English) — standard groove

This pickup is of the needle armature type, having a hollow armature fitted with a sapphire, tungsten carbide or diamond stylus. The armature suspension and damping are of rubber; the stylus, armature and rubber suspension are replaceable as one unit. The low frequency resonance is 25 c/s, while the armature resonance is about 17 000 c/s. The impedance of the pickup is 4200 ohms at 1000 c/s and the output 0.2 volt at the same frequency; lower impedances are also available. The frequency response corresponds to the velocity characteristic of the ffr record within ± 1 db. The whole armature including stylus and damping blocks is replaceable by the user. The stylus tip is available in both round and oval shapes.

Lateral compliance

1.1×10^{-6} cm/dyne

Impedance at arm resonance frequency (approx.)	17 000 dynes/sec./cm.
Distortion in pickup	less than 2%
Stylus force	22 to 24 grams (0.78 to 0.85 ounce).
Load resistance	100 000 ohms

(b) Medium and low level pickups

Connoisseur Super Lightweight pickup (English)—standard and microgroove

This is a high-fidelity pickup with interchangeable heads. Heads are available with 1 mil, 2.5 mil and 3 mil radii sapphire tips. The frequency response is level ± 2 db from 25 to 15 000 c/s. The 25 ohm model gives 10 millivolts output, or 300 millivolts from a 1 : 50 transformer. The 400 ohm model gives 40 millivolts, or 200 millivolts from a 1 : 6 transformer. The armature mass is 20 milligrams, and the dynamic mass* is 0.8 milligram. The stylus force is 8-10 grams (standard) or 4-6 grams (microgroove). The pressure is automatically corrected by weights in the plug-in head.

Goldring Headmaster (English)—standard and microgroove

This is a high-fidelity pickup with interchangeable heads. Heads are available with 1 mil, 2 mil, 2.5 mil and 3.5 mil radii sapphire tips. The frequency response with 2.5 mil needle is level to 7000 c/s, - 1 db at 10 000 c/s, + 1 db at 16 000 c/s, 0 db at 17 000 c/s and - 5 db at 20 000 c/s; at the other end it rises smoothly from 100 to 30 c/s where it is + 3 db. The output is 40 millivolts (from the pickup itself) and stylus force 20 grams (0.7 ounce). It has high lateral stylus compliance, low inertia, and high vertical compliance. This is a good-all-round pickup for home gramophones.

Pickering cartridges (American) standard and microgroove

Model S-120M (sapphire stylus), or D-120M (diamond), is for standard recordings, and has a 2.7 mil radius tip. A stylus force of 15 grams is sufficient for tracking.

Model S-140S (sapphire), or D-140S (diamond), is for microgroove recordings, and has a 1.0 mil radius tip. A stylus force of 6 grams is recommended.

Both models give an output of 70 millivolts with a recorded velocity of 10 cm/sec. The frequency response with a load resistance of 27 000 ohms is level from 30 to 9000 c/s, + 2 db at 20 c/s, + 2.5 db at 12 000 c/s and falling above that frequency. A lower load resistance attenuates the higher frequencies, while a higher load resistance reduces the damping on the pickup, decreases the signal-to-noise ratio, and is generally undesirable.

Constants of moving system

Lateral moment of inertia	11 mg cm ²
Lateral compliance of stylus	1.0×10^{-6} cm/dyne
Vertical compliance of stylus	0.2×10^{-6} cm/dyne

Pickering Turn-over pickup (American)—all records

This model 260 pickup may be turned over for either 78 r.p.m. or microgroove operation. It has an output of 30 millivolts at a recorded velocity of 10 cm/sec. It is available with diamond stylus only.

* Dynamic mass (also known as equivalent mass or effective mass) is that mass which, if concentrated at the stylus point, would possess the same inertia as that of the moving system.
See also Refs. 248, 283.

G.E. variable reluctance pickup (American)—standard and fine groove

This is a magnetic pickup having almost ideal characteristics except that the output voltage is low (10 millivolts at 4.8 cm/sec.). It has no "needle talk" and has considerable resistance to shock. It has a large degree of vertical compliance, while vertical movement does not cause any electrical output. The suspension is free from any deleterious effects such as standing waves or cross-modulation, and the construction is designed to reduce hum pickup. The frequency response is from 30 to 15,000 c/s. ± 2 db. The inductance is 520 mH for the home type, and 250 mH for the broadcast types (RPX-046 and RPX-047) which also have a lower output (8 mV). The normal stylus force is from $\frac{3}{4}$ to $1\frac{1}{4}$ oz. (1 oz. on home type) with 78 r.p.m., or 6-8 grams on microgroove.

Dynamic mass of stylus	8 milligrams
Suspension compliance (lateral)	0.87×10^{-6} cm/dyne
Load impedance, normal	6800 ohms.

The cartridge is fitted with interchangeable styli, including 1 mil, both diamond and sapphire. For a suitable pre-amplifier see Fig. 17.26.

References 93, 106, 187, 234, Catalogues.

R.C.A. Light weight pickup—transcription and fine groove

Model MI-11874 pickup, MI-11875 arm. See Refs. 296, 313 and R.C.A. catalogues.

A plug-in pickup head is used, permitting immediate change from 1.0 to 2.5 mils without necessitating any adjustment of arm balance. Stylus force is 8 grams for 1.0 mil and 12 grams for 2.5 mil. Diamond styli are used. Tone arm resonances are outside of the operating frequency range. The vertical and horizontal pivots have very low friction. Frequency response (1.0 mil) at output from filter 50 to 12 000 c/s ± 1 db, 40 c/s at -4 db. Voltage output at 1000 c/s on open circuit = 11 mV with 6.1 cm/sec. test record. Output from filter = 64 dbm. Test record 460625-6. Hum level = 139 dbm with magnetic flux density 1 milligauss. Output pickup impedance 135 ohms at 1000 c/s. Filter output should be connected to unloaded input transformer of amplifier designed to operate from 250 ohm source. Intermodulation distortion is low to the point where it is not possible to determine accurately whether the distortion is in the record or the pickup.

E.M.I. Unipivot transcription pickup (English)—standard and microgroove

This Model 17 pickup has interchangeable styli for standard and microgroove, and the arm has an oil damping system. Its impedance is 1 ohm at 1000 c/s, and the output at the secondary of the transformer is 30 millivolts (high ratio), or 4 millivolts (600 ohms), or 2.25 millivolts (200 ohms). The frequency response is sensibly level from 30 to 12 000 c/s with standard stylus (armature resonance above 15 000 c/s). Total harmonic distortion at 400 c/s is less than 5% for a recorded level of $+20$ db (0 db = 1 cm/sec). The stylus force is 6 grams.

Audak Polyphase (American)—two styli

This has two separate styli, each with its own vibrating armature. One stylus force (6-8 grams) is used for all records. Either sapphire or diamond styli may be used, and may readily be replaced. Output is about 20 millivolts, and frequency response 30 to 10 000 c/s, level ± 1 db from 80 c/s upwards, with gradual rise to $+2$ db at 30 c/s. Armature resonance is at 9000 c/s.

(iii) Dynamic (moving-coil) pickups

A dynamic pickup has a coil, with a stylus attached to cause movement of the coil, mounted in a magnetic field and operating as a generator.

With good design this construction is virtually distortionless at low frequencies, but the output voltage is very low and a high-ratio transformer is always used in conjunction with it. One possible difficulty is hum which may arise either through induction from the turntable motor to the moving coil, or through hum picked up

by the transformer; special mu-metal shielded transformers may be necessary to obviate the latter trouble.

Fairchild dynamic pickup (American)—transcription

The low frequency resonance is at 18 c/s and the armature resonance is over 12 000 c/s with only 2 db rise at the latter frequency. Tracking may be obtained on a flat and true record with a needle pressure of only 5 grams (say 0.2 ounce) but the normal needle pressure has been increased to 25 grams (say 0.9 ounce) for best performance under all conditions. The moving coil is supported by two plastic vanes, and a diamond point is used. Ref. 57.

Leak dynamic pickup (English)—home type

A diamond stylus is standard in the latest moving coil pickup developed by H. J. Leak. The height of the pickup is adjustable. The turntable should be non-magnetic. Spring loading is used without any counterweight. Gimbal mounting is used, with hardened steel pivots. This pickup cannot be used with automatic record changers. The frequency response is level ± 1 db 40-20,000 c/s, the high frequency resonance being above 27,000 c/s ($21,000 \pm 2000$ for LP). The low frequency resonance is 20 ± 5 c/s. The output is 11 mV per cm/sec. recorded r.m.s. velocity. The playing weights are 5-6 gm. on 78 r.p.m. and 2-3 gm. on long-playing records.

(iv) Piezo-electric (crystal) pickups

A piezo-electric crystal is one which, when strained, produces electric charges on certain of its faces, the magnitude of these charges being directly proportional to the strain. In practice, two slabs of a suitable piezo-electric material are usually cemented together with one electrode between the slabs and another in contact with both outer faces. The slabs are cut in such a manner that a torque (in the case of a "twister" crystal) or a flexure (in the case of a "bender" crystal) will produce a potential difference across the electrodes. This assembly is known as a "bimorph," the torsional variety being used in most crystal pickups. The output from a crystal pickup is directly proportional to the amplitude of the stylus displacement.

The most commonly used crystal is sodium potassium tartrate (Rochelle salt). This is seriously affected by both high temperatures (over 125°F) and high humidity; some units are protected from humidity by a water-tight casing.

Other materials include ammonium dihydrogen phosphate (Ref. 158) which is not affected by high temperature or humidity, and ceramic piezo materials (barium titanate etc.). The latter is described on page 721.

The equivalent circuit of a crystal pickup is a capacitance in series with a generator of zero impedance. At 1000 c/s the impedance of many typical pickups is about 0.5 megohm, indicating a capacitance of about $0.0003 \mu\text{F}$. One manufacturer (W.E.) produces pickups with impedances from 0.08 to 0.2 megohm, indicating capacitances from 0.002 to $0.0007 \mu\text{F}$ respectively.

Some crystal pickups are fitted with bent styli to provide vertical compliance for the "pinch effect" and to reduce "needle talk," while others make provision for vertical compliance inside the pickup.

Crystal pickups may be divided into general-purpose types and light-weight high-fidelity types, although there are some with intermediate characteristics. General-purpose crystal pickups have fairly high output, about 1 volt at 1000 c/s, with both arm and armature resonances within the working frequency range. A simple equalizer circuit is Fig. 17.29, although these pickups are frequently used without any equalizer. The stylus force of modern types is usually less than 2.5 ounces (70 grams). Some crystal pickups are available—both standard and fine groove—with a highly compliant drive and capable of tracking with a stylus force of about 8 grams (e.g. Shure "vertical drive").

The output from a crystal pickup, which may be 1 volt at 1000 c/s, may rise to more than 3 volts r.m.s. at frequencies around 100 to 250 c/s—if no equalizing is used, there is danger of overloading the first valve in the amplifier. A resistance attenuator may be used to reduce the voltage to any desired value.

volts. Since the pickup is a constant-amplitude device, special methods are required for frequency compensation. The pre-amplifier of Fig. 17.6 gives the required frequency compensation with continuously-variable controls (see Ref. 336 for settings for some American records) and an output of about 2 volts with types 6AU6 and 12AU7. The final stage is a cathode follower. Refs. 96, 303, 336.

A later model of the pickup has a resistance of 125,000 ohms, an output of 5 to 10 millivolts, and a compliance of 1.2×10^{-6} cm/dyne.

(vii) Ribbon pickups

Ribbon pickups operate on the same general principle as the ribbon microphone, and the output is necessarily very low. For this reason a high ratio step-up transformer, magnetically shielded, and a high gain pre-amplifier are required. One design is described below.

Brierley ribbon pickup (English)—home type (Type 4)

This pickup has two gold ribbons backed by a material selected for its self-damping properties. There is, in consequence, no measurable high frequency resonance and this is largely responsible for an extremely low level of buzz. For vibrations in the direction of the groove the damping is independently controlled and very high, but for lateral movements the restoring force is extremely low—lower than that of any other pickup known to the author. The vertical compliance is high, although only half that of the Pickering transcription pickup. The pickup is supplied with a transformer in a mu-metal case, the secondary being loaded by a 0.1 or 0.25 megohm resistance. This pickup may be used on any type of record, including microgroove, without changing tracking force. However the force on microgroove can be halved.

Normal tracking pressure	1/8 ounce (3.5 grams)
Lateral compliance	13×10^{-6} cm/dyne
Vertical compliance	0.09×10^{-6} cm/dyne
Arm resonance	5 c/s
Armature resonance not less than	32 000 c/s.
Frequency response flat from	30 to 20 000 c/s, rising to + 2 db at 20 c/s.
Voltage output (across secondary)	10 millivolts
Dynamic mass	about 2 milligrams.

Stylus tips are either diamond or tungsten carbide, the life of the latter being claimed to be much longer than that of sapphire under similar conditions (Refs. 157, 277). Stylus tip radii are 1 mil and 2.5 mils.

It seems likely that the **signal to hum ratio** of the pickup itself is approximately the same as that of a multi-turn moving coil pickup—however see Ref. 312. The hum introduced in the pickup leads and the hum introduced by the transformer are more significant with the ribbon pickup, but may be reduced to very low values by good design.

(viii) Capacitance pickups

A capacitance pickup, in which the movement of the stylus causes a change of capacitance, provides such a small output voltage that it normally requires a very high gain pre-amplifier. However, when it is used to change the frequency of an oscillator, and the output from the oscillator is applied to some form of F-M detector, the output voltage is ample to operate the usual 2-stage amplifier in a radio receiver. In the case of a F-M receiver, the output from the oscillator may be coupled directly to the aerial terminal or to some convenient point in the circuit. Care must be taken to avoid radiation on any band used for radio communication.

A simplified arrangement is shown in Fig. 17.7 in which V_1 is used as an oscillator tuned to resonance by L_1C_1 . The inductor L_2 in the grid circuit is made self-resonant at a frequency near that of the plate circuit. Conventional grid-resistor biasing is

Fig. 17.7. Using a capacitance pickup to provide audio frequency output from an oscillator (Ref. 119).

provided by R_1C_2 . The capacitance pickup is connected between grid and plate, and any variation in capacitance will affect the amount of feedback and therefore also the amplitude of oscillation and the voltage drop across R_1 . The latter, filtered by R.F.C. and C_3 , provides the a-f output which is of the order of 1 volt (Ref. 119).

References to capacitance pickups : 14, 45, 50, 119.

(ix) Eddy-current pickups

In this type of pickup the stylus moves a high-resistance vane in proximity to the inductor of a resonant circuit in an oscillator. The motion of the vane changes the resistance reflected into the tuned circuit and thereby produces amplitude modulation of the oscillator by varying the losses. The amplitude modulation is detected to provide the a-f output voltage. In the Zenith "Cobra" the total harmonic distortion does not exceed 2% and the frequency range extends from 50 to nearly 4000 c/s, with a sharp cut-off at 4000. The level from 1500 to 3500 c/s is 8 db below that at 500 c/s (Ref. 65).

SECTION 4 : TRACKING

(i) General survey of the problem (ii) How to design for minimum distortion (iii) The influence of stylus friction.

(i) General survey of the problem

With any pivoted pickup arm it is obvious that the angle between the axis of the pickup and the tangent to the unmodulated groove must change as the pickup moves across the record. This results in (1) harmonic and inharmonic spurious frequencies caused by frequency modulation ; (2) side thrust on the record grooves ; (3) increased record wear (in extreme cases only).

It is therefore advisable to take steps to reduce these effects to satisfactorily small values. The condition for minimum angular tracking error does not provide minimum distortion, because the tracking angle is most critical at the innermost groove. As a matter of interest, it is possible to design a pickup with an angular tracking error not exceeding $2\frac{1}{2}^\circ$ with a length of about $7\frac{1}{2}$ inches, but this is not the optimum design.

References to methods for minimizing angular tracking error : 54 (correction in Ref. 55), 56, 85.

The following summary is based on the detailed analysis by Baerwald (Ref. 228). The subject has also been dealt with in more popular form by Bauer (Ref. 52). The frequency modulation effect is a frequency modulation of the signal by itself, which produces "side band" frequencies. When the signal is a pure sine-wave of frequency f , the dominant "side band" frequency is $2f$, which is the same as the second harmonic. The distortion may therefore be treated as second harmonic distortion, the value being given by :

$$\begin{aligned} \text{Percentage 2nd harmonic} &= (\omega A \alpha / V) \times 100 & (1) \\ &= (v_o \alpha / V) \times 100 & (2) \end{aligned}$$

where $\omega = 2\pi f$

A = maximum groove amplitude in inches

α = tracking error expressed in radians (= angle in degrees divided by 57.3)

V = longitudinal groove velocity in inches per second.

and v_o = maximum transverse velocity in inches per second = ωA .

Equations (1) and (2) indicate that

(1) Distortion is directly proportional to the maximum transverse velocity.

(2) Distortion is directly proportional to the maximum groove amplitude at any one frequency.

(3) Distortion is directly proportional to the tracking angle.

(4) Distortion is inversely proportional to the revolutions per minute. For equal distortion, more careful tracking angle correction is required with 33-1/3 r.p.m. than with 78 r.p.m., other conditions being the same

(5) Distortion is constant over the "constant velocity" portion of a recording characteristic, other conditions being unaltered

(6) The angular tracking error may be increased in the same proportion that the radius is increased, for the same distortion (roughly 3 : 1 ratio over a 12 inch record).

Example of distortion

Consider the distortion with a 12 inch 78 r.p.m. record having 2° angular tracking at the innermost groove, recorded with a sine wave having a peak amplitude of 0.002 inch at a frequency of 250 c/s (this being the cross-over frequency), the r.m.s. velocity being 6.31 cm/sec.

Here $\alpha = 2/57.3$ radians ; $A = 0.002$; $\omega = 2\pi \times 250$; $r = 1.875$ inches ; $V = 2\pi r(78/60) = 15.3$ inches/second.

From equation (1)

$$\text{Percentage 2nd harmonic} = \frac{2\pi \times 250 \times 0.002 \times 2 \times 100}{57.3 \times 15.3} = 0.72\%.$$

If the cross-over frequency had been 500 c/s, with the same recorded velocity (i.e. half the amplitude), the distortion would have been the same. Some frequency test records are recorded with a velocity less than 6.31 cm/sec, so that the distortion due to tracking error would be less than the value stated above. The harmonic distortion as determined for sinusoidal signals gives a fair estimate of the relative tracking distortion produced by complex signals over the "constant velocity" portion of the characteristic.

FIG. 17.9

FIG. 17.10

Fig. 17.9. Constant velocity recording characteristics showing relative variation of groove amplitude with frequency.

Fig. 17.10. Frequency characteristic of ideal constant velocity pickup, for constant amplitude of needle point.

The constant velocity recording characteristic provides a groove amplitude which is inversely proportional to frequency (Fig. 17.9). The ideal constant velocity pickup (a high-fidelity electro-magnetic type is a close approximation) provides an output voltage which is proportional to the frequency, for constant amplitude at the stylus point. It follows that with tracking distortion (or any other form of distortion caused by the groove, needle, or pickup) the harmonics are accentuated in proportion to their frequencies. This effect has been taken into account in the derivation of equations (1) and (2).

It has been proposed (Ref. 228) that a suitable upper limit for tracking distortion is 2% with 0.001 inch peak amplitude as for transcriptions or 4% with 0.002 inch peak amplitude as for shellac discs; it seems that 1% is a preferable limiting value for good fidelity. On this latter basis the maximum tracking error for 12 inch discs will be 2.8° for 250 c/s cross-over frequency, or 1.4° for 500 c/s crossover frequency, both measured at the innermost groove, or three times these values at the outermost groove.

No additional record wear occurs due to tracking error with permanent needles having spherical tips. Additional record wear may occur with steel needles or with worn sapphire tips if the tracking error is serious.

(ii) How to design for minimum distortion

A straight-arm pickup (not offset) is shown in Fig. 17.11 where D represents the distance from the centre of the record to the pivot of the pickup arm, L represents the length of the arm measured from the pivot to the needle point while r_1 and r_2 represent the radii of the outermost and innermost grooves. In this example the pickup is mounted so that the needle point will pass over the centre of the record, but this is not the position giving the best results. It is obvious that the axis of the pickup is not a tangent to the groove.

Minimum distortion is always obtained from a straight-arm pickup when it is "underhung," that is when the needle point comes short of the centre of the record by a small distance d , the optimum value of which is given below.

FIG. 17.11

Fig. 17.11. Straight-arm pickup on record.

FIG. 17.12

Fig. 17.12. Offset-arm pickup on record.

Straight-arm—not offset (Fig. 17.11)

$$\text{Optimum underhang} = d_{opt} = \frac{r_1^2 r_2^2}{L(r_1^2 + r_2^2)} \quad (3)$$

For 10 inch discs $d_{opt} = 3.04/L$.

For 12 inch discs $d_{opt} = 3.18/L$.

These are based on the values:

For 10 inch discs $r_1 = 4.75$ $r_2 = 1.875$ inches.

For 12 inch discs $r_1 = 5.75$ $r_2 = 1.875$ inches.

With $L = 8$ inches, $d_{opt} = 0.380$ inch for 10 inch discs
 $= 0.397$ inch for 12 inch discs.

These values for d_{opt} are critical, and should be measured accurately. It is safer to keep below than to go above the optimum overhang.

The angular tracking error α at any position on the record is the angle between the axis of the pickup and the tangent to the groove at the needle point. (Figs. 17.11 and 17.12).

With a straight arm, using any value of underhang (Fig. 17.11),

$$\alpha \approx 57.3 \left(\frac{r}{2L} + \frac{d}{r} \right) \quad (4)$$

with an error less than 1° .

The optimum value of underhang is given by eqn. (3); using this value and also the values of r_1 and r_2 as for 12 inch discs, with $r = r_2$ (innermost groove) and $L = 8$ inches, the corresponding value of tracking error is approximately 18.6° . The distortion is therefore approximately 6.7% at this point, on the constant velocity characteristic.

Fig. 17.12 shows a pickup with an **offset arm** for the purpose of reducing distortion due to tracking error. This differs from the straight arm in that there is an offset angle β between the axis of the pickup and the straight line joining the pivot to the needle point. Note that this angle β is not equal to the angle of the bend in the arm. In this case minimum distortion is always obtained when the pickup is "overhung," that is when the needle point passes beyond the centre of the record by a distance $-d$, the optimum value of which is given below, on the assumption that the optimum value of offset angle is used.

When a pickup is mounted to provide minimum tracking distortion when used with ordinary needles, the use of bent-shank or trailing type needles will seriously affect the tracking distortion. In cases where either type of needle may be used, a compromise may be necessary. When bent-shank needles only will be used, the increased length of arm should be allowed for.

Offset arm (optimum offset angle) (Fig. 17.12)

$$\text{Optimum overhang} = -d_{opt} = \frac{r_1^2 r_2^2}{L[\frac{1}{4}(r_1 + r_2)^2 + r_1 r_2]} \quad (5)$$

For 10 inch discs $-d_{opt} = 3.99/L$.

For 12 inch discs $-d_{opt} = 4.60/L$.

When $L = 8$ inches:

For 10 inch discs $-d_{opt} = 0.499$ inch.

For 12 inch discs $-d_{opt} = 0.575$ inch.

The optimum offset angle (β in Fig. 17.12) is given by

$$\sin \beta_{opt} = \frac{r_1 r_2 (r_1 + r_2)}{L[\frac{1}{4}(r_1 + r_2)^2 + r_1 r_2]} \quad (6)$$

For 10 inch discs $\sin \beta_{opt} = 2.96/L$.

For 12 inch discs $\sin \beta_{opt} = 3.26/L$.

When $L = 8$ inches:

For 10 inch discs $\beta_{opt} = 21^\circ 41'$.

For 12 inch discs $\beta_{opt} = 24^\circ 3'$.

The harmonic distortion with optimum overhang and offset angle is given for 12 inch discs approximately by

$$\text{Percentage 2nd harmonic distortion} \approx \frac{5.5}{\sqrt{L^2 - 11.6}}$$

If $L = 8$ inches, 2nd harmonic distortion $\approx 0.76\%$.

(iii) The influence of stylus friction

The stylus friction gives rise to an undesirable excess pressure on the inner groove wall when the optimum offset angle is used. A moderate amount of side-thrust is not detrimental, because it helps to overcome pivot bearing friction, but unduly large values of side-thrust tend to pull the pickup and needle out of the groove towards the centre of the record; this effect is most pronounced towards the inner groove of the

record. In automatic record changers it is sometimes necessary to use an offset angle smaller than the optimum value, accompanied by a reduction in "overhang," and to put up with the increased distortion. With light-weight pickups, manually operated, the side-thrust is harmless when the design is based on minimum distortion.

SECTION 5 : RECORDING CHARACTERISTICS, EQUALIZERS AND AMPLIFIERS

(i) Recording characteristics (ii) Pre-amplifiers for use with pickups (iii) Introduction to equalizers (iv) High-frequency attenuation (scratch filter) (v) Equalizers for electro-magnetic pickups (vi) Equalizers for crystal pickups (vii) Equalizers applying negative feedback to the pickup (viii) Miscellaneous details regarding equalizing amplifiers (ix) Complete amplifiers (x) Pickups for connection to radio receivers (xi) Frequency test records.

(i) Recording characteristics

If a constant input voltage is applied to a recording amplifier, the curve relating frequency and the r.m.s. velocities recorded is known as the recording characteristic. Some ideal theoretical recording characteristics are shown in Fig. 17.13.

Fig. 17.13. Ideal recording characteristics.

The recording characteristic is usually regarded as having three sections—

1. A constant amplitude characteristic from the lowest recorded frequencies to the cross-over frequency. This has a slope of 6 db per octave.
2. A flat characteristic (constant velocity) from the cross-over frequency to the frequency at which high-frequency pre-emphasis commences.
3. A high-frequency pre-emphasis section.

When examining recording characteristics it is helpful to be able to convert readily from db per octave to db for a frequency ratio of 10* :

6 db/octave = 20 db/10 times frequency ratio.

3 db/octave = 10 db/10 times frequency ratio.

The recorded velocity is proportional to the output voltage from an "ideal" electro-magnetic pickup. When using such a pickup it is necessary to boost the output voltage at frequencies below the cross-over frequency, and to attenuate at frequencies covered by the pre-emphasis. This frequency selective amplification is called **equalizing**.

*A table of frequency ratios, octaves and decades is given in Chapter 7 Sect. 3(v), page 368.

Cross-over frequency

The most popular cross-over frequencies are 250, 300, 350 and 500 c/s, and these are compared in Fig. 17.13 on the basis of equal peak amplitude in the constant amplitude sections. For convenience the 250 c/s cross-over point has been taken as 0 db. The constant velocity section of the characteristic with 300 c/s cross-over frequency is at a level of + 1.5 db, while that of the characteristic with 500 c/s cross-over frequency is at a level of + 6 db relative to the characteristic with a 250 c/s cross-over frequency.

Thus it is possible to increase the level of recording of the constant velocity section of the characteristic without increasing the maximum amplitude, provided that the cross-over frequency is increased. This appears very attractive at first sight since it increases the signal-to-noise ratio, but for an increase of 6 db above the cross-over frequency it involves

- (a) Twice the recorded velocity,
- (b) Twice the tracking distortion,
- (c) At least twice the harmonic distortion from a given pickup,
- (d) An additional 6 db of "equalizing" amplification of low frequencies, tending to cause trouble with hum and rumble.

There is no "optimum" cross-over frequency because the choice is necessarily a compromise. Where distortion is the principal criterion, a low cross-over frequency from 250 to 350 c/s will be adopted for standard groove 78 r.p.m. Where needle scratch is troublesome with 78 r.p.m. a high cross-over frequency of say 500 c/s may be adopted. With fine groove recordings a cross-over frequency of 400 or 500 c/s is about the optimum choice.

In practice the sharp knee between sections 1 and 2 is rounded off; the cross-over frequency is then defined as the frequency of intersection of the two asymptotes, provided that the recording characteristic at this frequency is not more than 3 db below the point of intersection of the asymptotes.

If the recording characteristic includes high-frequency pre-emphasis, it is necessary to re-draw the curve for the condition without high-frequency pre-emphasis before determining the cross-over frequency as described above.

High-frequency pre-emphasis

The third section of the recording characteristic is the high-frequency pre-emphasis curve. This may, in the ideal case, be taken as a straight line with a slope of, say, 3 or 6 db/octave as in Fig. 17.13. Of course in practice the sharp junction is rounded off and the recording characteristic gradually approaches the "ideal" straight line. Alternatively the pre-emphasis may be specified in the form of a time constant such as, say, 100 microsecond pre-emphasis. The latter method is covered in Chapter 15 Sect. 1(vi); it is restricted to an asymptotic slope of 6 db/octave, but the time constant determines the frequency at which it becomes effective as tabulated below:

Time constant	40	50	75	100	150 μ secs.
Rise of 3 db at	4000	3220	2150	1610	1075 c/s.

All modern American and some English records use some degree of high-frequency pre-emphasis*, although they differ in degree. Assuming that in each case the amplifier is equalized* to provide a level-play-back characteristic, the greater the pre-emphasis the greater the possible dynamic range and the lower the scratch level.

However there are two factors which place a limit on the amount of pre-emphasis which may be used. The first of these factors is the radius of curvature of the groove which at high frequencies and high amplitudes, especially towards the inner portion of the record, cannot be tracked accurately. The radius of curvature is inversely proportional to the maximum amplitude of recording. If the maximum amplitude is reduced, the high frequency pre-emphasis may be increased and in the extreme case constant amplitude recording may be used throughout (Ref. 240).

*Any equalizing which is necessary to correct deficiencies of any of the components of the recording system is corrective equalization, not pre-equalization. The distortion of the frequency characteristic from flat (from air to record track) to some other characteristic is pre-equalization or pre-emphasis (Ref. 247).

There is reason to believe that some record manufacturers who nominally adopt 16 db pre-emphasis at 10 000 c/s use part of this for corrective equalization for deficiencies of their equipment at high frequencies, and only the balance for true pre-emphasis (Refs. 247, 256; 193 discussion by E. W. Kellogg).

The second factor is the peak frequency spectrum characteristic of the music being recorded. The effect of the decreased amplitudes at high frequencies in speech and music has been investigated (notably Ref. 42) but there is insufficient information available concerning the instantaneous distribution of energy within the recorded spectrum. Curves based on the work of Sivian, Dunn and White indicate that "no large increase in distortion occurs in reproducing the 16 db pre-emphasized continuous spectrum . . . yet the addition of a few prominent tones to this spectrum in the region above 2000 cycles will result in intolerable distortion" (Ref. 42).

Pre-emphasis on shellac discs

If the tracking* difficulty could be overcome, it is possible that the N.A.B. pre-emphasis characteristic would not be excessive (Ref. 193) but unfortunately it is the tracking* problem which is the stumbling block. In one test, three records were cut simultaneously with different values of pre-emphasis and played back on a system with the maximum de-emphasis. The record with the 6 db pre-emphasis "reproduced more highs and cleaner highs than the one with the 15, indicating that the overload on the latter was so bad that it was not being tracked*" (Ref. 193, discussion by J. P. Maxfield).

The use of the full N.A.B. pre-emphasis (16 db at 10 000 c/s) on standard shellac discs has come in for much criticism. It is claimed that the cymbals and certain brass instruments will overload the system at high frequencies, although this could be taken care of by the use of a limiting amplifier which reduces the gain for the short period required (Ref. 197). Another writer states that trouble had been experienced through overmodulation by second and third harmonics of the soprano voice when a rising characteristic between 1000 and 5000 c/s had been introduced (Ref. 174). Another writer refers to the "muddiness" and "smearing" in the high level, full-orchestra passages of many records (Ref. 117). Still another writer states that the present N.A.B. pre-emphasis curve effectively guarantees excessive distortion and he refers to the insufficient attention which is paid to the difference between transient response tests and the steady state (Ref. 257). Another refers to the fact that the N.A.B. characteristic unduly weights the importance of the signal to noise ratio and produces the undesirable condition of signals having high velocity with high amplitude (Ref. 189). Another again states "since the pickup stylus can track* the recorded high frequencies more clearly without excessive pre-emphasis, the high frequency reproduction from such records is notable for its clarity" (Ref. 241). Other criticisms have also been published (Refs. 155, 174).

It is interesting to note that one leading American manufacturer, R. C. A. Victor, limits the high-frequency pre-emphasis on home records to a maximum value of 12.5 db at 10 000 c/s in place of 16 db as with the N.A.B. characteristic, while the AES Standard Playback Curve provides for 12 db pre-emphasis at 10 000 c/s.

Pre-emphasis with fine groove recordings

Owing to the lower recording level, smaller radius stylus tip and more elastic material with fine groove records, a higher value of high frequency pre-emphasis may be used than with 78 r.p.m. shellac discs, for the same distortion in both cases.

Measurement of recorded velocities

The recorded velocities may be measured either by the light-pattern method (see (v) below) or by the use of a special high-fidelity pickup. These two methods do not give the same result, owing partly to the mechanical characteristics of the record material and partly to the finite needle size which causes tracing distortion (see Sect. 6). It is current practice to use the special pickup at low frequencies and the light-pattern method at high frequencies; the latter may be checked by the pickup after allowing for the loss caused by tracing distortion. It has been stated that the mechanical impedance limits at the reproducing point should be included in any standardization of frequency characteristic (Ref. 131).

*It is unfortunate that the word "tracking" should be used both here (meaning that the stylus tip is capable of following the modulations in the groove) and also in "tracking distortion" which is due to the angle between the axis of the pickup and the tangent to the unmodulated groove (see Sect. 4). No alternative nomenclature seems to be in current use.

Practical recording characteristics

There does not appear to be any generally accepted definition of published recording characteristics. In most cases, however, it is fairly safe to assume that the user is expected to provide an equalizer amplifier characteristic which is the inverse of the recording characteristic. Of course, some discretion is required in using full equalization for extreme high and low frequencies—this may be provided in the form of tone controls.

The recording characteristics used by English, Australian and the majority of European manufacturers are shown in Fig. 17.14. Curve 1 is that used by the E.M.I. group of companies for all normal 78 r.p.m. recordings. Curve 2 is that used by the Special Recordings Department of E.M.I. Studios Ltd. and is notable in that it extends to 20 000 c/s. Curve 3 is that used by Decca frr (1949). Curve 4 that used by the B.B.C. for transcriptions (Ref. 294).

The Decca (London) LP characteristic is not shown on the curves, but is -17.5 db at 30 c/s, -14 db at 50 c/s, -9 db at 100 c/s, -3 db at 300 c/s, 0 at 1000 c/s, $+14$ db at 10 000 c/s and $+16$ db at 15 000 c/s (Jan. 1951).

The recording characteristics used by most American record manufacturers are shown in Fig. 17.15. Curve 1 is that used in the Columbia long playing micro-groove

Fig. 17.14. Recording characteristics used by all English, Australian and the majority of European record manufacturers for 78 r.p.m., together with B.B.C. transcriptions.

Fig. 17.15. Recording characteristics used by most American record manufacturers.

records. Curve 2 is the N.A.B. (lateral 1949) standard for transcriptions. Curve 3 is that used by R.C.A. Victor for 78 r.p.m. shellac discs, 45 r.p.m. and 33-1/3 r.p.m. fine groove. Curve 4 is that used by Columbia for 78 r.p.m. shellac discs—the cross-over frequency is 300 c/s. Curve 5 is that used for Orthacoustic transcription recording—it follows very closely the N.A.B. curve from 60 to 10 000 c/s but is extended down to 30 c/s (-20 db) and up to 15 000 c/s.

Standard Playback Curve

For many reasons it has been impossible to achieve a standard recording characteristic, even in a single country and for a specified cross-over frequency. An entirely different approach has been made by the Audio Engineering Society of U.S.A. which has put forward a Standard Playback Curve with the idea of getting this adopted by all designers of equipment for reproduction from records (Ref. 307). The onus would then be on the record manufacturers to produce records which sound well when played with such equipment. The curve (Fig. 17.15A) is based on the frequency of 1000 c/s as a reference point, and the de-emphasis at 10 000 c/s is 12 db, being less than the N.A.B. de-emphasis at this frequency. However the AES playback curve is extended to 15 000 c/s with a de-emphasis of 15.5 db. Both the straight portions of the curve have slopes of 6 db/octave, and the intersections of the extensions of these straight portions with the reference axis occur at 400 c/s (the cross-over frequency) and 2500 c/s.

This playback curve may be duplicated on a flat amplifier with two sections of RC equalization, as shown in Fig. 17.15B, which is one possible arrangement. Alternatively the network of Fig. 17.15C may be used.

FIG. 17.15A

Fig. 17.15A. AES Standard Playback Curve (Ref. 307).

See Supplement for new Standard Playback Curve.

Fig. 17.15B. High impedance network to provide standard playback curve in grid circuit of amplifier stage (Ref. 307).

FIG. 17.15B

It seems that this Standard Playback Curve is what is really needed by the designers of equipment for reproduction from records. Even if record manufacturers do not accept it, the error for any cross-over frequency from 325 to 500 c/s is not more than 2 db, and no problems will be encountered in the reproduction of NAB recording, all fine groove records and most 78 r.p.m. discs except those with a cross-over frequency of 250 c/s and without any high frequency pre-emphasis. The latter may be covered by a separate network.

The C.C.I.R. (Geneva, June 1951) proposed a compromise characteristic with a 450 μ sec. curve below 1000 c/s and a 50 μ sec. curve above 1000 c/s, giving turnover frequencies of 360 and 2800 c/s, for radio programmes for international exchange.

FIG. 17.15C

Fig. 17.15C. Low impedance network to provide close approximation to standard playback curve, with total insertion loss 20 db at 1000 c/s (Ref. 307).

General comments

It has been shown that the choice of recording characteristic is necessarily a compromise between many factors.

By careful attention to all aspects of record manufacture, particularly the material used for the pressings, it is possible to produce records having extremely fine performance.

The best of the fine groove records have demonstrated by results that the performance obtainable is equal to that from the best shellac discs, and superior as regards noise. The fact that there are many mediocre recordings of all kinds proves nothing from the technical angle.

Reference to recording characteristics : 62, 63, 88, 131, 155, 156, 174, 197, 214, 240, 247, 307.

(ii) Pre-amplifiers for use with pickups

Pickups may be divided into three groups, those of the high impedance type (e.g. crystal) normally always used with direct connection to a grid circuit, those of the low impedance type normally always used with a step-up transformer, and those which may be either used with or without a transformer.

In all cases, pickups should be loaded by a substantially resistive load of the value specified by the manufacturer, or determined experimentally—see also Sect. 3. A change in load resistance usually results in a change of frequency characteristic.

The equalizer may be incorporated into the first stage of the pre-amplifier—see Sect. 5 : 2(iii), (v), (vi) and (vii)—or it may follow a normal pre-amplifier stage. In the latter case its design is quite straight forward and follows the general principles of r.c.c. amplifiers—see Chapter 12 Sect. 2 for triodes and Sect. 3 for pentodes ; also Chapter 18 Sect. 2 for microphone pre-amplifiers.

Pre-amplifiers for pickups with high output level (e.g. crystal) may usually be designed without special regard to hum or noise. In other cases the pre-amplifier should be designed as for a microphone pre-amplifier—see Chapter 18 Sect. 2.

A modified cathode follower for use as a low-noise input stage for a crystal microphone or pickup is described in Chapter 18 Sect. 2(vi)D and Fig. 18.6B.

(iii) Introduction to equalizers

(A) Low-frequency equalizers

The amount of bass boosting required by various "ideal" recording characteristics is given below. It is assumed that a constant amplitude characteristic is maintained below the cross-over frequency.

Cross-over frequency	250	300	350	400	500	800 c/s
Bass boost at 70 c/s	11.0	12.6	13.8	15.1	17.1	21.1 db
Bass boost at 50 c/s	14.0	15.6	16.8	18.0	20.0	24.0 db
Bass boost at 30 c/s	18.4	20.0	21.2	22.5	24.5	28.5 db

Cheap pickups usually have a peak in the bass region which reduces the amount of bass boosting required, and in some cases no bass boosting whatever is provided by the amplifier.

Some practical recording characteristics have an approach towards a constant velocity characteristic below some low frequency (e.g. Fig. 17.15 Curves 1, 2 and 5). The equalizing circuit should be designed to suit the individual recording characteristic. The following treatment, however, is based on the 6 db/octave constant amplitude characteristic as approached by Fig. 17.14 Curve 1 and Fig. 17.15 Curves 3 and 4.

Fig. 17.16. Bass equalizer characteristics (A) "ideal" characteristic with slope of 6 db/octave (B) characteristic with single stage r-c equalizer having total boost of 20 db and max. slope 4.9 db/octave (C) characteristic with two r.c. stages in cascade, each having total boost 10 db and max. slope 3 db/octave (circuit as Fig. 17.17).

Conventional resistance-capacitance equalizing circuits

The form of bass boosting which is normally used results in a "saturation" shape of curve as in Fig. 15.4. Maximum slope is obtained at the point of half total boost, the value being a function of the total boost (Chapter 15 Sect. 2):

Total boost	20	15	10	6	3 db
Slope at half-boost point	4.9	4.1	3.0	2.0	1.0 db/octave

The desired slope is 6 db/octave, so that there is an appreciable error even with a total boost of 20 db or more. This is plotted in Fig. 17.16 for a total boost of 20 db with alternative frequency scales for 250 and 500 c/s cross-over frequencies. With a cross-over frequency of 250 c/s the error is about -1 db at 50 c/s and -2.5 db at 30 c/s, which is generally acceptable, even though there is inevitably some additional loss in

the extreme bass, due to coupling condensers. In the case of a cross-over frequency of 500 c/s, however, the error is -3 db at 50 c/s and -4 db at 40 c/s, here again increased by the effect of coupling condensers. Some designers adopt a total boost of as much as 40 db to provide a satisfactory characteristic for use with high cross-over frequencies such as 800 c/s. In either case, it is good practice for the amplifier to include a bass tone control which will permit an adjustment to suit the circumstances. If no tone control is fitted, it is usually desirable to attenuate the extremely low frequencies; a value of coupling capacitance may be chosen to give, for example, an additional 3 db attenuation at 70 c/s and 5 db at 50 c/s.

In the circuit of Fig. 15.3 suitable values of components would be :

$V_1 = 6J5$ (half 6SN7-GT); $R_L = 50\,000$ ohms; $R_1 = 20\,000$ ohms; $R_2 = 1$ megohm; $R_4 = 2800$ ohms; $C = 0.25\ \mu\text{F}$ for very good bass response or $0.05\ \mu\text{F}$ for bass attenuation. Voltage gain at 1000 c/s = 1.5 times = $+3.5$ db. Total boost = 20 db. $C_2 = 0.2\ \mu\text{F}$ for cross-over 250 c/s or $0.1\ \mu\text{F}$ for 500 c/s.

Alternatively the total boost of 20 db could be obtained in **two separate stages** each having a total boost of 1.1 db at the cross-over frequency. By this means a maximum slope of 6 db is obtained at a frequency of 100 or 200 c/s with a cross-over frequency of 250 or 500 c/s and more accurate equalizing is possible. The frequency characteristic obtained is shown with a broken line (C) in Fig. 17.16, and the circuit diagram is given in Fig. 17.17.

Fig. 17.17. Circuit diagram of two stage bass equalizing amplifier with bass boosting in each stage. Pin 4 of the 6SN7-GT should be used for the input circuit. Total boost is 20 db and max. slope 6 db/octave. $C = 0.25\ \mu\text{F}$ for good bass response or $0.1\ \mu\text{F}$ for some bass attenuation; $C_2 = 0.1\ \mu\text{F}$ for cross-over 250 c/s or $0.05\ \mu\text{F}$ for 500 c/s. Voltage gain at 1000 c/s = 22 times = 26.8 dbvg.

Instead of having two networks separated by a valve, the complete two-section equalizer may be incorporated into a single network as in Fig. 17.18. The maximum slope is 7 db/octave which is adjustable down to 3 db/octave by means of control R_7 , which should be tapered; maximum slope is obtained with maximum value of R_7 . The plate load resistors may be increased if it is desired to increase the gain. This circuit provides 25 db bass boosting with a very close approach to the true 6 db octave slope (when R_7 is correctly adjusted) and has the additional merit of incorporating a tone control providing a total control of 13 db in the region 20 to 50 c/s depending on the cross-over frequency. With an input voltage of about 50 millivolts, the output will be about 1 volt.

Frequency-selective feedback to provide equalizing

A resistance-capacitance network may be used in the feedback loop of an amplifier to provide bass boosting which gives a close approximation to the correct degree of

Fig. 17.18. Two section equalizer to provide for 3 values of cross-over frequency and adjustable slope of characteristic (Ref. 127). $V_1 + V_2 = 6SL7$ or $6SC7$ or $7F7$ or any high- μ triodes.

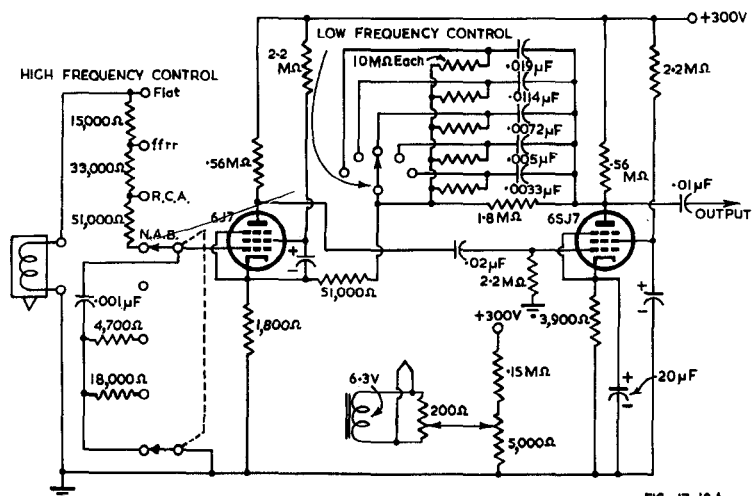

FIG. 17.19 A

Fig. 17.19B. Frequency characteristics of circuit of Fig. 17.19A with high frequency control in "flat" position (Ref. 239).

Fig. 17.19C. High frequency de-emphasis characteristics of the circuit of Fig. 17.19A (Ref. 239).

equalizing. The principle is demonstrated in the circuit of Fig. 15.11 and the frequency characteristics of Fig. 14.12, which are limited to a maximum boost of 12 db. Increased bass boosting could, of course, be obtained by increasing the feedback. With the value of capacitance used in Fig. 15.11 ($0.005 \mu\text{F}$) a satisfactory compromise is obtained for a cross-over frequency of 250 c/s; half this capacitance would be suitable for 500 c/s.

This same principle is used in the circuit of Fig. 17.19A to produce the low frequency characteristics of Fig. 17.19B (Ref. 239). The low-frequency control is a shorting type, while the 10 megohm resistors are click suppressors. This circuit also provides four values of high frequency de-emphasis (curves Fig. 17.19C).

Another variation of the same general principle is incorporated in Fig. 17.20 (Ref. 144). It is suitable for use with the GE variable reluctance pickup, or any other low level electro-magnetic pickup which has been equalized to give a constant-velocity characteristic. The values of components are designed for a cross-over frequency of 500 c/s and a high-frequency hinge frequency of 2000 c/s with a slope of 6 db/octave.

Fig. 17.20. Circuit diagram of equalizing amplifier for low-level electromagnetic pickup using negative feedback over the second stage to accomplish equalization (Ref. 144).

A different form of frequency-selective feedback is used in Fig. 17.21 which provides correct equalizing for English (H.M.V.) records from 25 to 8500 c/s within 2.5 db. V_1 is the first pre-amplifier valve having a series tuned circuit L_1C_1 (with a minimum impedance below 25 c/s) in its cathode circuit so that at higher frequencies an increasing proportion of the input signal is fed back. The condenser C_2 in series with R_3 serves to flatten the response above 1000 c/s; no provision is made for de-emphasis. The level between 250 and 1000 c/s is flattened by the network $L_2C_3R_4$ in which L_2 and C_3 are tuned to 250 c/s. R_4 and L_2 carry the plate current of the valve, and the value of R_1 primarily determines the degree of feedback at 1000 c/s.

FIG. 17.21

Fig. 17.21. Frequency selective negative feedback used to provide equalizing for English records. (Ref. 199). $V_1 = \text{MH4}$ ($\mu = 40$, $r_p = 11\,000$ ohms), load resistance = 50 000 ohms.

Fig. 17.22. Bass equalizer incorporating L , C and R (Ref. 188).

Bass equalizers incorporating L , C and R

A network incorporating L , C and R may be used to provide a very close approach to the 6 db/octave ideal characteristic, or even higher values if desired. The simplified circuit is shown in Fig. 17.22 in which L_1 is tuned by C_1 to the cross-over frequency, R_2 controls the shape of the band and R_4 controls the slope of the characteristic.

Suggested values for a cross-over frequency of 400 c/s are— $L_1 = 2.9$ henrys; $C_1 = 0.07\ \mu\text{F}$; $C_3 = 1.0\ \mu\text{F}$; $R_2 = 6800$ ohms; $R_4 = 2200$ ohms.

For a slight change in cross-over frequency only C_1 and R_2 need be altered (Ref. 188).

References to equalizers (general): 15, 54, 106, 108, 109, 113, 117, 120, 126, 127, 133, 144, 187, 188, 197, 198, 199, 209, 220, 226, 239, 240.

(B) High-frequency equalizers (de-emphasis)

A shunt capacitance provides for attenuation at the nominal rate of 6 db/octave (see Chapter 15 Sect. 6). The attenuation is 3 db when the reactance of the shunt condenser is equal to the resistance of the circuit across which it is connected, that is when

$$C = 1/(2\pi f_o R) \quad (1)$$

or capacitance in microfarads = $157\,000/(f_o R)$ (2)

where C = shunt capacitance in farads

f_o = frequency at which the attenuation is 3 db (it is also the "hinge point" of the ideal 6 db/octave line)

and R = resistance of circuit across which C is connected, in ohms.

If it is desired to limit the attenuation to a specified value, while approaching the nominal slope of 6 db/octave, the circuit of Fig. 17.23A may be used. Here R_1 represents the resistance of the input circuit; R_3 should be as high as is practicable—it is assumed to be very much greater than R_2 . The maximum attenuation in decibels will be given by

$$\text{max. attenuation (x db)} = 20 \log_{10} [R_2 / (R_1 + R_2)] \quad (3)$$

Eqns. (1) and (2) may be used with reasonable accuracy for maximum attenuations not less than 10 db—at lower values the attenuation at the "hinge point" frequency f_o will be less than 3 db (the actual values are 2.4 db for 10 db total boost, 2 db for 6 db total boost, 1.2 db for 3 db total boost). The frequency characteristic is indicated in Fig. 17.23B.

Fig. 17.23. (A) Circuit providing high-frequency attenuation with a specified limit to the attenuation (B) Frequency characteristics.

If the maximum attenuation is 10 db, the maximum slope (which occurs at half maximum attenuation) is 3 db/octave. This may therefore be used to provide a 3 db/octave de-emphasis characteristic within the limitations of its range.

High frequency equalizers are incorporated in the circuits of Figs. 17.19, 17.20, 17.27.

For general treatment of equalizers see Ref. 258.

(iv) High-frequency attenuation (scratch filter)

In addition to the normal manual tone control it is advisable in good amplifiers to incorporate a filter which provides very rapid attenuation above a certain frequency, say 7000 c/s, so that the upper scratch frequencies on old or noisy records may be rendered inaudible. This is provided by the circuit of Fig. 17.24A (Ref. 15) which has negligible attenuation at 7000 c/s, -60 db at 8700 c/s and over 36 db attenuation at all frequencies above 8000 c/s. The filter is designed for an impedance of 24 000

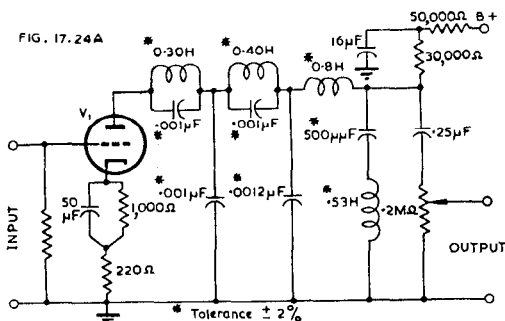

Fig. 17.24A. Amplifier stage incorporating filter with 7000 c/s pass-band and very rapid attenuation at higher frequencies (Ref. 15). $V_1 = 6X4$, $\mu = 40$, $r_p = 15\,000$ ohms.

FIG. 17.24 B

Fig. 17.24B. Circuit of pre-amplifier and filter circuit with high attenuation at 10 000 c/s (Ref. 113).

ohms; the plate resistance of V_1 is increased to this value by means of a partially unbypassed cathode resistor, while the output end is loaded directly. See reference for coil winding and other details.

An alternative method is used in the pre-amplifier circuit of Fig. 17.24B to produce the response characteristic of Fig. 17.24C. This is suitable for use with low level electro-magnetic pickups. The 10.6 Kc/s parallel-T network provides a maximum attenuation of 34 db, while the 6 Kc/s parallel-T network in the feedback loop removes the attenuation which would otherwise occur at this frequency and thus give a sharper knee (Ref. 113).

There appears to be substantial evidence that too sharp a knee on the attenuation characteristic gives an unpleasant effect to the listener. If the knee is initially too sharp, it may be slightly rounded by the addition of a "roll-off" characteristic at some suitable point—e.g. in the preceding stage.

FIG. 17.24 C

Fig. 17.24C. Response curve of amplifier and filter shown in Fig. 17.24B (Ref. 113).

(v) Equalizers for electro-magnetic pickups

The general principles of equalizing have been covered in the earlier portion of this section, and may be applied directly to electro-magnetic pickups (Figs. 17.17, 17.18, 17.19, 17.21, 17.22, together with high-frequency de-emphasis). Fig. 17.24B is directly applicable.

With any form of electro-magnetic or dynamic pickup the pickup itself has an impedance which, above about 1000 c/s, is almost entirely inductive reactance. If a capacitance is connected in shunt with the pick-up, or across the secondary of the transformer, this capacitive reactance will resonate with the inductive reactance of the pickup at some frequency determined by L and C . As a result, the output voltage is boosted at the frequency of resonance and falls rapidly at higher frequencies. If, now, a variable resistance is also connected in shunt with the pickup or across the secondary of the transformer, there will be found a value at which the resonance peak just disappears—this value of shunt resistance is the maximum which can be used to permit the condenser to act purely as an attenuator. For an analysis of this effect on the E.M.I. No 12 pickup see Ref. 109 and for that on the Pickering and G.E. variable reluctance pickups see Ref. 117. The inductance of the E.M.I. No. 12 pickup is of the order of 1 mH. The inductance of the Pickering pickup is approxi-

mately 100 mH and that of the G.E. pickup* 120 mH. The correct value of shunt-resistance is given by

$R \text{ (ohms)} = 1.2 f_c$ for the Pickering pickup

and $R \text{ (ohms)} = 0.9 f_c$ for the G.E. pickup

where f_c is the frequency at which the attenuation is 3 db. Beyond this frequency the rate of attenuation is approximately 15 db/octave.

The shunt capacitance required for various values of the cut-off frequency is :

Frequency	4000	5000	6000	7000 c/s
Capacitance Pickering	0.02	.013	.009	.0065 μF
G.E.	0.03	.019	.013	.0095 μF

Fig. 17.25. Equalizer for use with E.M.I. and Marconiphone Model 12A pickup. Output as shown is 200 ohms; with link closed, output is 600 ohms. For English E.M.I. records join terminals 1 and 2, also 3 and 4; for N.A.B. and American records leave unjoined. (E.M.I. Australia).

FIG. 17.25

Pre-amplifier for E.M.I. and Marconiphone Model 12A

A suitable equalizer is shown in Fig. 17.25 which gives the following output levels at 1000 c/s with Decca Z718 frequency record.

Termination	Equalizer English	Equalizer N.A.B
200 ohms	— 49 dbm	— 50 dbm
600 ohms	— 54 dbm	— 55 dbm

Pre-amplifier for use with G.E. variable reluctance pickup

The circuit of Fig. 17.26 is suitable for use with the G.E. variable reluctance pickup. This pickup gives an output of about 10 mV (with recorded velocity of 4.8 cm/sec.), the amplifier has a voltage gain of 35 db at 1000 c/s, so that the output voltage is about 0.6 volt. The input shunt resistor of 6800 ohms (which is suitable for the N.A.B. characteristic) may be varied to control the frequency response, a higher value increasing the high frequency response. A low plate voltage is desirable. A slight improvement in response may be effected by shunting the $0.01\mu\text{F}$ condenser by a resistance of 180 000 ohms (Ref. 187). See also Fig. 17.34 for input transformer arrangement and Fig. 17.24B as an alternative pre-amplifier.

FIG. 17.26

Fig. 17.26. Pre-amplifier and equalizer for use with the G.E. pickup (Ref. 187).

Continuously-variable equalizing pre-amplifier

If a sufficiently flexible equalizer is used, it does not require any additional tone control. Such a circuit is shown in Fig. 17.27A in which the additive method of equalization is employed. This has three transmission channels, one channel having a characteristic which is essentially flat below 1000 c/s, falling off at the rate of 12 db/octave at higher frequencies; a second channel having 40 db more gain than the basic channel at very low frequencies but with its gain falling off at the rate of 12 db/octave above about 50 c/s; and a third channel whose gain rises at the rate of 12 db/octave up to 15 000 c/s, above which frequency its gain is 40 db more than the basic

*Later models of G.E. pickups have inductances of 250 mH (Broadcast type RPX-046) and 520 mH (Home type).

Equalizers applying feedback to the first pre-amplifier stage

It has been demonstrated by Ellis (Ref. 209) that the feedback circuit may be made frequency-selective to give a close approach to the required equalizing characteristic for an electro-magnetic pickup, as in Fig. 17.28. This circuit does not apply any appreciable feedback to the pickup itself, owing to the isolating resistor R_1 . The cross-over frequency may be adjusted by changing either C or R_2 , but changing R_2 without making a similar change in R_1 affects the gain. This arrangement is said to be "the quietest and most stable" (Ref. 287), and a very low hum level is possible if the cathode is well by-passed. The input impedance of the stage is low, owing to the feedback circuit. The resistor R_1 should be at least 10 times the nominal impedance of the pickup. The normal gain, above the cross-over frequency, is approximately (R_2/R_1) , so that unity gain is obtained when $R_2 = R_1$. By making $R_2 > R_1$ this circuit can provide gain as well as bass boosting, but this reduces the available increase for low frequencies, since the upper limit of gain is the normal gain of the valve without feedback.

Fig. 17.28. Equalizer which applies negative feedback to an electro-magnetic pickup (Ref. 209). Original values were $V_1 = \text{EF36}$, $R_1 = R_2 = 1 \text{ M}\Omega$, $R_L = 0.22 \text{ M}\Omega$, $R_3 = 2.2 \text{ M}\Omega$, $C = 600 \mu\text{F}$, $E_{bb} = 250 \text{ volts}$, unity gain.

Suggested adaptation for 19 db gain and bass boost of 26 db is : $V_1 = 6\text{J7}$ or 1620, $R_1 = 0.1 \text{ M}\Omega$, $R_2 = 1 \text{ M}\Omega$, $R_L = 0.47 \text{ M}\Omega$, $R_3 = 3.0 \text{ M}\Omega$, $C = 330 \mu\text{F}$ for 500 c/s, or $510 \mu\text{F}$ for 300 c/s, or $620 \mu\text{F}$ for 250 c/s. V_1 may also be replaced by a high- μ triode (6AT6) where $R_1 = 0.1 \text{ M}\Omega$, $R_2 = 0.33 \text{ M}\Omega$, $R_L = 0.22 \text{ M}\Omega$, R_3 omitted, $C = 1200 \mu\text{F}$ for 500 c/s, $2000 \mu\text{F}$ for 300 c/s or $2400 \mu\text{F}$ for 250 c/s, giving gain of 8 db and bass boost of 26 db (see Ref. 287).

A modification of the circuit of Fig. 17.28 is described in Ref. 280 which gives both bass boosting (with a "very low frequency roll-off") and high frequency de-emphasis. Values of components are : $R_1 = 0.33 \text{ megohm}$, $R_2 = 1.0 \text{ megohm}$, $R_L = 0.22 \text{ megohm}$, $C = 600 \mu\text{F}$ approx. (adjustable), $C_2 = 25 \mu\text{F}$ approx. (adjustable) shunted across R_{22} and $V_1 = \text{EF37}$.

A different modification of this circuit is given in Fig. 15.13 ; see Chapter 15 Sect. 2(iv)C. This modified circuit enables adjustment to be made for any cross-over frequency by means of a continuously variable potentiometer ; unfortunately no measured frequency characteristics have been published but this circuit seems to be close to the ideal for simplicity and to provide a response characteristic as good as that of any other RC feedback amplifier.

(vi) Equalizers for crystal pickups

A crystal pickup, when working into a high load resistance of the order of 2 to 5 megohms gives a practically level response characteristic over the constant amplitude section of a gliding-tone frequency test record (A in Fig. 17.30). If the load resistance is decreased to 0.5 megohm (Curve B) the output at 50 c/s may fall in a typical case by 6 db, the attenuation ratio at other frequencies being inversely proportional to the frequency.

High temperatures cause a reduction in bass response ; an increase from 68°F to 104°F causing a decrease of about 5 db at 50 c/s in a typical case (Curve B).

The output from a crystal pickup is so high that, if it is not attenuated between the pickup and the first amplifier stage, it may overload the valve. Unless the equalizer provides heavy attenuation, it is advisable to place the volume control between the pickup and the first grid.

Above the cross-over frequency the output voltage from an unequalized high-fidelity crystal pickup tends to fall at the rate of 6 db/octave. In popular types there is usually a resonance peak which gives some additional lift to the top end of the characteristic, thus decreasing the amount of equalization required.

A simple equalizer for use with crystal pickups is shown in Fig. 17.29. If $R_2 = 0.5$ megohm, R_1 may be taken as $10R_2$ or 5 megohms. This gives an attenuation at very low frequencies of 20.8 db. The effect of variation of C_1 is shown in curve C Fig. 17.30; these response curves are only satisfactory when considerable high-frequency de-emphasis is required.

Better equalization is obtained when $R_1 = 40R_2$, thus giving a maximum attenuation of 32 db. Suitable values are: $R_1 = 5$ megohms, $R_2 = 0.125$ megohm, $C_1 = 100 \mu\mu F$. The resultant response curve is shown in curve D.

A more flexible equalizer suitable for use with a high-fidelity crystal pickup is shown in Fig. 17.31 (Ref. 127). This gives a choice of three load resistors, thus giving some control of the bass, and three values of capacitance suitable for three cross-over frequencies.

An improved equalizing circuit suitable for use with the Acos GP12 high-fidelity pickup is shown in Fig. 17.32 (Ref. 120). This gives correct equalization for H.M.V. records within $+2.5$ db, -3.5 db from 30 to 8000 c/s.

An equalizer suitable for use with the Brush high-fidelity pickup is shown in Fig. 17.33 (Ref. 106). Position (1) is for quiet shellac records with a 500 c/s cross-over

(vii) Equalizers applying negative feedback to the pickup

It is advantageous in all cases to apply negative feedback to the pickup, whether electro-magnetic or crystal. This may be accomplished in any conventional manner and the feedback reduces non-linear distortion and the effects of mechanical resonances.

Various possible combinations of *CR* and *LCR* in the feedback network of both crystal and electro-magnetic pickups are described in Ref. 220. Most of these apply a very limited amount of feedback, but the same principle could be applied to a high-gain pre-amplifier stage with increased feedback. It is evident that any type of pickup may be equalized by this method, with the additional advantages of increased damping on the pickup. It seems that more detailed investigation of the subject is well merited.

(viii) Miscellaneous details regarding equalizing amplifiers

Position of equalizer

In general it is preferable to place the equalizer following the first stage of the pre-amplifier in the case of low level pickups. With high level pickups it may be possible to incorporate the equalizer in the main amplifier.

Input transformers

Although input transformers are not necessary with electro-magnetic pickups, they have some distinct advantages. The step-up ratio provides useful gain, while they permit the use of a balanced-to-earth input line which gives improved signal-

Choke : CH₃ 50 H at 20 mA. Resistance about 1500 Ω .

Mains Transformer—

Primary : 200-220-240 V, 50 c/s.

Secondaries : 1. 325-0-325 V, 20 mA d.c.

2. 6.3 V, 0.6A.

3. 6.3 V, 1.5A.

*Switches—**S₁ Single pole single throw.**S₂ Double pole single throw.**S₃ Single pole single throw.**S₄ 5 bank, 5 position selector switch.*

7. A high frequency attenuator or filter for worn or noisy records (may be omitted if a sufficiently flexible tone control is fitted). One very effective form of filter is a capacitance connected across the secondary of the output transformer—see page 214.

An example of a complete amplifier is given in Fig. 17.35A. This is a 25 watt amplifier suitable for operation from a G.E. variable reluctance pickup, or Pickering 120M. The total harmonic distortion is under 1%. The pre-amplifier consists of a triode with proper compensation in the output circuit. Bass boosting is obtained by the use of frequency-selective negative feedback in the second and third stages. Hum from the heater is reduced to the vanishing point by making the heaters of the first two twin triodes part of the cathode resistor of the output stage. The output stage draws approximately 300 mA, which is the correct current for the heaters of the 6SL7 valves, and the additional bias required for the output valves is obtained by a resistor (Ref. 240).

Another example of a complete amplifier is that due to D. T. N. Williamson (Ref. 270) shown in Figs. 17.35 B, C, D, E, F and G. The main amplifier (Fig. 17.35F) is a new version of the earlier Williamson amplifier of which one adaptation is Fig. 7.44. The circuit differs in minor details only from Fig. 7.44; the balancing adjustment on V_1 and V_2 has been omitted as unnecessary, provided that R_4R_7 , R_{11} and R_{13} have the specified values and tolerances, while a transitional phase-shift network $R_{26}C_{10}$ has been added to increase the margin of stability at high frequencies.

Output transformer specifications (3.6 ohm secondaries)—Williamson Amplifier :

Core : $1\frac{3}{4}$ in. stack of 28A Super Silcor laminations (M. and E.A.). The winding consists of two identical interleaved coils each $1\frac{1}{2}$ in. wide on paxolin formers $1\frac{1}{4}$ in. \times $1\frac{3}{4}$ in. inside dimensions. On each former is wound :

5 primary sections, each consisting of 440 turns (5 layers, 88 turns per layer) of 30 S.W.G. enamelled copper wire interleaved with 2 mil. paper, alternating with

4 secondary sections, each consisting of 84 turns (2 layers, 42 turns per layer) of 22 S.W.G. enamelled copper wire interleaved with 2 mil. paper.

Each section is insulated from its neighbours by 3 layers of 5 mil. Empire tape. All connections are brought out on one side of the winding, but the primary sections may be connected in series when winding, two primary connections only per bobbin being brought out. Windings to be assembled on core with one bobbin reversed, and with insulating checks and a centre spacer.

Curves showing the loop gain and phase-shift characteristics of the main amplifier are shown in Fig. 17.35G.

The pre-amplifier Fig. 17.35B has a voltage gain of 250 times from the grid of the first valve to the voltage across the output terminals. The input grid voltage must not be less than 0.8 mV; this minimum voltage can readily be provided by a suitable transformer from any pickup. Care should be taken to avoid overloading the pre-amplifier by too high an input voltage. The overall frequency response, when tested with an ideal "velocity" pickup on an English Decca disc is level within 1 db from 20 to 14 000 c/s; below 20 c/s there is attenuation at the rate of 30 db/octave to eliminate rumble. For the English E.M.I. characteristic, switch S_1 should be opened. Other recording characteristics can be handled by the use of the tone compensation unit.

This overall frequency characteristic, which provides bass boosting and high-frequency de-emphasis to suit the recording characteristic, together with a rumble filter, is provided by a careful combination of

- (1) bass boosting by V_{13} together with the feedback network C_{54} C_{55} R_{63} R_{64} .
- (2) Attenuation produced by the combined inter-valve couplings.

(3) Feedback over V_{14} , through the parallel-T network. This provides a peak at 20 c/s which is used to give a sharp knee to the frequency characteristic instead of the gradual attenuation produced by the inter-valve couplings. (Note that the recording characteristic contributes 6 db/octave to the slope below 20 c/s).

The final stage V_{15} is merely a cathode follower to permit the use of long leads between the pre-amplifier and the tone-compensation unit.

If a high-impedance output is permissible, and an attenuation of 8 db at 10 c/s is sufficient to reduce the rumble, stage V_{13} may be used as a single stage pre-amplifier with a gain of 11 times. Under these circumstances $C_{53} = 0.05 \mu\text{F}$, $C_{54} = 4000 \mu\text{F}$, $R_{64} = 22\,000$ ohms, $R_{66} = 2.2 \text{ M}\Omega$, R_{67} is omitted, and the output is taken from the junction of C_{53} and R_{66} .

In the cathode circuit of V_{13} , closing the switch S_5 reduces the gain to zero in about 1 second for use while changing records.

The noise level, with R_{57} adjusted for minimum hum, is about 3 to 5 μV at V_{13} grid, excluding the noise due to the pickup transformer and auxiliaries. The total harmonic distortion of the pre-amplifier and tone compensation units combined, is considerably less than 0.1%.

The tone compensation and filter unit Fig. 17.35C provides—

FIG. 17.35D

Fig. 17.35D. Measured overall response of low-pass filter (stage V_{11} in Fig. 17.35C together with network controlled by switch S_4 . Ref. 270.

FIG. 17.35E

Fig. 17.35E. Response curves of the tone compensation circuit following V_9 in Fig. 17.35C. Curves are limiting positions for continuously-variable controls (Ref. 270).

(1) A universal tone control (switches S_2S_3 and controls $R_{40}R_{44}$) with frequency characteristics as Fig. 17.35E. The curves may be shifted bodily along the horizontal axis by modifying the capacitance values shown by the arrows in Fig. 17.35E.

(2) A low-pass filter with nominal cut-off values of 5000, 7000, 10 000 and 13 000 c/s, together with a flat position (switch S_4) providing response characteristics as Fig. 17.35D. This characteristic is provided by a parallel-T network in the feedback loop of V_{11} which gives a symmetrical valley at the frequency of resonance. A capacitor from the grid of V_{11} to earth introduces a lagging phase shift which gives

positive feedback below resonance and negative feedback above resonance, thereby unbalancing the characteristic and giving a sharp knee before the attenuation commences. The addition of an independent RC network controlled by S_{4A} gives further treble attenuation and leads to the final result in Fig. 17.35D.

(x) Pickups for connection to radio receivers

When a separate pickup and turntable unit is used in conjunction with a radio receiver, it is often most convenient for the user to operate the device at some distance (say up to 15 feet) from the receiver. The most desirable arrangement is a Record Player in the form of a small cabinet enclosing the motor, turntable, pickup, and (possibly) volume control, pre-amplifier and equalizer, with the top of the cabinet about 20 inches from the floor so as to be accessible from an easy chair.

The design problem hinges on the use or otherwise of a pre-amplifier. **If no pre-amplifier is permissible**, on account of cost or other factors, it is necessary to employ a pickup delivering a high output voltage or whose output voltage is capable of being stepped up by a high ratio transformer.

When pickup terminals are fitted to receivers, they usually provide a resistive load of the order of 0.5 megohm, with some capacitive shunting. The input voltage required to give full power output is usually about 0.25 volt, although some receivers require a higher voltage. If a receiver is being designed specially for good performance with a pickup, full power output should be obtained with an input voltage not exceeding 0.1 volt. This usually demands a pentode first a-f amplifier, especially if negative feedback is used.

If bass equalization of 20 db is required for use with an electro-magnetic pickup, the available voltage must be at least 10 times the input voltage to the amplifier, e.g. 1 volt and 0.1 volt respectively. There is a strong temptation to use a popular pickup which provides at least part of the bass boosting by arm resonance, but this is very undesirable on account of record wear, distortion and heavy stylus force required. There are electro-magnetic pickups capable of providing an output of about 1 volt from the secondary of a transformer, which do not employ arm resonance in the vicinity of 100 c/s; these are much to be preferred to those employing arm resonance. However, the high cost of a good quality transformer, and the hum and poor frequency response with a cheaper transformer, make this a rather unsatisfactory arrangement. The necessary bass boosting may be provided by a resistor and capacitor in series, connected across the secondary of the transformer. A choice of cross-over frequency may be provided by a tapping switch and several values of capacitance. High-frequency de-emphasis may be provided by one or more values of shunt capacitance,

although there is danger of pickup resonance unless an isolating resistor is used, with consequential loss of gain. Volume control may be provided by a potentiometer having a total resistance preferably not exceeding 50 000 ohms. A screened cable may be used to link the record player to the pickup terminals of the receiver.

If a crystal pickup is used, it is quite satisfactory to incorporate the equalizer and volume control in the Record Player. In this case there is no danger of hum from the pickup or transformer. With a general-purpose crystal pickup the arrangement of Fig. 17.29 may be used in which $R_1 = 2$ megohms, $R_2 = 0.5$ megohm and $C_1 = 0.000\ 25\ \mu\text{F}$ for a cross-over frequency of 250 c/s or half this value for 500 c/s. Some measure of tone control may be provided by a variable resistance of 1 megohm in series with C_1 .

With a high fidelity crystal pickup, the circuit of Fig. 17.31 or any similar equalizer may be used.

In all cases it is advisable for the listener, if possible, to set the volume control on the record player to about half-way, then to adjust the volume control on the receiver for satisfactory operation under normal conditions, and to make all adjustments (during listening) with the control on the record player.

There will be some inevitable loss of the higher frequencies due to the screened cable. This may be kept within reason by arranging that the total effective impedance of the line, under operating conditions, is of the order of 50 000 ohms or less. For example, the equalizer of Fig. 17.32 may be modified by changing the 0.1 megohm fixed resistor into a volume control.

If a pre-amplifier is used, both it and the equalizer will normally be incorporated into the receiver chassis. A volume control may readily be fitted across the pickup, and shunt capacitances may be used in conjunction with a tapping switch for high frequency de-emphasis, with due precautions against resonance. With this arrangement it is difficult to make any adjustment for cross-over frequency in the record player.

Alternatively the pre-amplifier and equalizer may be incorporated into the record player, thus giving the maximum flexibility of control. The final stage in the record player may be either a cathode follower, or a general-purpose triode with a low ratio transformer in its plate circuit. The record player may incorporate a power transformer, rectifier and filter, or it may obtain its plate supply from the receiver. Trouble may be experienced with hum owing to the proximity of the motor, transformer and pre-amplifier, particularly if a low level pickup is used. However, in spite of these design problems, the arrangement is practicable.

(xi) Frequency test records

Frequency test records are of two general types—banded tone and gliding tone. **Banded tone records** are recorded with a number of constant frequencies which may be played in sequence; they are generally used when measurements are being made. Gliding tone records are useful when it is desired to check for peaks but may also be used for frequency response measurements by appropriate timing. These normally commence at a high frequency f_1 , maintain constant velocity characteristics down to the cross-over frequency f_0 , then follow the recording characteristic down to the final frequency f_2 (approximately at the rate of 6 db/octave). In some cases the high-frequency response follows the recording characteristic—details are given in the table. The frequency response may be checked to a fair degree of accuracy by the optical method (see below). Over the “constant velocity” range the width of the light pattern should be constant, while over the “constant amplitude” range the width should taper downwards in proportion to the frequency.

References to frequency test records: Refs. 161, 254, 260; record catalogues.

The optical method of testing frequency test records

A frequency test record, either of the stepped-frequency or gliding-tone type, may be checked optically to indicate the amplitude at all parts of the record, with a possible error of about 1 or 2 db. The lamp should have a concentrated filament and clear bulb; it should be at least 8 feet from the record and only high enough above

the plane of the record to give a brilliant pattern. The eye should be directed vertically downwards on to the side of the record nearer to the lamp, and should be as far above the record as possible.

A pair of dividers may be used to measure the width of the reflected light pattern for each frequency; the width of the light pattern is proportional to the voltage output from a perfect constant-velocity pickup. This method becomes increasingly less accurate below the cross-over frequency, although it is very satisfactory at higher frequencies.

The theoretical analysis and calculation of errors is given by Ref. 243.

(12-5-17) 10 in. 78 r.p.m. Shellac DF	As (12-5-15). Same both sides.
(12-5-21) 12 in. 78 r.p.m. Unfilled vinyl DF	For checking automatic record changers. Three modulated bands with large eccentric groove. Bands define standard 10 and 12 in. landing areas without lead in grooves. Inner band 936 c/s (1 minute) for checking wow.
(12-5-23) 12 in. 78 r.p.m. Unfilled vinyl DF	Various modulated bands joined by spiral grooves to indicate limits of standard recording dimensions (12-5-21 on other side).
(12-5-29) 7 in. 45 r.p.m. Unfilled vinyl DF	For checking landing and tripping action of changer mechanisms. Bands 1000 ; 400 ; 1000 c/s.
(12-5-35) 7 in. 45 r.p.m. Unfilled vinyl DF	For checking landing and tripping action of changer mechanisms ; for checking pickup sensitivity, turntable flutter and rumble.
(12-5-37) 7 in. 45 r.p.m. Unfilled vinyl DF (RL-419)	Bands of 400 and 4000 c/s signals combined, the 4000 c/s being 12 db below the 400 c/s level. Peak velocities from 3.8 to 18 cm/sec. in approx. 2 db steps. 0 db = 6 cm/sec. Intermodulation distortion in the record is less than 4%. For testing pickup "tracking" at various levels and stylus forces (Ref. 285).
(12-5-39) 12 in. 78 r.p.m. Unfilled vinyl DF (RL-420)	Bands of 400 and 4000 c/s signals combined, the 4000 c/s being 12 db below the 400 c/s level. Peak recorded velocities run from 27 to 4.4 cm/sec. in approx. 2 db steps. 0 db = 9.1 cm/sec. Intermodulation distortion in the record is less than 3%. Groove has small bottom radius suitable for testing with 1.0 or 3.0 mil styli. Same use as 12-5-37.

(12-5-41) 12 in. 33.3 or 78 r.p.m. Unfilled vinyl DF	For routine testing of record changer operation with 1.0 or 3.0 mil styli. Standard R.M.A. landing areas for 10 and 12 inch records are defined by short interrupted tones. Short bands of 400 and 1000 c/s tones are included for routine pickup sensitivity measurements.
Clarkstan 1000 A 12 in. 78 r.p.m. vinylite SF 1000 D 12 in. 78 r.p.m. vinylite SF.	Sweep frequency record for oscillographic observation of equipment response. Frequency range 70 to 10 000 c/s, flat within ± 1 db. Sweep frequency rate 20 times/sec. Crossover 500 c/s. Sweep frequency record as 1000A but covering range from 5000 to 15 000 c/s.
E.M.I. Studios JH138 10 in. 78 r.p.m. for use with 2.5 mil radius stylus.	Side 1 : 400 c/s (+22.5 db) with approx. 4000 c/s (+10.5 db) superimposed additively for I.M. testing of pickups. Peak lateral velocity of combined wave is equal to that of a sine wave at a level +24.5 db. The succeeding 10 bands have levels of both tones reduced 2 db below those of the foregoing band. Side 2 : 60 c/s (+8.6 db) with 2000 c/s (+10.3 db) superimposed additively. When the 2000 c/s is reduced in the pickup bass correction equalizer by the correct amount relative to 60 c/s (i.e. 13.7 db), its effective level will be -3.4 db, i.e. 12 db below the 60 c/s tone. On a velocity basis, the peak lateral velocity of the combined wave is equal to that of a sine wave at a level +15.5 db. The peak combined amplitude is equivalent to that of a 60 c/s sine wave having a level of +10 db. The succeeding 10 bands each have the level of both tones reduced by 2 db below those of the foregoing band. 0 db = 1 cm/sec. r.m.s. (Ref. 310).

See Supplement for additional Frequency Test Records.

SECTION 6 : DISTORTION * AND UNDESIRABLE EFFECTS

(i) *Tracing distortion and pinch effect* (ii) *Playback loss* (iii) *Wow, and the effects of record warping* (iv) *Distortion due to stylus wear* (v) *Noise modulation* (vi) *Pickup distortion* (vii) *Acoustical radiation* (viii) *Distortion in recording.*

(i) Tracing distortion and pinch effect

Tracing distortion (also known as playback distortion) is non-linearity introduced in the reproduction of records because of the fact that the curve traced by the centre of the tip of the reproducing stylus is not an exact replica of the modulated groove.

Detailed mathematical analyses of tracing distortion have been made (Refs. 41 and 213, 42, 224, 264) and some popular articles have been written (Refs. 40, 146). The distortion arises from the shape of the cutter, which has a chisel edge, so that a spherical tipped needle follows a different path—in other words it introduces harmonic distortion. Odd harmonics are shown up in the lateral movement of the needle, while even harmonics make their presence felt through vertical movement of the needle—the “**pinch effect**.”

* See also Chapter 37 Sect. I (vi) N for I.R.E. tests on phonograph combinations.

Harmonic tracing distortion

It had earlier been believed (Ref. 42) that the dominant harmonic was the third, but a more recent analysis (Ref. 264) has proved that the higher harmonics also should be considered. The values of the fundamental and harmonics up to the seventh may be calculated from the equations below. The harmonic distortion, when reproducing with a constant velocity pickup, is given by the ratio of the harmonic to the fundamental, multiplied by the harmonic number (e.g. 3 for third harmonic).

$$\begin{aligned} \text{Fundamental amplitude} = & A - \frac{1}{16}R^2A^3\left\{1 - \frac{1}{4}A^2 + \frac{5}{64}A^4 - \dots\right\} + \\ & \frac{1}{768}R^4A^5\left\{1 - \frac{1}{8}A^2 + \dots\right\} - \frac{1}{73\,728}R^6A^7\left\{1 - \dots\right\} + \dots \quad (1) \end{aligned}$$

$$\begin{aligned} \text{Third harmonic amplitude} = & -\frac{1}{16}R^2A^3\left\{1 - \frac{3}{8}A^2 + \frac{9}{64}A^4 - \dots\right\} + \\ & \frac{9}{512}R^4A^5\left\{1 - \frac{1}{4}A^2 + \dots\right\} - \frac{81}{40\,960}R^6A^7\left\{1 - \dots\right\} + \dots \quad (2) \end{aligned}$$

$$\begin{aligned} \text{Fifth harmonic amplitude} = & \frac{1}{128}R^2A^5\left\{1 - \frac{1}{8}A^2 + \dots\right\} + \\ & \frac{25}{1536}R^4A^5\left\{1 - \frac{5}{4}A^2 + \dots\right\} - \frac{625}{73\,728}R^6A^7\left\{1 - \dots\right\} - \dots \quad (3) \end{aligned}$$

$$\begin{aligned} \text{Seventh harmonic amplitude} = & -\frac{1}{1024}R^2A^7\left\{1 - \dots\right\} - \\ & \frac{49}{6144}R^4A^7\left\{1 - \dots\right\} - \frac{2401}{368\,640}R^6A^7\left\{1 - \dots\right\} - \dots \quad (4) \end{aligned}$$

where $A = 2\pi a/\lambda$

$R = 2\pi r/\lambda$

a = amplitude of lateral modulation of groove, measured in the plane of the record

r = stylus radius

and λ = wavelength of sinusoidal modulation measured in the direction of an unmodulated groove.

These formulae only hold when RA does not exceed $\sqrt{2}$.

Example: Groove velocity 10 inches/sec., lateral groove velocity 2 inches/sec for $f = 4000$ c/s,

$r = 2.3$ mils.

Wavelength $= \lambda = 10/4000 = 0.0025$ inch.

Amplitude $= a = 2/2\pi(4000) = 1/4000\pi$ inch.

$A = 2\pi a/\lambda = 0.2$.

$R = 2\pi(0.0023)(400) = 1.84\pi$.

From (1): Fundamental amplitude $= 0.1839$ (this is 91.9% of the groove amplitude).

From (2): Third harmonic amplitude $= -0.0113$.

Percentage third harmonic with constant velocity pickup $= 3 \times 0.0113 \times 100/0.1839 = 18.4\%$.

From (3): Fifth harmonic amplitude $= +0.0035$.

Percentage fifth harmonic with constant velocity pickup $=$

$5 \times 0.0035 \times 100/0.1839 = 9\%$.

Total r.m.s. distortion $= 20\%$.

Intermodulation tracing distortion

The harmonic distortion so far discussed implies the existence of intermodulation distortion which causes the most distressing effects on the listener and is still audible when the offending harmonics are inaudible. The ratio of intermodulation distortion

to total harmonic distortion may be as high as 10 times (Ref. 110). Intermodulation distortion may, in severe cases, be audible as a buzz.

Since the higher order harmonics are substantial, the most convenient method of comparison for different conditions is given by intermodulation distortion (Ref. 264) and four curves for selected operating conditions are given in Fig. 17.37A. Under these operating conditions the upper limit for good reproduction is 10% intermodulation—this does not hold for other conditions.

The minimum groove diameters for reasonable fidelity (less than 10% calculated intermodulation distortion as given by Fig. 7.37A) are :

R.P.M.	Stylus radius	Min. groove diameter
78	3.0 mils	6.1 inches
45	1.0	4.9
33-1/3	1.0	6.5
33-1/3	2.3	10.1

Fortunately, owing to the smaller amplitudes which usually occur in both speech and music at the higher frequencies, the actual distortion under the prevalent listening conditions is usually less than the values given above. In addition, the yield of the record material reduces the distortion (Ref. 265); this is appreciable with vinyl, but negligible on shellac records. A further effect is the translation loss which may be

about 6 to 8 db at 10 000 c/s at the inner radius with 78 r.p.m. standard groove, whereby both fundamental and harmonics are reduced. All these subsidiary effects tend to decrease the actual tracing distortion.

However, the deterioration in both frequency response and fidelity is plainly audible to a critical listener as the groove radius decreases towards the end of a record; this applies to 78 r.p.m., transcriptions and all types of fine groove recording.

The effect of recording characteristics on tracing distortion

Over the range of constant velocity recording, the tracing distortion is proportional to the square of the frequency

With high-frequency pre-emphasis followed by the correct amount of de-emphasis, at the rate of 6 db/octave above a "hinge frequency" f_1 (P in Fig 17.37B) the third harmonic tracing distortion at a recorded frequency f_1 will be one third of the value calculated by the procedure outlined above provided the constants are the same in both cases. This relationship will, however, not hold at any other point. For example, at frequency f_2 where $f_2 = 2f_1$, the amplitude at Q' will be twice that at Q and the

FIG. 17.37A

Fig. 17.37A. Variation of calculated intermodulation tracing distortion with record diameter (based on Ref. 292).

Fig. 17.37B. Ideal recording characteristic for calculating tracing distortion.

FIG. 17. 37 B

distortion will therefore be four times as great with pre-emphasis : de-emphasis as at point P. This may be expressed in the general form

$$\frac{H_3\% \text{ (constant amplitude)}}{H_3\% \text{ (constant velocity)}} = \frac{m^2}{3} \quad (5)$$

where $m = f_2/f_1$

f_2 = recorded frequency

f_1 = hinge frequency of pre-emphasis

and the pre-emphasis and de-emphasis are both at the rate of 6 db/octave above f_1

If $f_2 = f_1$ $m = 1$

Ratio of $H_3\%$ = 1/3

$f_2 = 2f_1$ $m = 2$

Ratio of $H_3\%$ = 4/3

$f_2 = 4f_1$ $m = 4$

Ratio of $H_3\%$ = 16/3

Other distortion effects

In the foregoing treatment it is assumed that the pickup stylus and armature are able to follow ideally all the sharp and sudden changes in the modulation of the groove which occur with complex sounds. In many cases this is obviously not the case, so that additional causes of spurious intermodulation products (mainly inharmonic) arise. These are reduced by the use of a really good pickup but in most cases it is probably true that the best available pickup will introduce distortion additional to the theoretical tracing distortion.

The distortion arising from overmodulation at high frequencies due to a high value of pre-emphasis has already been covered in Sect. 5(i). Similar effects may occur at low frequencies with organ music, but may be avoided by the use of a low frequency limiter in the recording amplifier.

The effect of finite size of needle tip on the reproduction of the fundamental recorded frequency is covered in Sect. 2(i), also translation loss.

The **pinch effect** has already been mentioned. It causes increased combination products, forced vibration of the armature at its high resonant frequency, increased noise in the output voltage and needle talk. Fortunately these bad effects may be considerably reduced by the introduction of vertical compliance either in the needle (bent shank or trailer type) or in the pickup itself.

References to tracing distortion, intermodulation distortion and pinch effect : 11, 40, 41, 42, 47, 110, 146, 193, 212, 213, 223, 224, 225, 248, 264, 265, 285.

(ii) Playback loss

Playback loss has been defined as the difference between the recorded and the reproduced level at the very same point of a record. It is due to the physical properties of the record material, being evident as a loss of the higher frequencies. A comparatively stiff and hard material such as is used with shellac pressings has very little playback loss ; vinyl and lacquer are very much more flexible and exhibit appreciable playback loss. It is also a function of the pickup used. Reference 227.

(iii) Wow and the effects of record warping

Wow is a low-frequency modulation effect caused by spurious variations in groove velocity, either in recording or in reproduction. In recording, the American N.A.B. recommends that the maximum instantaneous deviation from the mean speed of the recording turntable shall not exceed $\pm 0.1\%$ of the mean speed. The B.B.C. "D

channel" limit is $\pm 0.05\%$ (Ref. 297). In reproduction, most turntables used in combination sets suffer from an appreciable slowing down on heavily recorded passages. This effect is reduced by the use of a light-weight pickup with high lateral compliance. The effect may be noticed, in severe cases, by a movement in the pattern produced on a stroboscopic disc at the commencement and end of a heavily recorded passage.

A warped disc or wobbling turntable will produce greater wear and eventually greater scratch level on the high portions of the record. This is much less with well-designed light-weight pickups than with older models. However, it is important that the stylus force should be considerably more than the minimum for correct tracking on a perfectly flat record. A record with warp in excess of $1/16$ inch is likely to cause trouble.

An eccentric disc or turntable will tend to cause wow; a very small amount of eccentricity is sufficient to be noticeable in recording (max. ± 0.002 inch N.A.B.; also English—Ref. 235). This will produce a tonal pitch variation of 0.1% on reproduction (10 or 12 inch records).

Flutter is similar to wow but at a high frequency; the ear is very sensitive to this form of distortion. This also may occur both in recording and in reproduction.

References to wow etc. in recording: 84, 90, 193, 231.

Reference to tests on wow in phonograph combinations: 267.

See also Chapter 37 Sect. 1 (vi) N for I.R.E. tests on phonograph combinations.

(iv) Distortion due to stylus wear

All theoretical work on disc reproduction assumes that the needle point is perfectly spherical. A jewel or other form of permanent tip suffers wear on two opposite faces. The wear is usually measured in terms of the width of the nearly flat portion. The distortion arising from the worn stylus is independent of amplitude, and consists principally of odd harmonics. The distortion is a function of d/l where d = width of flat on needle and l = wavelength of recorded tone.

The following table has been calculated from published data (Ref. 59) for standard groove constant velocity recording:

d/l	fundamental	H_3	H_5	at innermost groove	
				$f = 1000$ c/s	$f = 10\,000$ c/s
0.16	— 1 db	4.8%	6.6%	$d = 1.5$ mil	$d = 0.15$ mil
0.22	— 2 db	10%	12%	$d = 2.4$ mil	$d = 0.24$ mil
0.275	— 3 db	20%	17%	$d = 3.3$ mil	$d = 0.33$ mil
0.36	— 5 db	44%	—	$d = 4.1$ mil	$d = 0.41$ mil
0.5	—10 db	—	—	—	—

The distortion becomes very severe before there is any appreciable attenuation of the fundamental caused by the needle wear. Although the harmonics of the higher frequencies may be outside the frequency range of the equipment, the intermodulation products will be apparent.

If the recording characteristic is constant amplitude (6 db/octave high frequency pre-emphasis followed by de-emphasis) the values of distortion in the table should be divided by 3 and 5 for H_3 and H_5 respectively. In this case pre-emphasis : de-emphasis shows to considerable advantage over constant velocity, in that styli last longer before requiring replacement, for the same distortion.

It is obvious that, for high fidelity, no observable stylus flat is permissible. This seriously limits the life of sapphire styli, even when using a good quality pickup with high lateral and vertical compliance—see Sect. 2(vi).

(v) Noise modulation

The noise level is usually measured as the high-frequency noise developed by an

unmodulated groove. When a high degree of noise is present and the groove is modulated by a single-frequency signal, it is found that the signal tends to modulate the noise. The noise modulation reaches a maximum twice each cycle, and the peak amplitude may be over ten times the peak amplitude of the measured noise in an unmodulated groove. The use of pre-emphasis : de-emphasis is to reduce the noise itself but to increase noise modulation. This effect is not apparent when the intermodulation is less than 4%.

This effect may be minimized during recording, by special means suggested in the article.

Reference 145. See also Ref. 193 (proposed standards).

(vi) Pickup distortion

Non-linear distortion in a pickup may vary from practically nil in the best high-fidelity types to over 5% total harmonics in some types. The total harmonic distortion with a well designed crystal pickup is well under 2% (Ref. 120).

The usual method to test harmonic distortion is to use a suitable frequency test record, check it for distortion with a pickup which is known to have very low distortion, then measure the distortion with a wave analyzer. A simple test is to use a C.R.O., but this is not capable of indicating less than about 2% or 3% total harmonic distortion. The distortion is always a function of frequency, so that it should be checked at all practicable frequencies. "The minimum stylus force for a given pickup to track a given frequency recorded at a given level can be determined . . . by the observation of waveform on an oscilloscope. The waveform produced by failure to track has a characteristic 'spiked' appearance, and a very small trace of this form of distortion is easily detectable"—Ref. 310(b).

Intermodulation distortion is preferable to total harmonic distortion as a general indication of pickup performance. Recommended test frequencies are 400 and 4000 c/s, with the latter 12 db lower than the former. Test records are available with bands recorded at different levels, from below normal level, increasing by 2 db steps to +10 db (e.g. R. C. A. Victor RL-419, RL-420, E.M.I. JH 138).

In most cases the intermodulation distortion of a pickup increases very gradually up to a certain level, and then rises very rapidly as the level is further increased. This "knee" should occur at a level of about +6 db, on record RL-420, that is at about 18.2 cm/sec. A high fidelity pickup, tested on record RL-420 shows about 2.5% intermodulation distortion at a level of +6 db; most of this distortion is due to the record (Ref. 291). Other modern lightweight pickups give up to 8% intermodulation at 0 db (9.1 cm/sec.).

The "tracking" capability of a pickup may be checked by plotting a curve of intermodulation distortion against recorded level, for selected values of vertical stylus force (for details see Ref. 285).

Intermodulation distortion may be measured either as the r.m.s. sum or as the arithmetical peak sum—see Chapter 14 Sect. 3(ii) and (v). An intermodulation analyser using the peak sum method is described in Ref. 291.

(vii) Acoustical radiation

Acoustical radiation or needle chatter varies considerably among pickups. Some pickups have no audible radiation. In other cases the radiation may be reduced, if desired, by the use of a bent-shank needle or trailer type (Ref. 225).

(viii) Distortion in recording

If the distortion in the cutter head includes, say, 1% third harmonic distortion, this will result in 4% third harmonic distortion if both the fundamental and the harmonic frequencies are recorded and reproduced at constant velocity. On the other hand pre-emphasis followed by de-emphasis will reduce this form of harmonic distortion, although intermodulation products will still be present (Ref. 189).

See also Sect. 9(i) for distortion on original recordings.

Proposed standards for the measurement of distortion in sound recording :
Ref. 193.

SECTION 7 : NOISE REDUCTION

(i) *Analysis of noise* (ii) *High-frequency attenuation* (iii) *High-frequency pre-emphasis and de-emphasis* (iv) *Volume expansion* (v) *Olson noise suppressor* (vi) *Scott dynamic noise suppressor* (vii) *Price balanced clipper noise suppressor*.

(i) Analysis of noise

Noise in the reproduction of sound from records may be divided into two distinct groups, low frequency noise such as hum and rumble, which has already been dealt with, and surface noise (scratch) which is the subject of this section.

Surface noise, when reproduced with a high fidelity pickup, covers the whole audible frequency range and beyond, but is most distressing to the ear at frequencies from about 1500 to 15 000 c/s. The surface noise per 1 c/s increases with increasing frequency.

When a pickup is used which has a pronounced peak in the region of 3000 to 6000 c/s, the noise in the output appears to have a peak at this frequency. This effect is due partly to the increased response of the pickup at the frequency in question (which could be removed by equalization) and partly to shock excitation of the pickup armature. The remedy is to use a better quality pickup.

References 15, 21.

(ii) High-frequency attenuation

The distressing effects of surface noise on the listener may be reduced by any form of high-frequency attenuation. Soft needles, such as fibre, thorn, bent shank or trailer type, introduce attenuation of this kind but it is not controllable and, in the case of fibre and thorn needles, variable.

Electrical attenuation is to be preferred, although it may be combined with the use of, say, a bent shank needle. Best results are obtained with a combination of two attenuation characteristics—

1. A very rapid attenuation above a fixed frequency (say 7000 c/s, or a choice between 4500, 7000 or 10 000 c/s) for use with old or noisy records. A suitable circuit is Fig. 17.24A.

2. A gradual attenuation characteristic with a hinge point at about 1500 c/s with variable rate of attenuation up to at least 6 db/octave, in addition to any de-emphasis as such. Some possible circuits are described in Chapter 15 Sect. 6. See also Figs. 17.19, 17.23 and 17.27. Crystal pickups used without an equalizer give an attenuation approaching 6 db/octave.

If it is not practicable to have two independent attenuation characteristics, a single characteristic may be used provided that it is capable of giving an attenuation of at least 30 db at 7000 c/s, for use with worn records.

(iii) High-frequency pre-emphasis and de-emphasis

This method has already been described, and reduces the noise by approximately half the amount of pre-emphasis at 10 000 c/s (for characteristics which follow the time-constant roll-off).

(iv) Volume expansion

Volume expansion provides an increase in the dynamic range and, effectively, reduces the surface noise level with reference to the maximum power output. Full details are given in Chapter 16. On account of the limitations of available types of volume expanders, a maximum expansion of 8 db is suggested as a satisfactory compromise.

A combined volume expander and scratch suppressor is described in Ref. 211.

(v) Olson noise suppressor

The Olson noise suppressor works on the principle of the threshold effect. If the noise is below a certain low threshold value it is not amplified. The output versus

input voltage characteristic is approximately horizontal for an input up to, say, 0.5 volt; this may be accomplished by means of a network incorporating voltage-delayed diodes (such as 6H6) or germanium crystal diodes. The distortion products (all harmonic and most of the intermodulation) are eliminated by splitting the high frequency part of the amplifier into channels each covering only one octave. Some possible combinations are

1. 0-3000 c/s; 3000-6000 c/s (2 channels).
2. 0-2000 c/s; 2000-4000 c/s; 4000-8000 c/s (3 channels).
3. 0-1500 c/s; 1500-3000 c/s; 3000-6000 c/s; 6000-12 000 c/s (4 channels).

Filters are used which provide attenuation at the rate of approximately 30 db/octave at both ends of each channel, except the low frequency end of the first channel. A filter network for two channels is given in Ref. 115, while one for four channels is given in Ref. 138.

The only known defects are that signals below the threshold value are lost, and that there are some intermodulation products.

(vi) Scott dynamic noise suppressor

The Scott dynamic noise suppressor controls the bandwidth of the amplifier by means of separate high-frequency and low-frequency tone controls which are automatically controlled by the signal. Fig. 17.38 shows one simple application suitable for home use (Ref. 251 based on Ref. 114). V_1 is an amplifying stage which also provides the voltage for application to both high-frequency and low-frequency control circuits which in turn control the grid voltages of V_2 and V_3 . The parallel resonance between L_1 and C_1 provides an attenuation at high frequencies and a high attenuation above the normal operating range; it may also be used as a whistle filter. V_2 is used as a reactance valve providing variable capacitive reactance which, together with C_2 and its companion series condenser, forms a series resonant circuit with L_2 . The low-frequency gate including V_3 is quite readily understood. Switch S_1 allows the suppressor to be opened, providing maximum frequency range when no suppression is desired. When S_1 is closed, R_3 controls the amount of suppression. For bad records, switch S_2 allows restriction of the maximum frequency range. Switch S_3 closes the high-frequency gate and leaves the low-frequency gate open.

The frequency characteristics of an experimental model built in our Applications Laboratory is given in Fig. 17.39 (Ref. 251). Scott recommends that C_1 should be

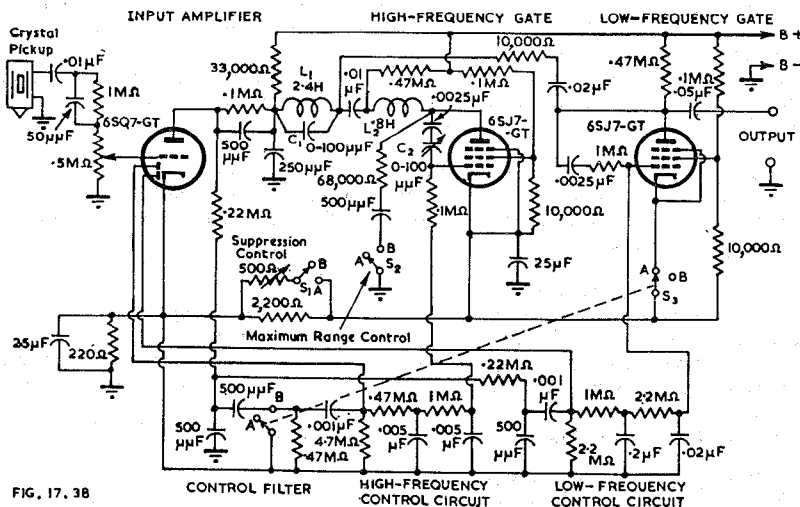

Fig. 17.38. Simple Scott dynamic noise suppressor (Ref. 251 based on Ref. 114).

adjusted for minimum output at 9000 c/s, but it was found preferable to tune C_1 and L_1 for minimum output at 7500 c/s to avoid too great a rise in output between the two frequencies of maximum attenuation. This simple circuit cannot provide a response extending above about 6000 c/s.

A more recent model with minimum output at 10 000 c/s is described in Ref. 184. Performance data of a more flexible dynamic noise suppressor built into a complete amplifier are given in Ref. 173.

Fig. 17.39. Frequency characteristics of circuit of Fig. 17.37 (Ref. 251).

A modified circuit for home use is that used in the Goodell radio-phonographs (Ref. 133 Fig. 1). This includes provision for a switch to short-circuit the high-frequency filter (L_1C_1 in Fig. 17.38); the sharp cut off is at a frequency from 10 000 to 16 000 c/s. This and the Scott amplifier (Ref. 173), are to be preferred to the earlier circuit of Fig. 17.38.

A more elaborate circuit, which also includes a pre-amplifier suitable for use with a low-level electromagnetic pickup, a 3 stage power amplifier, frequency-compensated volume control and bass and treble tone controls, is described in detail in Ref. 250. See also Ref. 188 for further information.

A simpler modification is described in Ref. 165 in which a combined equalizer suitable only for use with low-level electro-magnetic pickups (such as G.E. or Pickering). This uses one 12SG7 valve and two 12SL7 twin triodes, with d.c. heater supply.

Much more elaborate dynamic noise suppressors for use in broadcast stations are described in Refs. 114, 133, 275.

An analysis of the filter characteristics for the dynamic noise suppressor are given in Ref. 140.

References to Scott dynamic noise suppressor : 83, 114, 133, 165, 173, 184, 188, 250, 275.

To obtain the best results from the dynamic noise suppressor requires intelligent attention from the operator, using the minimum degree of suppression rather than the maximum. The level should be controlled at some point after the suppressor (see comments, Ref. 149).

A comparison between the Scott, Fisher and Goodell versions of the dynamic noise suppressor is given in Ref. 182.

(vii) Price balanced clipper noise suppressor

This is a modification of the Olson noise suppressor described above. It differs from the Olson design in that a push-pull clipper is used in order to eliminate second harmonic distortion and thus permit an increase in the frequency coverage of each high-frequency channel. Possible arrangements are 0-3500; 3500-8000 c/s or 0-3000; 3000-7000; 7000-15 000 c/s (Ref. 150).

The principle of operation is open to the objection that it will respond to certain intermodulation products, more so than the Olson design.

SECTION 8 : LACQUER DISC HOME RECORDING (DIRECT PLAYBACK)

(i) *General description* (ii) *Recording characteristic* (iii) *Cutting stylus* (iv) *Cutter head* (v) *Equalization of cutter* (vi) *Motor and turntable* (vii) *Amplifier* (viii) *Pickups for use on lacquer discs* (ix) *Recording with embossed groove.*

(i) General description

Lacquer discs for home recording usually consist of a thin coating of cellulose nitrate on an aluminium disc, but other coating and disc materials are also used. There are considerable differences in the performance obtained with the best quality discs as compared with others.

The principal defects shown by some lacquer discs are

1. High noise level.
2. Loss of high frequencies on play-back.
3. Distortion, particularly due to drying out after cutting.

Lacquer discs can be used either with a standard stylus or a fine groove stylus. The following details apply to the standard stylus except where otherwise indicated.

With a suitable light-weight pickup, as many as 100 playings are possible. The discs may be processed for making a large number of pressings (for studio use). The signal to noise ratio with the best lacquer discs under the best conditions with a standard stylus may be between 50 and 60 db, the noise level being lowest at the greatest recording diameter and increasing by 2 to 8 db at a recording diameter of 5 inches. With a fine groove stylus the signal-to-noise ratio may be about 58 to 60 db at 10 in. recording diameter, 54 to 58 db at 8 in. and 40 to 50 db at 5 in. diameter. The signal-to-noise ratio may be less than the values quoted above, owing to the use of poor discs and technique; the difference between a good and a poor disc may exceed 10 db. The overall distortion under the best conditions may be less than 5%.

Discs are available with diameters of 5, 6, 7, 8, 10, 12, 13½ and 16 inches. Discs for home recording are usually limited to 12 inches. If recording is made at 33-1/3 r.p.m. it is wise not to record below a diameter of 8 inches, owing to the loss of high frequencies and increased noise. With 78 r.p.m. it is wise not to record below a diameter of 5 inches, for good fidelity.

The thread (swarf) is highly inflammable, and should be disposed of in water or a closed metal container.

Standards for "Disc Home Recording"

(based on R.M.A. REC-105, Aug. 31, 1947)

Drive pin at radius of 1 in. from centre of turntable.

Drive pin diameter 0.180 to 0.185 in.

Drive pin hole 1/4 inch nominal.

Centre hole of rigid base discs, 0.284 in. min. diameter.

Cutting stylus length 5/8 in.

shank diameter 0.0625 in.

face angle 87°

heel angle 50°

shank flat length 3/8 in.

shank flat depth 0.010 in.

max. tip radius (if any) 0.002 in.

Cutting face to be parallel with stylus axis.

(ii) Recording characteristics

The most generally used cross-over frequency is 500 c/s. It is usual to adopt a close approach to the N.A.B. pre-emphasis characteristic (+16 db at 10 000 c/s) followed by de-emphasis. The soft coating material causes some loss of higher frequencies during playback, so that a smaller amount of de-emphasis is required than would be used with hard discs, such as shellac.

(iii) Cutting stylus

The usual cutting stylus has a tip radius of about 2 mils with an included angle of about 90° . The depth of cut is usually between 1.5 and 2.5 mils. Steel cutting styli are cheap, but give poor performance all round, and only last for about 15 to 30 minutes of recording. Sapphire cutting styli are very much to be preferred; they may be reground when necessary. Some alloys (e.g. stellite) approach the sapphire performance, and are readily re-ground.

The shape of the cutting stylus is vitally important; it normally has burnishing facets to produce a noise-free polished groove (Refs. 95, 222).

A hot stylus recording technique has been developed to reduce the noise level by 12 to 18 db while retaining good high-frequency response. No burnishing facets are required (Refs. 288, 289, 315).

(iv) Cutter head

The cutter head requires an available electrical driving power of at least 10 watts, with a higher value preferred. Electro-magnetic cutters with good characteristics (Ref. 233) are preferable but expensive. Crystal cutters with reasonably flat characteristics from about 50 to 9000 c/s are cheaper and satisfactory for home use.

The cutter head is mounted on a feed mechanism which usually provides 96, 112 or 120 grooves per inch.

(v) Equalization of cutter

Equalization is required, firstly to correct any shortcomings in the cutter itself, and secondly to provide the desired recording characteristic. In home recorders using electro-magnetic cutters it is usual to omit the first, and to limit the second to high-frequency pre-emphasis. The cross-over frequency is thus fixed by the cutter design.

High-frequency pre-emphasis (treble boosting) may be provided in a conventional manner to give any desired characteristic. Home recorders usually limit the maximum frequency to 8000 c/s or less, with a maximum boost from 10 to 14 db.

If a crystal cutter is directly connected to the secondary of the output transformer, and if the output resistance of the amplifier (reflected on to the secondary) is less than the capacitive reactance of the crystal at the highest frequency, the recording characteristic will be constant amplitude. The Brush RC-20 crystal cutter has a capacitance of $0.007 \mu\text{F}$, with a reactance of about 2500 ohms at 9000 c/s. The maximum signal voltage across the cutter (RC-20) should be about 50 volts; the step-down ratio of the transformer should be calculated to provide this voltage at maximum power output. The English Acos cutting head requires an input of the order of 150 volts for 1 mil amplitude. This method is only satisfactory with triode valves.

If pentode valves are used it is necessary to connect a suitable shunt dummy load to provide correct matching at about 500 c/s.

The conventional constant velocity characteristic above a specified cross-over frequency may be achieved with a crystal cutter by designing so that the impedance of the driving source is equal to the capacitive reactance of the cutter at the cross-over frequency. With a low impedance source it is necessary to use a series loading resistance.

(vi) Motor and turntable

Motors and turntables for recording purposes must be specially designed for the purpose, as higher power, less vibration and more constant speed are required than with play-back alone. Some equipments are designed for 78 r.p.m. alone, while others are designed for either 33-1/3 or 78 r.p.m.

(vii) Amplifier

The amplifier should be capable of an output of at least 10 watts, with low distortion and good frequency response. The noise and hum level should be at least

45 to 50 db below maximum power output (40 db is an extreme limit for poor recordings). The amplifier should preferably have push-pull triodes with negative feedback, although triodes without feedback or beam power valves with feedback may be used.

(viii) Pickups for use on lacquer discs

The pickup must be a light-weight type, preferably well under 1 ounce (28 grams) needle pressure. The play-back needle should be of the permanent type, usually sapphire, with a point radius of about 3 mils. The needle or pickup must have vertical compliance, and a trailer type of needle is frequently used.

Reference 252.

(ix) Recording with embossed groove

An embossed groove in place of a cut groove has, so far at least, had very limited use. One application (Ref. 103) makes use of 33-1/3 r.p.m. discs with 220 grooves per inch which provide 15 minutes playing time on each side of a 7 inch disc. The frequency range is from 150 to 4000 c/s, being suitable for dictation machines. Smaller discs provide 7½ minutes playing time. A special application called for 330 grooves per inch with 30 minutes playing time on each side of a 7 inch disc, working at 22 r.p.m.

See also Refs. 63, 210, 242.

SECTION 9 : REPRODUCTION FROM TRANSCRIPTION DISCS

(i) *Introduction* (ii) *Characteristics of record material, wear and noise* (iii) *Sound track* (iv) *Recording characteristics and equalization* (v) *Translation loss and radius compensation.*

(i) Introduction

Reproduction from transcription discs follows the same general principles as other disc reproduction, and will only be dealt with briefly. The special features of transcription disc recording and reproduction have been adequately covered in the literature, to which a number of references have been given.

The principal characteristics of N.A.B. (Ref. 237) and B.B.C. (Ref. 214) 16 inch 33-1/3 r.p.m. transcription discs are given below :

Detail	N.A.B. (1949)	B.B.C.
Outer diameter	15-15/16 \pm 3/32	16 ins.
Outermost groove diameter	15-1/2 \pm 1/16 (for inside start, 15-9/16 ins. max.)	15-1/2 ins.
Innermost groove diameter	7-1/2 ins. min.	
Grooves per inch	96, 104, 120, 128, 136 etc.	120
Width of groove at top	< 4.0 mils	—
Radius at bottom of groove	1.5 mils max.	1.5 mils
Angle of groove	88° \pm 5°	90°
Turntable speed	33-1/3 \pm 0.3%	33-1/3 r.p.m.
Wow factor	\pm 0.1%	—
Reproducing stylus : Angle	40° — 55°	—
Bottom radius (primary standard)	2.0 \pm 0.1 mils	2.5 mils
(secondary standard*)	2.5 \pm 0.1 mils	—
Recorded level† (1000 c/s)	Peak velocity 7 cm/sec.	—
Direction of recording	either	outside-in

Some 10 inch and 12 inch discs are also used, but these have been covered in Sect. 2.

The pickups to be used with transcription discs should have a stylus force not exceeding 1-1/2 ounces (42 grams). Only permanent points should be used.

The total harmonic distortion on an original recording at 1000 c/s or less, in accordance with good practice, would be less than 2% (Ref. 219).

Intermodulation distortion measured on recordings made by three recording heads, with low frequency peak amplitudes of 2.5 mils and high frequency velocity 12 db lower, were approximately 1.0, 9.2 and 52% (Ref. 269). The first head is one giving exceptionally low distortion, while the second is representative of good practice. The readings were very little affected by the choice of low or high frequency. When the level was reduced 6 db, the I.M. distortion was reduced to 23% with the third recording head (say 6% harmonic distortion).

Standards : Refs. 2, 87, 214, 237 : Specifications : 185 ; Bibliography : 105.

(ii) Characteristics of record material, wear and noise

Most processed transcription disc are made of vinyl. Vinyl records will reproduce up to 1000 playings with a suitable light-weight pickup and permanent tip. For the effects of elastic deformation see Ref. 212.

*Compromise for reproduction of both lateral transcriptions and 78 r.p.m. shellac discs.

†This is the deflection of a standard volume indicator. Programme peaks up to 21 cm/sec. would be anticipated.

Wear of stylus tips is covered in Sect. 2(vi).

The N.A.B. (1949) standard for **signal to noise ratio** states that the noise level measured with a standard volume indicator (ASA Standard C.16.5-1942) when reproducing a record on a flat velocity basis over a frequency range between 500 and 10 000 c/s shall be at least 40 db below the level obtained under the same conditions of reproduction using a tone record of 1000 c/s having a peak velocity of 7 cm/sec. Response of the system at 500 c/s shall be 3 db below the response at 1000 c/s, and the response shall fall at the rate of at least 12 db/octave below 500 c/s. Response of the noise measuring system at 10 000 c/s shall be 3 db below the response at 1000 c/s and the response shall fall at the rate of at least 12 db/octave above 10 000 c/s.

The standard N.A.B. pre-emphasis will increase this value by approximately 8 db, resulting in an effective signal to noise ratio (under minimum conditions) of 48 db. The peak signal to noise ratio will be at least 10 db better than this figure, with normal programme material—say 58 db. Lacquer discs (direct recordings) under similar conditions may have peak signal to noise ratios up to 68 db or even higher (Ref. 63).

(iii) Sound track

The ratio of maximum to minimum groove radius (N.A.B.) is 2.07 : 1. The groove speed varies from 27 to 13.1 inches per second. As the groove diameter approaches 7-1/2 inches there is a progressive loss of high frequencies and increase in harmonic distortion during both recording and play-back. For an analysis of the radius of curvature see Ref. 146. For tables giving groove/land ratios see Ref. 205.

(iv) Recording characteristics and equalization

The recording characteristic standardized by N.A.B. (1949) is given in Fig. 17.15 Curve 2, while that used by the B.B.C. is given in Fig. 17.14 Curve 4. The Orthacoustic recording characteristic is given in Fig. 17.15 Curve 5.

Equalization has been covered in Sect. 5. De-emphasis of the high frequencies (N.A.B.) may be accomplished by a capacitor connected across a resistive network. The value of the capacitance is given by

$$C = 100/R \quad (1)$$

where C = capacitance in microfarads

R = total circuit impedance (supply resistance and load resistance in parallel) across which C is placed

and 100 = time constant in microseconds.

This provides de-emphasis of approximately 16 db at 10 000 c/s.

(v) Translation loss and radius compensation

Translation loss is defined as the loss in the reproduction of a mechanical recording whereby the amplitude of motion of the reproducing stylus differs from the recorded amplitude in the medium (N.A.B. 1949). The translation loss is a function of the record, the needle tip radius and the pickup. Usual values are from 8 to 16 db at 10 000 c/s at the inner groove.

Radius compensation (diameter equalization)

In order to reduce the loss of high frequencies during play-back some recording organizations boost the higher frequencies during recording, the degree of boosting increasing as the stylus approaches the innermost groove. It is important to remember that the purpose of radius compensation is to give, as nearly as practicable, constant output at all frequencies and at all positions along the groove, when played by a pickup with the recommended needle tip dimensions.

The R.C.A. automatic recording equalizer MI-11100 provides two degrees of radius compensation. The low setting gives 10.8 db at 8 inches diameter and 8 db at 9 inches, both for 10 000 c/s. The high setting gives 13.5 and 9.9 db respectively under the same conditions.

The B.C.C. have a maximum radius compensation of 10 db, but the frequency at which it reaches 10 db is decreased as the diameter becomes smaller (minimum 8-3/4 inches).

There is no doubt that with certain kinds of music it is impossible to apply the full N.A.B. pre-emphasis of 16 db at 10 000 c/s together with the necessary amount of radius compensation to provide a nearly level frequency characteristic without serious over-modulation and distortion. The only answer seems to lie in the use of fine groove recording.

(i) General survey

Microphones may be divided into two basic groups, pressure- and velocity-operated. Any microphone that has its diaphragm exposed to sound waves on one side only, is a **pressure-operated type**—that is, the displacement of the diaphragm is proportional to the instantaneous pressure developed in the sound waves. At low frequencies a pressure-operated microphone is non-directional, that is to say it responds uniformly to sounds from all directions. As the frequency increases, however, the response becomes more and more uni-directional and there is a peak in the high frequency response for sound impinging directly on the diaphragm; this peak may be reduced or eliminated by placing the diaphragm at an angle of 45° to 90° to the direction of the sound.

Examples of pressure-operated microphones are carbon, crystal, moving coil and pressure-ribbon microphones.

A **velocity-operated microphone** is one in which the electrical response corresponds to the particle velocity (or pressure-gradient) resulting from the propagation of a sound wave through the air. Examples are the free-ribbon velocity microphone and pressure-gradient microphones. There are also combinations of pressure-operated and velocity-operated microphones.

For good fidelity a microphone should have a wide frequency response without peaks, low distortion and good transient response. For public address a microphone need not have such a wide frequency response, particularly at the bass end, and a slight peak in the 3000 to 5000 c/s region is not usually considered detrimental, while distortion requirements are less stringent.

The **output voltage** from a microphone is approximately proportional to the sound pressure.

The **peak r.m.s. sound pressure** at a distance of 1 foot from a man's mouth is of the order of 10 dynes/cm² with conversational speech. It decreases 6 db each time the distance is doubled. When speaking with the mouth as close as possible to the microphone, the peak r.m.s. sound pressure is about 100 dynes/cm².

General references A5, D3, D4, D7, D11.

Microphone ratings

Microphones may be rated in terms of either voltage or power, as described in detail in Chapter 19 Sect. 1(iv). Ratings in common use include

Voltage ratings

- A. Open circuit voltage (0 db = 1 V) for sound pressure 1 dyne/cm², expressed in dbv*.
- B. Open circuit voltage (0 db = 1 V) for sound pressure 10 dynes/cm², expressed in dbv.
- C. Volume units (as read by a standard Volume Indicator) for sound pressure 1 dyne/cm², expressed in vu.
- D. High impedance grid circuit voltage (0 db = 1 V, $Z = 40\,000$ ohms) for sound pressure 1 dyne/cm², expressed in dbv.

Power ratings

- E. Output power† (0 db = 1 mW) for sound pressure 1 dyne/cm², expressed in dbm.†
- F. Output power† (0 db = 1 mW) for sound pressure 10 dynes/cm², expressed in dbm.
- G. Output power (0 db = 6 mW) for sound pressure 1 dyne/cm². This rating is now rarely used.
- H. Output power (0 db = 6 mW) for sound pressure 10 dynes/cm². This rating is now rarely used.
- J. Output power (0 db = 1 mW) for sound pressure 0.0002 dyne/cm². This is the R.M.A. Microphone System Rating G_M (R.M.A. Standard SE-105; see Chapter 19 Sect. 1(iv)D).

Voltage ratings—To convert from A to B, add + 20 db.

To convert from B to A, add - 20 db.

If a voltage rating is used for a low impedance microphone, the impedance across which the voltage occurs should be specified.

Volume units—This is not an official microphone rating, but is sometimes used as a convenient method of measurement. The Volume Indicator is effectively a voltmeter in which 0 vu = 0.77 volts r.m.s. across 600 ohms. To convert vu (Rating C) to voltage (rating A), add - 2 db. When the output from a low impedance microphone is quoted in terms of vu, it may be inferred that this is equivalent to the power output in milliwatts (Rating E).

Power ratings—The power rating is the power developed in a load of specified value. Power ratings E, F, G and H may be calculated one from the other as under :

To convert from	add	To convert from	add	To convert from	add
E to F	+ 20 db	F to J	- 94 db	H to G	- 20 db
E to G	- 8	G to E	+ 8	H to J	- 86
E to H	+ 12	G to F	+ 28	J to E	+ 74
E to J	- 74	G to H	+ 20	J to F	+ 94
F to E	- 20	G to J	- 66	J to G	+ 66
F to G	- 28	H to E	- 12	J to H	+ 86
F to H	- 8	H to F	+ 8		

Relationship between voltage and power ratings†

Provided that the sound pressure is the same in both cases : Microphone rating in dbv (0 db = 1 volt) = microphone rating in dbm (0 db = 1 milliwatt) + correction factor (db)

*dbv indicates a voltage, expressed in decibels, with 0 db = 1 volt.

†Also applies to effective output level.

‡In calculations involving Power Rating J there may be an error, not greater than 2.5 db, due to the Rating Impedance differing from the actual impedance.

where the correction factor (C.F.) is given by.

Z =	25	50	150	250	600	25 000	40 000 ohms
C.F. =	-16	-13	-8	-6	-2	+14	+16 db

Crystal and condenser microphones cannot be rated in terms of power, while other types of microphones can only be compared directly with crystal and condenser types on the basis of the voltage on the unloaded grid circuit. To make this comparison it is here assumed that the nominal secondary impedance of the transformer is 40 000 ohms and that the voltage across the secondary is the voltage that would occur across a resistance of 40 000 ohms which was dissipating a power equal to the output rating of the microphone. This voltage is here called the high impedance grid circuit voltage (Rating D).

To convert from	add	To convert from	add
A to D (crystal mics.)	0 db	F to D	- 4 db
B to D (crystal mics.)	-20 db	G to D	+ 24 db
C to D	- 2 db	H to D	+ 4 db
E to D	+16 db	J to D	+ 90 db

Typical microphone ratings (db)

Rating	A	B	D	E
Type	0 db = 1 V 1 dyne/cm ² dbv	0 db = 1 V 10 dynes/cm ² dbv	0 db = 1 V Z = 40 000 Ω 1 dyne/cm ² dbv	0 db = 1 mW 1 dyne/cm ² dbm
Carbon (S.B.)	-50*	-30*	-23	-39

Velocity ribbon	-54 to -63	-82 to -91	-62 to -71	-148 to -157

(ii) Carbon microphones

An example of the **single button** type is the modern telephone inset, which gives an output of about 1 mW with close speaking. The frequency response is seriously peaked, while non-linear distortion and noise level are very high.

The **double button** (push-pull) type has a wider frequency range (70 to 7000 c/s

in one example), and the second harmonic distortion is considerably less, but the output is about 10 db lower than that of the single button type.

Carbon microphones require a source of low voltage to pass a current of from 10 to 50 mA through each button. When the circuit is broken by a switch there is a tendency for the carbon granules to cohere—this may be reduced by connecting two condensers and three inductors as shown in Fig. 18.1.

All carbon microphones have a tendency to blasting, while their other defects including high noise level limit their application. The principal advantage is the high output level.

References A5, A21, A23, D1, D3, D4, D7, D13, D14.

(iii) Condenser microphones

A condenser microphone consists of a stretched diaphragm and a back plate, with a polarizing voltage between them. Owing to the high impedance, the pre-amplifier must be mounted very close to the microphone. A possible circuit arrangement is shown in Fig. 18.2. The response may be made almost flat from 30 to 10 000 c/s with an incident angle of 90° —on the axis there is a high frequency peak of about 8 db as with all pressure microphones. The average response is about -60 dbv across the microphone itself ($0 \text{ db} = 1 \text{ volt per dyne/cm}^2$).

References A5, A7, A23, D1, D3, D4, D7, D11, D13, D14.

The high frequency peak which occurs with microphones of standard size may be reduced by making the diaphragm smaller. A miniature condenser microphone with a diaphragm having the area of a human ear drum has been introduced with non-directional pickup characteristics (Refs. A18, A26). The output level from the pre-amplifier is -50 dbm in a sound field of 10 dynes/cm^2 .

(iv) Crystal and ceramic microphones

Crystal microphones are of two types, directly-actuated and diaphragm types. Directly-actuated (sound-cell) microphones, as a class, have lower sensitivity but flatter frequency characteristics and they are almost non-directional. Uniform response up to 17 000 c/s can be obtained. There is a resonance at the high frequency limit causing a rise of response ($+12$ db in a typical case)—this should be equalized or else high frequency attenuation provided.

The frequency response of diaphragm type crystal microphones is less uniform than with the sound-cell type, and varies from 80 to 6000 c/s for speech only (with a pronounced peak in the 3500 c/s region) and from 50 to 10 000 c/s (± 5 db) for improved fidelity. The diaphragm type is more directional at high frequencies than the sound-cell type. There are also cardioid directional crystal microphones—see (xi) below.

FIG. 18.1

FIG. 18.2

FIG. 18.3

Fig. 18.1. Circuit diagram of double button carbon microphone with filter (optional) to reduce cohering ($L = 0.0014 \text{ H}$, $C = 0.02 \text{ } \mu\text{F}$, $E = 4.5 \text{ to } 6 \text{ V}$).

Fig. 18.2. Circuit diagram of condenser microphone.

Fig. 18.3. Circuit diagram of crystal microphone.

All crystal microphones using Rochelle salt or similar materials tend to be affected by excessive humidity and temperatures above 125°F . Most of the crystals are now coated to provide considerable protection against humidity, although their use under tropical conditions appears to be risky.

A crystal microphone is effectively a capacitance, of the order of $0.03 \text{ } \mu\text{F}$ for a diaphragm type or 0.0004 to $0.015 \text{ } \mu\text{F}$ for a sound-cell type. This is effectively in series

with the generated voltage and following grid resistor. The following-grid resistor* (R in Fig. 18.3) should be from 3 to 5 megohms for a sound cell type, or 1 to 5 megohms for a diaphragm type. A low resistance causes attenuation of low frequencies.

A long connecting cable will result in loss of output voltage, but will not affect the frequency response. The loss is given by

$$\text{db loss} = 20 \log [1 + (L \times C_L)/C_M]$$

where L = length of cable in feet

C_L = capacitance of cable in microfarads per foot

and C_M = capacitance of microphone in microfarads.

A few crystal microphones are equipped with step-down transformers for use in impedance circuits.

Ceramic piezo-electric microphones have advantages over crystal types as regards high temperature and humidity. These have substantially similar performance to that of crystal microphones. One model has a nearly flat response from 30 to 10 000 c/s with an output level of -62 dbv ($0 \text{ db} = 1 \text{ V per dyne/cm}^2$).

References to crystal and ceramic microphones : A5, A21, A23, D1, D3, D4, D7, D13, D14.

(v) Moving coil (dynamic) microphones

A dynamic microphone is, in essence, a small version of a dynamic loudspeaker, and some are even used in a dual capacity. It is pressure-operated and there is the usual tendency towards a rise in the high-frequency response for sound waves impinging directly on the diaphragm. It may be mounted vertically to make the microphone non-directional for horizontal sound waves, but this causes some attenuation of the higher frequencies.

In its simplest form the level frequency range is limited but in the more elaborate types it may extend from 60 to 10 000 c/s. It is a general-purpose good-quality microphone widely used for public-address and indoor and outdoor broadcasts.

References A5, A21, A23, A32, D1, D3, D4, D7, D11, D13, D14.

(vi) Pressure ribbon microphones

The pressure ribbon microphone has a ribbon, suspended in a magnetic field, that is exposed on one side and terminated in an acoustical resistance on the other. It is non-directional but has the characteristic, in common with all pressure types, of a high frequency response that is a function of the direction of the incident sound. The distortion may be around 2% or 3% at low frequencies and 100 dynes/cm².

This construction is generally combined with a manual control of the size of an aperture on the enclosed side which gives control of the directional characteristics (e.g. R.C.A. 77-D).

A small unobtrusive pressure type ribbon microphone has been produced (R.C.A. BK-4A) which employs a small angle horn coupled to a cylindrical tube which in turn is coupled to the front of the ribbon by means of a round-to-rectangular connector of constant cross-section. The back of the ribbon is coupled to the damped folded pipe or labyrinth by means of a rectangular-to-round connector. This is non-directional, has a frequency response from 70 to 15 000 c/s and an effective output level of -61 dbm (sound pressure 10 dynes/cm²). (Refs. A25, A21, D3.)

(vii) Velocity ribbon microphones

This is a free ribbon type in which the ribbon resonance is usually below the audible limit. With good design it is capable of a very wide frequency response (e.g. 30 to 15 000 c/s for response ± 5 db), while over the most useful part of the range the variations of level are very slight and gradual. It is strongly bi-directional. This is undoubtedly the best type of microphone for high fidelity, particularly for transients, but it is not suitable for general use outdoors. The distortion in one case is less than 0.33% at 80 c/s and 1000 dynes/cm². When a velocity microphone is placed very

*For maximum values of grid resistance see Sect. 2(vi).

close to the source of sound, the low frequencies are strongly accentuated. For this reason, a good, quiet studio and correct placement of speakers at a reasonable distance is necessary if a normal velocity microphone is used for speech. The bi-directional characteristic is useful where there are two speakers, or two groups, arranged on opposite sides of the microphone.

One model incorporates a switch and compensating reactor to reduce the accentuation of low frequencies with close speaking (R.C.A. KB-2C, Ref. A27).

A modified form incorporates a large amount of acoustical resistance to give a nearly flat response at all frequencies when speaking very close to the microphone (1 to 6 inches away), and noise cancellation for sounds originating at a distance. This is particularly suitable for outdoor public address (R.C.A. KB-3A, Ref. A28).

References A5, A21, A23, A27, A28, D1, D3, D4, D7, D11, D13, D14.

(viii) Throat microphones

A throat microphone is one which is actuated by direct contact of the diaphragm with the throat. The high frequency response must be accentuated to obtain intelligible speech. Both carbon and magnetic types have been used (Refs. A19, D3).

(ix) Lapel microphones

Normal types of carbon, crystal, dynamic and velocity microphones have been used for this application (Refs. A21, D3).

(x) Lip microphones

The velocity ribbon microphone has been used for this application (Ref. A5).

(xi) The directional characteristics of microphones

Pressure microphones are **non-directional** (Curve A Fig. 18.4) for low frequencies but at high frequencies the response is a function of the angle of sound incidence—this effect becomes smaller as the diaphragm diameter is reduced.

Velocity ribbon microphones are **bi-directional** (Curve B) and the sound source should be on one, other or both sides.

There are various types of **uni-directional** microphones, among which the cardioid (Curve C) is most popular. This characteristic may be achieved by a carefully designed combination of a velocity and a pressure microphone. Similar characteristics may be achieved by the use of acoustical delay systems in combination with any pressure microphone such as dynamic or crystal. A reduction of response of about 15 db at the back of the microphone with respect to that at the front is obtainable with a typical cardioid microphone. A single-element ribbon type microphone has been developed which has a reduction of 20 to 25 db at the back of the microphone (Ref. A22). A complete survey of directional microphones is given by Olson (Refs. A17, D3).

Polydirectional microphones provide a choice of two or three directional characteristics or a continuously variable characteristic. A typical example is the R.C.A. 77-D ribbon type.

The correct use of directional characteristics in microphone placement minimizes room reflection and reduces acoustical feedback and background noise.

References to directional microphones A17, A21, A23, D3, D13.

FIG. 18.4

Fig. 18.4. Polar diagrams showing directional characteristics of microphones (A) Non-directional; (B) bi-directional; (C) cardioid.

(xii) The equalization of microphones

It is usual, both in broadcasting and recording, to provide frequency equalization in the microphone or in its pre-amplifier to give a flat or any other desired characteristic. In other applications it is advisable to equalize, or at least to attenuate any high peaks in the response characteristics, so as to reduce acoustical feedback and other bad effects.

It is sometimes desirable to reduce the low-frequency response of a microphone (e.g. velocity type) to reduce the effects of accentuated low frequency response due to "close talking" or to reduce "building rumble."

(xiii) Microphone transformers

There is at present a very unhappy state due to the lack of accepted standards for microphone transformer output impedances. The American R.M.A. Standard for broadcasting is 150 ohms (Ref. A16). See also (xiv) below.

Most microphones are designed to work into an unloaded transformer. The best quality microphone transformers have special provision for reducing hum, such as outer steel shields, inner alloy shields and hum-bucking core construction. By this means it is possible to reduce hum to a level far below the level of random noise.

(xiv) Standards for microphones**(A) Microphones for sound equipment**

The following summary is based on R.M.A. Standard SE-105 (Ref. A20).

A microphone is defined as an electro-acoustical transducer which converts acoustical energy into electrical energy, the waveform in this conversion remaining substantially unaltered.

The field response of a microphone at a given frequency is defined by

$$20 \log_{10} (E/p)$$

where E is the open circuit voltage generated by the microphone at its accessible terminals and p is the undisturbed sound pressure in dynes/cm² at the specified frequency . . . , the microphone being placed at a specified angle with respect to the wave front.

The electrical impedance of a microphone at a given frequency is equal to the complex quotient at the specified frequency of the alternating voltage applied to the accessible terminals divided by the resulting alternating current when the microphone is placed in a free air field It shall be expressed in terms of its magnitude and phase angle and plotted as a function of frequency.

The nominal microphone impedance is the electrical impedance at 1000 c/s. The nominal impedance of low-impedance microphones shall lie between 120 and 180 ohms, or between 19 and 75 ohms. The nominal impedance of high impedance magnetic microphones shall lie between 20 000 and 80 000 ohms. The nominal impedance of any other microphone shall be specified.

The microphone system rating G_M (sensitivity) is described in Chapter 19 Sect. 1(iv)D.

The microphone rating impedance (R_{MR}) is a pure resistance to be taken from the table below

Magnitude of nominal microphone impedance	Rating impedance
19 to 75 ohms	38 ohms
75 to 300 ohms	150 ohms
300 to 1 200 ohms	600 ohms
1 200 to 4 800 ohms	2 400 ohms
4 800 to 20 000 ohms	9 600 ohms
20 000 to 80 000 ohms	40 000 ohms
80 000 ohms or more ohms	100 000 ohms

The directional pattern of a microphone at a specified frequency is the variation in the field response at that frequency for different angles of sound incidence measured from a specified zero position. Zero position refers to that microphone orientation in which the direction of the wave propagation lies along the axis of normal usage

This pattern shall be plotted in the form of a polar diagram as a function of the angle of incidence. The electrical output at any one angle, E_θ , shall be referred to the output at the zero position, E_0 , by the relation $20 \log_{10} (E_\theta/E_0)$.

The directional characteristic of a **bi-directional microphone** shall be at least -20 db for all frequencies of a specified frequency range for sounds arriving from any point in a plane perpendicular to the axis of normal usage. For a **uni-directional microphone** the angle of minimum response . . . shall be on an average of at least -10 db, the average to be based on minimum values for a number of frequency bands.

Standards for microphones : Refs. A8, A15, A16, A20.

(B) Microphones for radio broadcasting

Extract from R.M.A. Standard TR-105-B (Ref. A16). The nominal impedance of all microphones intended for broadcasting service shall be $150 \text{ ohms} \pm 10\%$ when measured at a single frequency of $1000 \text{ c/s} \pm 10\%$.

SECTION 2 : PRE-AMPLIFIERS

(i) *Introduction* (ii) *Noise* (iii) *Hum* (iv) *Microphony* (v) *Valves for use in pre-amplifiers* (vi) *Microphone pre-amplifiers* (vii) *Pickup pre-amplifiers* (viii) *Gain-controlled pre-amplifiers* (ix) *Standard pre-amplifiers for broadcasting* (x) *Standard pre-amplifiers for sound equipment.*

(i) Introduction

A pre-amplifier is a voltage amplifier suitable for operation with a low level input and whose output is intended to be connected to another amplifier operating at a higher input level. Pre-amplifiers are commonly used with low-level microphones and pickups. When a pre-amplifier has to feed the a-f amplifier in a typical radio receiver, the output voltage is usually taken for design purposes as 1 volt r.m.s. across a high impedance. This allows for a volume control between the pre-amplifier and the main amplifier. In some cases it is necessary to incorporate the volume control in the pre-amplifier itself in order to avoid overloading with abnormally high input levels. In such cases this volume control is usually placed between the first and second stages of the pre-amplifier—with very high input levels it may be necessary to incorporate either a volume control or a fixed attenuator prior to the first grid.

A pre-amplifier follows the same general principles of design as any other voltage amplifier (see Chapter 12) except that particular attention has to be paid to hum, noise and microphony, all of which tend to be troublesome.

(ii) Noise

(A) The characteristics of random noise

Random noise includes both **thermal agitation noise** and **valve noise**. The energy of such noise is distributed uniformly over the frequency spectrum. The distribution of amplitude with time has been covered in Ref. B1—occasional peaks exceed four times the r.m.s. value.

Random noise voltages must be added in quadrature—that is to say as the root of the sum of the squares.

(B) Circuit noise

The **thermal agitation noise** of resistors has been covered in Chapter 4 Sect. 9(i) and in Chapter 23 Sect. 6.

When two or more resistances are in parallel, the total thermal agitation noise is that corresponding to the resultant resistance. For example, if a microphone having a d.c. resistance of 30 ohms is loaded by a resistance of 100 ohms , the noise voltage is that corresponding to 23 ohms .

When a resistance R is shunted by a capacitance C , the thermal agitation voltage is decreased, and at 30°C (80°F) is given by

$$e = 1.29 \times 10^{-10} \sqrt{RF_0 [\tan^{-1}(F_2/F_0) - \tan^{-1}(F_1/F_0)]} \quad (1)$$

where R = resistance in ohms

C = capacitance in farads

$F_0 = 1/(2\pi RC)$

F_1 = upper frequency limit

and F_2 = lower frequency limit.

(See Reference B19, also B8 giving chart and B45 giving theory).

In any network comprising L , C and R it is only the resistive elements which generate noise voltages.

References to circuit noise : A23, B8, B13, B28, B40, B44, B45, B51, D1, D2, D9, D12.

(C) Valve noise

Valve noise has been covered in a general way in Chapter 23 Sect. 6. In this chapter we are only concerned with its effects in pre-amplifiers.

It is convenient to express the **shot-effect noise** of a triode in terms of an **equivalent noise resistance** (R_{eq}) at room temperature, connected from grid to cathode in a noiseless valve. The value of R_{eq} for triodes is given approximately by

$$R_{eq} \approx 2.5/g_m \quad (2)$$

where R_{eq} = equivalent noise resistance in ohms

and g_m = mutual conductance in mhos at operating point.

Pentodes produce additional noise due to the random partition of the cathode current between screen and plate, known as **partition noise**. In general, the noise energy from a pentode will be from 3 to 5 times as great as that from a triode producing the same amplification.

There are other, but minor, sources of noise in valves. The **flicker effect** produces low frequency variations, while any gas in the valve causes **ionization noise**.

References to valve noise : B2, B7, B13, B17, B40, B44, B51, D1, D2, D9.

(D) Methods used in the design of amplifiers to ensure low noise level

Noise in low level amplifiers is due to three principal causes—noise in the plate load resistor of the first stage, valve noise, and noise in the grid (input) circuit. If the stage gain is of the order of 20 or more, the effect of noise in the following stage may usually be neglected. Obviously any unnecessary loss of signal voltage through any form of attenuator between the signal source and the grid should be avoided.

Noise in the plate load resistor (**current noise**) may be avoided by using some form of special low-noise resistor, such as a high-stability cracked carbon resistor described in Chapter 4 Sect. 9(i)m. The plate supply voltage may be from 100 to 180 volts—if, as is usual, a higher supply voltage is available, it is merely necessary to incorporate a RC filter to drop the voltage and by-pass any noise and hum components. Such components are frequently required for decoupling in any case. Composition resistors may be used as screen resistors with pentode valves, because the noise voltage is by-passed to earth. Current noise, however, occurs in the grid circuit due to the negative grid current of the valve. Cathode bias resistors (if used) should be wire wound.

Valve noise may be made low, if necessary, by the use of a r.e.c. **triode valve** in the first stage. The equivalent resistance for shot-effect valve noise is inversely proportional to the mutual conductance (see eqn. 2) so that a high mutual conductance at the operating point is desirable if reduction of shot-effect noise is the principal object. Triodes in common use have published values of mutual conductance from 1000 to 5000 μ mhos giving calculated values of noise resistance from 2500 to 500 ohms respectively under published conditions. The noise resistance of a resistance loaded valve is greater than that for the same valve under published conditions. For example type 6J5 operating with a plate current of 1 mA has $g_m = 560 \mu$ mhos and a calculated noise resistance of 4500 ohms, which is about 4 times the value under published conditions.

The calculated values of noise resistance for three typical r.e.c. **pentodes** are given below :

Operating conditions : $E_{bb} = 180$ volts ; $R_L = 0.1$ megohm.

Type	6J7 or 1620	6SJ7	6AU6
g_m (working)*	1000	1200	1700 μmhos
Noise resistance	8000	6000	2000 ohms

*Actually the slope of the dynamic characteristic.

There are two other possible sources of valve noise. **Leakage in the valve** from the grid to any other electrode, and particularly to any positive potential electrode, is a possible source of valve noise. **Reverse grid current** is another source of valve noise. It is advisable to use valves which have been tested and selected both for low leakage and reverse grid current, if a very low valve noise level is desired. Under all circumstances the d.c. resistance from grid to cathode should be as low as possible, and no composition resistors should be used in the grid circuit.

If the input source, whether microphone or pickup, is of low impedance and is coupled to the grid by means of a **step-up transformer**, it is usually not necessary to design for minimum valve noise. It is then only necessary to design the input circuit so that the impedance of the microphone reflected on to the grid is at least twice, and preferably four times, the valve noise resistance. With a low impedance microphone and transformer this may readily be accomplished by selecting a transformer secondary impedance of the order of 25 000 or 40 000 ohms. Valve noise will then have a negligibly small effect on the total noise, and pentodes or high- μ triodes may be used satisfactorily.

It is usual to employ as high a ratio in the microphone transformer as is possible, consistent with the frequency response required—very high step-up ratios can be used where the frequency response is not very important. Even in "high fidelity" applications (with a frequency range from 30 to 15 000 c/s) by using nickel-alloy cores, it is practicable to obtain a reflected secondary impedance up to 100 000 ohms, although somewhat lower values are more common.

For the measurement of noise in amplifiers see page 829.

(iii) Hum

The general features of power supply hum filtering and neutralization have been covered in Chapter 31 Sections 4 and 5. Hum due to conditions within the valves and hum due to circuit design and layout have been covered in Chapter 31 Sect. 4. Hum in voltage amplifiers has been covered in Chapter 12 Sect. 10(vi).

In pre-amplifiers the permissible hum voltage on the grid of the first valve depends on the maximum signal level at this point. If a high ratio transformer is used, with a reflected secondary resistance of 25 000 ohms or more, the signal level will be high and an extremely low hum level will not be necessary. On the other hand, if a low level pickup is coupled directly to the grid circuit without a step-up transformer, extreme care and ingenuity will be required to make the hum inaudible.

Some of the precautions which may be necessary in certain cases to reduce hum to a sufficiently low level are given below—

1. Complete electrostatic shielding of first pre-amplifier valve and associated components and wiring. The grid and plate circuits should be separately screened, so that there is negligible capacitive coupling between them—in the case of single-ended valves this requires care in wiring and either a shield or its equivalent between grid and plate.

2. Electromagnetic and electrostatic shielding of microphone transformer (if any). The more elaborately screened microphone transformers may include two or three concentric magnetic shields of permalloy or equivalent, with copper shields between (Ref. D2). For the lowest hum levels, hum-bucking is sometimes also provided in the transformer.

3. It is usual for the pre-amplifier to be built on a separate, preferably non-magnetic, chassis situated a considerable distance from the main amplifier chassis carrying the power transformer and filter chokes. If this is not possible, the power transformer should be designed to have low leakage flux and be mounted independently of the chassis, with the laminations vertical, and all a-f transformers should either be avoided or elaborately screened.

4. If insufficiently screened a-f transformers are used in the pre-amplifier, they should be oriented experimentally to the position giving least hum pickup.

5. With very low level pre-amplifiers it sometimes happens that less hum is obtained with a direct earth connection to a metal stake in damp soil than to a water pipe.

6. The leads from the power transformer to the valve heaters should be twisted, mounted as far as possible from all hum-sensitive components and wiring, and covered with earthed metal braid (for details see Ref. B42).

7. The loop formed by the valve, grid connection, input source and return lead to cathode should include as small an area as possible. Single-ended valves are preferable to double-ended types in this respect.

8. Metal valves are less sensitive to magnetic fields than glass types—they may sometimes be used with advantage if magnetic fields are unavoidable (Ref. B42).

9. If glass valves are used in a magnetic field they should be mounted so as to produce the minimum hum. This occurs when the flux vector is perpendicular to the valve axis and normal to the plane of the grid side rods. The ratio of maximum to minimum hum voltage is of the order of 30 to 40 db. Similar results occur with metal valves but the ratio is only from 10 to 20 db. Glass types may be fitted with a metal shield if desired (Ref. B42).

10. The waveform of the heater current should be closely sine wave, to eliminate capacitance coupling effects with harmonic frequencies.

11. A low leakage socket (e.g. isolantite or polystyrene) may be used to reduce leakage. With single-ended valves, leakage causing hum may occur from the heater pins to the grid or to the plate—the latter is normally the more serious because the grid pin is protected from hum leakage by adjacent pins. With double-ended valves the only possible socket leakage is from the heater pins to the plate. Valves with synthetic resin bases may have appreciable base leakage—for this reason, valves of the all-glass type (e.g. miniature) are preferable to those with separate bases.

One way of avoiding this trouble is to use a pentode valve with the plate, or plate and suppressor, earthed or returned to the cathode. The screen then is used as the anode, and the valve is thus effectively a triode with approximately the same characteristics as with the screen connected to the plate. The screen dissipation should be checked to see that it does not exceed the maximum, but it may be reduced, if necessary, by increasing the grid bias. See (v) below for application to type 6AU6.

12. A low resistance potentiometer may be connected across the heater supply, with the moving arm earthed—this may be adjusted for minimum hum. In some cases less hum may be obtained with the moving arm returned to a point of positive (or sometimes negative) voltage of the order of 5 to 50 volts (see Fig. 17.19A). Minimum hum may be obtained by optimum adjustment of both potentiometer and voltage.

13. A low resistance potentiometer may be used to inject heater voltage in anti-phase to the hum at some convenient point such as the suppressor of a pentode valve. In this case a single heater winding is satisfactory with one potentiometer as in (12) above, together with one anti-phase control for each low level stage (Ref. B26).

14. In very low level stages the heaters are sometimes supplied with direct current. However, with good design (including the use of a high step-up ratio transformer) it is possible to achieve, with a.c. heating, a hum level which is entirely inaudible with a frequency range up to 15 000 c/s. Thus a d.c. heater is not really necessary, but rather an alternative method of achieving a similar result. If the frequency band of the amplifier is 5000 c/s or less, the hum usually dominates the noise, even with the best design—in such a case d.c. heater supply may be desirable.

There are many possible methods of providing the d.c. supply for the heaters, including

- (a) Connecting the heaters of the low level valves in series at the low voltage end of the plate supply, with a shunt—if necessary—across either the heaters or the plate circuit. This method is most convenient when a heavy plate current is drawn by the amplifier, so that no power is wasted by a shunt across the plate circuit (e.g. Fig. 17.35A). It has the disadvantage that the heater current of the

low-level valves is dependent upon the total plate current of the amplifier, which is liable to vary. Ref. B52.

- (b) The heaters may be connected in series, and supplied from a separate full-wave rectifier and filter, using a thermionic or selenium rectifier—alternatively a selenium bridge circuit may be used. Refs. B25, B52.
- (c) The heaters may be connected in parallel, and supplied from a selenium or other suitable rectifier, using either a full-wave or bridge circuit. Refs. B25, B52.

All methods employing rectified and filtered heater supply have a ripple component which may be large enough to cause audible hum.

15. A r-f oscillator with a frequency of 30 or 40 Kc/s may be used as an alternative to d.c. heater supply (Ref. B25).

16. If a.c. is supplied to the heater of the first stage, the voltage of this stage alone may be decreased to about 70% to 85% of normal. This is only permissible with a limited number of valve types and even so may require selection of valves. A cathode current well under 1 mA is essential (Ref. B20).

17. The cathodes of all pre-amplifier valves should preferably be earthed directly to the chassis. However, in practice this is sometimes inconvenient and it may be found that a minimum capacitance of 100 μ F shunted across the bias resistor from cathode to chassis is satisfactory. High resistance grid-leak bias has not been found satisfactory for low level operation.

18. An electrostatic shield in the power transformer is essential, even where the transformer concerned supplies only heaters.

19. The pre-amplifier valves may be de-magnetized in a decreasing a.c. field. This is only useful when the valves have become magnetized by some means.

20. Magnetic shielding of power leads and all conductors carrying a.c. may be accomplished by the use of an iron pipe, flexible conductor or—most effective—a permalloy wrap similar to that used for continuous loading of submarine cable (Ref. B51).

Additional notes on hum with pentode valves

1. Hum due to lack of sufficient filtering in the plate supply may be neutralized by some suitable form of neutralizing circuit (e.g. Fig. 12.57).

2. The hum voltage caused by a magnetic field decreases more rapidly than the gain as the load resistance is decreased. A low load resistance is therefore desirable if there is a strong magnetic field (Ref. B42).

3. Hum caused by heater-to-plate leakage is also reduced more rapidly than the gain as the load resistance is decreased.

4. In pentode valves operating with low input levels there is a further source of hum in that the magnetic field of the heater varies the partition of current between plate and screen and so introduces hum. This hum is worse with remote cut-off valves than with those having sharp cut-off characteristics. This form of hum may be made zero by a suitable adjustment of grid or screen voltage (Ref. B46). See also Refs. B23 (Jan. 1949) and B50.

(iv) Microphony

There are very large variations between valves with regard to microphony, and special low-level types are recommended. Individual selection is, however, desirable in addition if the valves are required to operate at very low levels. In all cases some improvement may be made by a cushion socket and a thick rubber pad around the valve.

(v) Valves for use in pre-amplifiers

It is generally desirable to use valve types manufactured and tested for low level operation (e.g. types 12AY7, 1620 and 5879) but even with any one of these types there are large variations in hum, noise and microphony. If a particular pre-amplifier is required to meet stringent test conditions it is advisable to select valves to meet its requirements, and to use the balance of the valves in other less-stringent pre-amplifiers, or in later sockets of the same pre-amplifier.

A choice is possible in the American range between pentode types 1620 and 5879. The former is very much more expensive than the latter, and its use can generally be avoided by careful design.

If the designer decides to use ordinary radio valves for the first stage in a pre-amplifier, it is advisable to test and select the valves in accordance with the following procedure. A sufficient number of valves should be operated for about 48 hours under the same electrode voltages as in the pre-amplifier. They should then be tested for reverse grid current, and only those with reverse grid currents less than $0.1 \mu\text{A}$ should be used in very critical positions. If a sensitive microammeter is not available, a 1.0 megohm grid resistor may be cut in and out of circuit and the change in plate current measured—see Chapter 3 Sect. 3(iv)A. Low reverse grid current not only reduces the noise, but also permits a higher grid resistor to be used. The valves with low reverse grid currents should then be tested in the first socket of the pre-amplifier for noise, hum and microphony.

Some single-ended pentodes have one heater pin adjacent to the plate, and very high leakage resistance is required to avoid hum (except when this heater pin is earthed).

Type 6AU6 may be used as a triode with earthed plate and suppressor, using the screen as the anode, to reduce hum from leakage between heater and plate.

This device is only suitable for the first stage in the pre-amplifier owing to the limited screen dissipation rating (0.65 watt). The following operating conditions are suggested with a plate supply voltage of 180 volts (Ref. B48):

Load resistance	0.05	0.1	0.25 megohm
Cathode bias resistance	450	750	1600 ohms
Plate current	2.4	1.3	0.59 mA
Stage gain*	21	23	21

*With following grid resistor 0.5 megohm .

Characteristics of some special low-noise valve types

Type 5879 is a 9-pin miniature low-noise pentode with published $g_m = 1000 \mu\text{mhos}$ at a plate current of 1.8 mA . The grid resistor (pentode or triode operation) may be up to 2.2 megohms under maximum rated conditions, while the voltage gain with 180 volts supply is 87 with $R_L = 0.22 \text{ megohm}$ and following grid resistor 0.47 megohm . As a pentode, the noise referred to No. 1 grid with a bandwidth of $13\,000 \text{ c/s}$ is of the order of $7.2 \mu\text{V}$ with grid resistor* 0.1 megohm , with only 10% exceeding $16 \mu\text{V}$. It may also be used as a triode having $\mu = 21$, $g_m = 1530 \mu\text{mhos}$ and $I_b = 5.5 \text{ mA}$ at $E_b = 250$, $E_c = -8 \text{ volts}$. As a triode, the noise under the same conditions as for the pentode is of the order of $6 \mu\text{V}$ with only 10% exceeding $12 \mu\text{V}$.

Conditions: Triode operation

Hum

- | | |
|---|-------------------|
| 1. One side of heater earthed, cathode by-passed ($40 \mu\text{F}$), zero grid resistance—median value | 9 μV |
| 2. One side of heater earthed, cathode unby-passed, zero grid resistance—median value | 100 μV |
| 3. One side of heater earthed, cathode by-passed ($40 \mu\text{F}$), grid resistor $0.1 \text{ m}\Omega$ —median value | 13 μV |
| 4. Centre-tapped resistance across heater supply, returned to fixed bias point ($+20$ to $+50 \text{ volts}$) will reduce hum on most valves to less than | 20 μV |
| 5. Centre-tapped resistance across heater supply, returned to voltage to give minimum hum, cathode by-passed ($40 \mu\text{F}$), grid resistor 0.1 megohm —median value | 3.5 μV |
| —less than 10% exceeding | 8 μV |

When adjusted for minimum hum, this feeds a small hum bucking signal into the grid to oppose other minor sources of hum in the amplifier (Ref. B16).

Type 12AY7 is a low noise twin triode (Ref. B17) with $\mu = 40$, $g_m = 1750 \mu\text{mhos}$ and $I_b = 3 \text{ mA}$ at $E_b = 250$, $E_c = -4 \text{ volts}$. The following tests were made with a grid resistor 0.1 megohm and plate load resistor $20\,000 \text{ ohms}$. Shot-effect noise (40 to $13\,000 \text{ c/s}$) referred to the grid—median value $4.7 \mu\text{V}$, maximum limit $8 \mu\text{V}$.

*The noise due to the grid resistor alone is about $3.8 \mu\text{V}$.

Hum referred to the grid—median valve $3.9 \mu\text{V}$, maximum limit $12 \mu\text{V}$ with cathode resistor by-passed ($40 \mu\text{F}$).

When used in a typical circuit, placed with the electron stream in a magnetic field* of 1 gauss, the hum voltage on the grid is about $10 \mu\text{V}$.

With a grid resistor of 30 000 ohms, approximately $4 \mu\text{V}$ of hum per volt of heater potential per μF of capacitance between heater circuit and grid circuit will appear at the grid. If the heater voltage is 6.3, this will give approximately $25 \mu\text{V}$ per μF of coupling. For applications see Figs. 18.7A, 18.7B.

(vi) Microphone pre-amplifiers

The limit on practicable amplification is placed by the noise level caused by the thermal agitation noise in the grid circuit of the first stage together with some valve noise. The thermal agitation noise alone is at a level of about -129 dbm with a matched load (Ref. B28), or -132 dbm without loading, for a bandwidth of 15 000 c/s. If the effective microphone level is taken as -60 dbm , with an unloaded microphone the maximum possible signal-to-noise ratio will be 72 db, or 69 db with a loaded microphone. In practice with multiple mixers and other contributing factors†, a broadcast station overall noise can be considered satisfactory if within 10 db of the thermal noise.

If the valve noise is at least 3 db below the thermal agitation noise, it may be neglected as an approximation since the resultant is given by the root of the sum of the squares, and the additional noise will be less than 1 db. This may be put in the alternative form, that the equivalent valve noise resistance should be less than half the effective thermal agitation noise resistance.

In the case of crystal microphones the whole of the microphone noise arises from the grid resistor, but the signal-to-noise ratio is worst for values of about 0.1 megohm, and improves as the grid resistor is made smaller or larger than this value. For low noise the resistor should be at least 5 megohms, but better signal-to-noise ratio is obtained with 50 megohms and even better with no grid resistor at all (Ref. B19).

However, for ordinary applications, a resistance of 5 megohms is a good compromise, giving a noise voltage of about $4 \mu\text{V}$ or -108 dbv (0 db = 1 V). The noise resistance of a triode or pentode valve is negligibly small in comparison. This permits a signal-to-noise ratio of at least 60 db with all diaphragm types and the more sensitive sound cell types. With the less sensitive sound cell types a very high grid resistance may be necessary.

Values of grid resistor greater than 1 megohm may only be used satisfactorily in low-level pre-amplifiers where the valve is one specially manufactured or tested for this class of service, under a specification which ensures that the reverse grid current is very low. With a maximum reverse grid current of $0.2 \mu\text{A}$ and with μ not greater than 40, a grid resistor up to 5 megohms may be used provided that the plate load resistor is not less than 0.05 megohm from a plate supply of 150 volts, or proportionately higher than 0.05 megohm for voltages greater than 150 volts.

Hum from the plate supply may be made as small as desired by filtering, neutralizing, and possibly the use of a triode in the first stage. Hum from other sources, including a.c. heaters, may be made completely inaudible in wide frequency range amplifiers (up to 15 000 c/s) by careful design, using some of the methods in (iii) above.

Pre-amplifiers for use with crystal microphones

The pre-amplifiers described below (A, B and C) have an output level of about 1 volt r.m.s. and are suitable for use with a diaphragm type crystal microphone.

(A) Single stage pentode pre-amplifier (Fig. 18.5)

This is the simplest possible pre-amplifier, with a voltage gain of 118 (41 dbvg^\ddagger). The input voltage to provide the specified output level is -41 dbv (0 db = 1 V). It may therefore be used with an average diaphragm-type crystal microphone with a

*Flux densities from 1 to 3 gauss are found quite frequently as far as 7 inches from a typical radio power transformer.

†The effective noise bandwidth of a studio amplifier is usually wider than 15 Kc/s.

‡dbvg = decibels of voltage gain—See Chapter 19 Sect. 1(ii).

Fig. 18.5. Single stage pentode pre-amplifier for use with diaphragm-type crystal microphone.

FIG. 18.5

sound pressure of 10 dynes/cm², allowing a margin of 5 db for attenuation by the volume controls.

This is reasonably satisfactory for simple public address systems, home recording and amateur transmitters, although the margin of gain is small. It may also be used to feed the pickup terminals of any normal radio receiver.

Higher gain (45 dbvg*) may be obtained by the use of a selected type 6AU6 with $R_L = 0.22$ megohm, $R_2 = 0.43$ megohm and $R_k = 1700$ ohms. Under these conditions VC_2 may be adjusted to give about 10 db attenuation, VC_1 set to provide the desired output level under average conditions, and VC_2 then used as the control—this will prevent overloading of the valve.

The recommended maximum value of VC_1 is 1 megohm. Higher values may be used without damage to the valve, on account of the plate and screen resistors, but the operating point may be seriously shifted by reverse grid current, leading to distortion and loss of gain. Normally VC_1 would be set at maximum, and only reduced for very close working.

This arrangement has many limitations, and the noise level is high, but it is good enough for the simplest and cheapest applications mentioned above.

(B) Single stage pentode pre-amplifier followed by cathode follower (Fig. 18.6)

This circuit has the advantage over Fig. 18.5 that the pre-amplifier may be some distance from the main amplifier, the two being linked by a low impedance line, and that low impedance mixing may readily be applied. The gain and performance are very similar to those of Fig. 18.5 except that the second volume control would normally be incorporated in the low impedance line (reflected impedance about 400 ohms).

Fig. 18.6. Single stage pentode pre-amplifier followed by cathode follower, for use with diaphragm-type crystal microphone.

FIG. 18.6

This circuit has the disadvantage that the cathode follower stage may give rise to audible hum. It should therefore be restricted to use with a sensitive type of crystal microphone or to applications where a low hum level is not essential.

(C) A preferred arrangement is a good transformer in the cathode circuit of the 6J5, stepping down from 20 000 ohms primary impedance to any desired line impedance.

(D) Cathode follower as low-noise input stage

Fig. 18.6A shows the conventional cathode follower, and Fig. 18.6B shows the modified circuit for use as a low-noise input stage in connection with crystal microphones

*dbvg = decibels of voltage gain—see Chapter 19 Sect. 1(ii).

or pickups. It has been shown (Ref. B53) that the modified circuit will have the same stability as the conventional circuit if $R_4 = (1 + G)R_1$, where G is the voltage gain of the valve defined as the ratio of the voltage across R_3 to that across R_1 . If Z_I is high, as it will be if coupled to another valve grid, then G will be approximately constant and a real number. In a properly designed circuit R_4 can be made considerably higher than R_1 .

FIG. 18.6 A

FIG. 18.6 B

Fig. 18.6A. Conventional cathode follower circuit.

Fig. 18.6B. Modified cathode follower for use as low-noise input stage with crystal microphone or pickup. (Ref. B53).

The circuit of Fig. 18.6B shows an improvement in signal to noise ratio compared with that from the conventional circuit, the ratio being $\sqrt{(R_4/R_1)}$ for thermal noise produced by R_1 and R_4 . For noise generated in R_2 and R_3 , noise from the power supply, valve noise and hum and microphony voltages other than those due to capacitance coupling or resistance leakage into the grid circuit, the noise ratio is

$$\frac{R_4(Z_s + R_1)}{R_1(Z_s + R_4)}$$

When Z_s is large compared with R_1 , this represents an improvement by a factor R_4/R_1 . When $Z_s = R_1$ the ratio is $1/2$ or 6 db. When $Z_s = jR_1$ it is approximately $1/\sqrt{2}$ or 3 db. When Z_s is small the ratio is negligible.

Thus if Z_s is a crystal microphone or pickup, its impedance will rise as the frequency is reduced, and in the conventional circuit this causes an increase in noise level at low frequencies. The modified circuit shows a distinct improvement under these conditions.

Great care should be taken with the insulation of the grid circuit.

Pre-amplifiers for use with low-impedance microphones

In broadcast stations it is usual to have a gain of about 30 or 40 db in the pre-amplifier, and for this to be followed by mixing (with a loss of about 18 db for four or

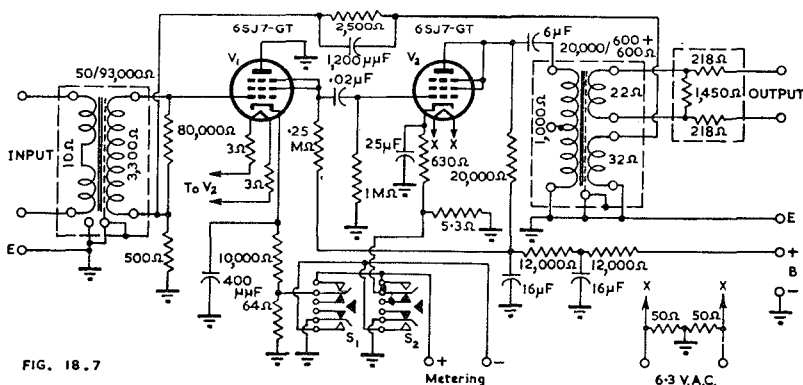

FIG. 18.7

(vii) Pickup pre-amplifiers

This subject has been covered in Chapter 17 Sect. 5.

(viii) Gain-controlled pre-amplifiers

This subject has been covered in Chapter 16 Sect. 5.

(ix) Standard pre-amplifiers for broadcasting

(Extracts from R.M.A. Standard TR-105-B, Ref. A16.)

Standard input signal is 2.45 millivolts r.m.s. in series with 150 ohms (for purposes of calculating insertion gain this corresponds to an input level of -50 dbm).

Standard output level for feeding telephone lines is $+18$ dbm ; for feeding radio transmitters is $+12$ dbm. The equivalent "complex wave" level is 10 db lower than these sine wave equivalent testing level values (i.e. $+8$ vu and $+2$ vu respectively) to provide a margin of 10 db for peaks.

Source and load impedances—600/150 ohms.

Frequency range and harmonic distortion—see Ref. A16.

Signal to noise ratio (noise below standard output)—minimum 65 db (50-15 000 c/s).

(x) Standard pre-amplifiers for sound equipment

(Extracts from R.M.A. Standard SE-101-A, Ref. A30.)

To operate from a **source impedance** of 150 ohms and into a load impedance of 600 and/or 150 ohms.

Noise level—for measurement see Chapter 19 Sect. 6.

Amplifier gain is defined as the ratio, expressed in db, of the power delivered to the load to the power which would be delivered to the same load if the amplifier were replaced by an ideal transformer which matches both the load and source impedances. Frequency response, distortion and power output—see Ref. A30.

SECTION 3 : ATTENUATORS AND MIXERS

(i) *Potentiometer type attenuators (volume controls)* (ii) *Single section attenuators—constant impedance* (iii) *Single section attenuators—constant impedance in one direction only* (iv) *Multiple section attenuators* (v) *Electronic attenuators* (vi) *Mixers and faders—general* (vii) *Non-constant impedance mixers and faders* (viii) *Constant impedance mixers and faders.*

An attenuator is a resistance network used for the purpose of reducing voltage, current or power in controlled (and usually known) amounts. An attenuating network is sometimes called a “pad.”

In this section only a brief outline is given of the most popular audio frequency applications of attenuators. Additional information is available from the references.

(i) Potentiometer type attenuators (volume controls)

The continuously variable volume control is widely used in radio receivers and a-f amplifiers (Fig. 18.8). The voltage ratio is proportional to the resistance ratio only when the load across the output terminals is very much greater than R . Characteristics commonly used include linear and several types of logarithmic characteristics of resistance versus angular rotation—see Chapter 38 Sect. 3(viii). The input loading is constant (R) only when the output load resistance is infinite. When the output terminals are connected to the grid of a valve which does not draw grid current, the input capacitance together with strays will bring about some change in frequency characteristics as the setting is varied. Direct current through R and through the moving contact should be avoided if a composition type resistor is used, to avoid noise.

Fig. 18.8. Continuously variable volume control (potentiometer).

Fig. 18.9. Step-type volume control.

The step-type volume control (Fig. 18.9) has some advantages over the continuously variable type—it is more reliable, has lower noise as the contact is being moved, and the degree of attenuation is definitely known. In all the best designs, wire-wound resistors are used. It is usually designed with logarithmic characteristics so that there is a constant step (in decibels) between successive tapping points, e.g. 2 db. The method of calculating R_0 , R_1 etc. is given below.

Let R = total resistance of attenuator (Fig. 18.9)

N = voltage ratio corresponding to the decibel step between successive tapping points (N less than unity)

and $M = (1 - N)$.

Then $R_0 = MR$; $R_1 = MNR$; $R_2 = MN^2R$ etc.

$R_n = MN^nR$; $R_r = R - R_0 - R_1 - R_2 \dots - R_n$.

As a practical case take $R = 100\,000$ ohms with 2 db steps.

Then $N = 0.794$ and $M = 1 - 0.794 = 0.206$. By simple calculation $R_0 = 20\,600$; $R_1 = 16\,340$; $R_2 = 12\,980$; $R_3 = 10\,300$; $R_4 = 8\,190$; $R_5 = 6\,500$; $R_6 = 5\,170$; $R_7 = 4\,100$; $R_8 = 3\,260$; $R_9 = 2\,590$ and $R_{10} = 10\,000$ ohms (all values correct to three significant figures).

Slide rule or logarithm accuracy is sufficient for most purposes; for greater accuracy see Ref. C9.

(ii) Single section attenuators—constant impedance

It is assumed that it is required to maintain constant input and output impedances (Z), that the attenuator is terminated at both ends with resistive impedances Z , and that all impedances are purely resistive. The T type section in Fig. 18.10 may be designed to provide any desired attenuation.

Let $K = E_i/E_o$, this being the voltage or current ratio corresponding to the desired attenuation in db (K being greater than unity).

$$\text{Then } R_1 = Z \left(\frac{K-1}{K+1} \right) \text{ and } R_2 = \frac{2ZK}{K^2-1} \quad (1)$$

It is possible to select any desired values of attenuation in a single T section by varying the values of the three resistors by means of a tapping switch. Values of R_1 and R_2 are given in Table 1 on page 796.

The Π type section in Fig. 18.11 is equivalent to the T type section in Fig. 18.10 provided that the values of the resistances are given by

$$R_3 = Z \left(\frac{K^2-1}{2K} \right) \text{ and } R_4 = Z \left(\frac{K+1}{K-1} \right) \quad (2)$$

Values of R_3 and R_4 are given in Table 1 on page 796. For formulae giving transformations from T to Π or from Π to T forms see Ref. C12.

Both T and Π sections may be arranged in a "balanced" form for use with an earthed centre-tap—in this case the series resistors R_1 and R_3 are divided into two halves, one on each side of the centre (for table of formulae see Ref. D6). They may also be designed to match unequal source and load impedances (see Refs. C7, C12, D6, D11).

For the derivation of the equations above, see Ref. C13.

If the output impedance is increased beyond the design value, the input impedance will be increased (although to a less extent) and the attenuation will be reduced—see Refs. C6, C12, D6.

There are many other forms of constant impedance attenuators, but none does more than the T or Π section—they may be preferred for practical reasons in certain applications. See Refs. C12, D6, D8, D11.

(iii) Single section attenuators—constant impedance in one direction only

The L section of Fig. 18.12 may be used when it is not necessary for the looking-backwards output impedance of the attenuator to be constant. In this case

$$R_5 = Z(K-1)/K \text{ and } R_6 = Z/(K-1) \quad (3)$$

For further information see Refs. C12, D2.

The values of R_5 and R_6 have been tabulated for steps from 1 to 10 db (Table 1 on page 796).

FIG. 18.12

Fig. 18.10. Constant impedance T section attenuator.

Fig. 18.11. Constant impedance Π section attenuator.

Fig. 18.12. The L type single section attenuator.

The values of resistances given in Table 1 are for $Z = 100$ ohms. For any other value of Z , the tabulated values of resistances should be multiplied by $(Z/100)$. See Figs. 18.10, 18.11 and 18.12.

TABLE 1 (SINGLE T, Π AND L SECTIONS)

db	K	T section		Π section		L section	
		R_1	R_2	R_3	R_4	R_5	R_6
1	1.122	5.76	866	11.6	1740	10.9	819

10	3.162	51.9	70.3	142	193	68.4	46.2

The following references will be found helpful in supplying further general information on attenuators :

Periodicals C6, C12 (the most comprehensive of all), C13, C17 (the basic treatment).

Books D2, D6, D8, D11 (brief treatments are given in several other books).

(iv) Multiple section attenuators

Any convenient number of Π sections may be connected in tandem, and the effective resultant is the "ladder" attenuator of Fig. 18.13 in which the two parallel resistors at the end of each section and the commencement of the next are drawn as a single equivalent resistor ($R_4/2$). The values of R_3 and R_4 are calculated as for a single Π section (eqn. 2 and Table 1) to provide the desired attenuation per stage. The value of R_8 is given by $R_4 Z/(R_4 + Z)$. The minimum attenuation is 3.5 db on tapping point P_1 . The input impedance varies considerably as the tapping point is changed but may be made constant, if desired, by inserting resistors at the points marked X. The output impedance also varies, although less so than the input impedance. This device may also be used when the impedance of the source differs from Z .

FIG. 18.13

Fig. 18.13. Ladder attenuator (Π section).

FIG. 18.14

Fig. 18.14. Modified form of ladder attenuator.

A modified form of ladder attenuator is shown in Fig. 18.14 which has a minimum attenuation of 6 db but whose input impedance is nearly constant except for high values of attenuation and whose output impedance is nearly constant except for low values of attenuation. This can only be used when the impedance of the source is equal to Z . The values of R_3 , R_4 and R_8 are the same as in Fig. 18.13. This is the commonest type for broadcast station "mixer" control equipment.

A form of ladder attenuator suitable for connecting a low impedance line to a high impedance grid circuit is shown in Fig. 18.15. This is built up from three L sections and the input impedance is equal to Z under all conditions but the output impedance varies (this being unimportant). The values of R_5 and R_6 are given by eqn. (3) and Table 1, while R_7 is given by $ZR_6/(Z + R_6)$. As an example take $Z = 600$ ohms and 2 db steps. Then the voltage ratio corresponding to 2 db is $K = 1.259$. From eqn. (3)

$$R_5 = 600 \times 0.259/1.259 = 123.6 \text{ ohms}$$

Fig. 18.15. Ladder attenuator for connection to high impedance grid circuit (L section).

$R_0 = 600/0.259 = 2316$ ohms
while $R_7 = 600 \times 2316/2916 = 477$ ohms.

References to multiple section attenuators : C11, C12 (Part 6) ; C14, D2, D6, D11. References to non-uniform sections, C11, C14.

A multiple T section attenuator is shown in Fig. 18.16. This has the advantage of no loss in the zero attenuation position, and is suitable for use in positions where no power loss is permissible, such as an attenuator on a tweeter loudspeaker. The values of resistors for 1 db steps for $Z = 100$ ohms are tabulated below—for any other impedance multiply the resistances by $(Z/100)$.

Loss (db)	Series arm (each)	Shunt arm	Loss (db)	Series arm (each)	Shunt arm
1	5.8 ohms	867 ohms	6	33.2 ohms	134 ohms

(v) Electronic attenuators

For some purposes an electronic attenuator may be advantageous, and one practicable circuit is a cathode follower in which the screen voltage may be varied, while in addition the desired value of cathode resistor may be selected by means of a tapping switch (Fig. 18.17). Any sharp cut-off pentode valve is suitable, but one with high mutual conductance will limit the maximum attenuation. A valve with $g_m = 2000$ μ mhos has an attenuation range from 4 to 74 db with values of cathode resistors from 1000 ohms to 0.1 ohm ; this may be extended by about 10 or 20 db by screen voltage

Fig. 18.16. Multiple T section attenuator.

Fig. 18.17. Electronic attenuator using cathode follower (Ref. C15).

adjustment provided that the input level is not too high. Fixed grid bias must be used. A universal design curve is given in Fig. 18.18 (Ref. C15).

A circuit using type 6BE6 as a fader-mixer is shown in Fig. 18.18A. This has a voltage gain of 62 from grid 1 input, and 25 from grid 3 input. The distortion for

FIG. 18.18

Fig. 18.18. Universal design curve for electronic attenuator (Ref. C15).

an output of 5 volts is 0.19% with input to grid 1, and 1.4% with input to grid 3. A plate load resistor of 50 000 ohms gives lower gain and distortion. For electronic gain control purposes, it is advisable to apply the signal to grid 3 and the control voltage to grid 1 (Ref. C20).

FIG. 18.18A

Fig. 18.18A. Fader-mixer circuit using type 6BE6 (Ref. C20).

(vi) Mixers and faders—general

When more than one input source is employed, some form of control is necessary to enable the operator to change from one to the other, or to mix the outputs of two or more sources. A properly designed mixer and fader system enables these objects to be achieved without perceptible jumps.

Mixers (as the complete system will here be called) may be divided into high impedance and low impedance; constant impedance and non-constant. In addition there are those that have sources at approximately the same level and those with sources having a considerable difference in level. To achieve correct functioning of mixers, it is necessary to provide for the control of the level of individual input sources. Any frequency equalization of input sources is applied prior to the mixer.

(vii) Non-constant impedance mixers and faders

These are commonly used in public address systems, amateur transmitters and other applications which do not require precise adjustment to a predetermined level. The controls are of the continuously variable potentiometer type, and the mixing is usually carried out between a pre-amplifier and a subsequent amplifying stage—under these conditions there is no necessity for maintaining either constant input or output im-

pedance. In some cases the mixing is carried out between the input sources and the grid of the first amplifier stage, and here the load impedance presented to each source must be maintained constant.

The simplest type of fader*, which does not provide mixing, is shown in Fig. 18.19. It is only suitable for high level pickups, or the secondaries of step-up transformers, since the noise from the moving contact is appreciable. The control is a centre-tapped potentiometer with a total resistance $2R$. The value of R should be that recommended for each pickup.

Fig. 18.20 shows a series network mixer which may be used as a fader, but it has serious drawbacks. Both sides of input source A are above earth, and any hum picked up in this channel is fed without appreciable attenuation to the following grid. Moreover stray capacitances to earth of channel A tend to by-pass the high frequency signal voltages of channel B. This arrangement is not recommended.

A modified series network mixer is shown in Fig. 18.21 in which one side of each channel may be earthed, but a transformer must be used to couple the outputs to the grid. This may be used for fading and mixing.

FIG. 18.19

FIG. 18.20

FIG. 18.21

Fig. 18.19. Simple type of fader for two pickups.

Fig. 18.20. Series network mixer.

Fig. 18.21. Modified series network mixer.

The parallel network mixer is shown in Fig. 18.22 where three input sources are provided for, although any number may be used. The value of R_4 may be made equal to or greater than R_1 , and similarly with the other channels. If the mixer is connected between two amplifying stages, all resistances may be equal (say 0.5 megohm) and the maximum insertion loss will be 6 db for 2 channels, 9.5 db for 3 channels or 12 db for 4 channels. The insertion loss varies when the controls are moved—the maximum variation in insertion loss caused by any one potentiometer is 2.5 db for two channels but less for more channels. This interaction is less if the source impedance is considerably smaller than the resistances in the mixer, so that triode valves are preferable to pentodes in the preceding stage.

FIG. 18.22

Fig. 18.22. Parallel network mixer.

The circuit of Fig. 18.22 may also be used when the sources are microphones or pickups, but R_1 , R_2 and R_3 should be the correct load resistance in each case. The isolating resistors R_4 , R_5 and R_6 may be made equal to the highest of the load resistances. This arrangement is only practicable with fairly high source levels, on account of the insertion loss and its effect on the signal-to-noise ratio.

One application of the parallel network mixer is given in Fig. 18.23—this general set-up may be modified to suit any practical case when there is a considerable difference in level between the two sources.

Probably the most popular of all mixing circuits in this class is the method using a common plate load for two or more valves. When two valves are used with a common

*The word "fader" is here used in the sense of fading out one input source and fading in another. The fading of a single source is here called attenuation. Mixing is the combination of two (or more) sources so that both are amplified simultaneously; a mixer may however be used also for fading.

FIG. 18.23

Fig. 18.23. Complete pre-amplifier incorporating parallel network mixer, for use with high level crystal microphone and crystal pickup. $R_1 = 1$ to $5M\Omega$; $R_2 = 0.5M\Omega$ or higher. Gain in V_1 is 30 dbvg.

plate load resistor, the plate resistance of each valve acts as a shunt load on the other, thereby reducing the gain and the output voltage for a limited distortion. With triodes, the gain is equal to the normal gain for a single valve multiplied by $(r_p + R_L)/(r_p + 2R_L)$. If R_L is considerably greater than r_p , the gain is slightly greater than half that for a normal valve. With pentodes, the loss of gain due to shunting is slight, and may be neglected in most calculations. The effect of the shunting on the maximum output voltage is much more severe than on the gain. The output voltage for limited distortion is approximately equal to the normal output voltage multiplied by $r_p/(r_p + R_L)$. If $R_L = 5r_p$ as for a typical triode, then the output voltage is reduced to one fifth of its normal value. For this reason it is suggested that $R_L = 2r_p$ would be more suitable, giving a reduction to one third of the normal value. Here again, the effect on pentodes is small.

One simple but very effective mixer incorporating common plate load mixing is Fig. 18.24. V_1 may be any twin triode, R_L may be determined as outlined above, while the plate supply voltage may be about 250 volts, or higher if a high output voltage is required with low distortion. If desired, a second twin triode with a further two input channels can be added. Alternatively, two r-f pentodes may be used in place of V_1 to provide increased gain. Various combinations may be devised incorporating one or more common plate load mixers with other types of mixers or faders to meet almost any possible requirements. Fig. 18.25 is one example— V_1 and V_2 may be any suitable twin triodes, R_1 provides fading for the two microphones and R_2 is a combined microphone volume control, R_4 and R_5 provide fading and mixing for the pickups while R_3 is a master volume control. V_2 has a common plate load resistor.

FIG. 18.24

Fig. 18.24. Simple mixer using twin triode with common plate load resistor.

One of the problems with mixers of the common plate load type is the control of volume without introducing noise or circuit complications. This problem may be overcome by the use of 6L7 type valves in which the amplification is controlled by varying the voltage on the third grid (Fig. 18.26). This mixer is intended for use

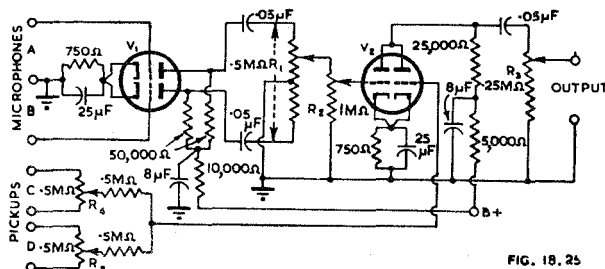

FIG. 18.25

Fig. 18.25. Mixer for two microphones and two pickups. Values of resistors are for $V_1 = V_2 = 6SN7\text{-GT}$.

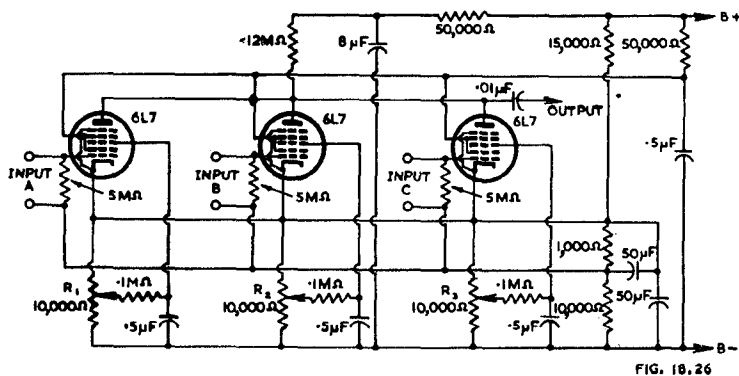

Fig. 18.26. Three channel mixer with electronic volume control (Ref. C4).

with three high-level crystal microphones; the volume controls operate on d.c. and may therefore be placed some distance from the mixer (Ref. C4).

References to non-constant impedance mixers: C3, C4, D10.

(viii) Constant impedance mixers and faders

Constant impedance* attenuators may be used to provide both attenuation and mixing, and are widely used in studio equipment. In such equipment they usually work out of and into 600 (sometimes 500) or 150 (sometimes 200) ohm circuits.

The constant impedance attenuators may be of the T, bridged T, Π , ladder, bridge, or any other form, together with their balanced equivalents. They may be arranged in parallel, series, series-parallel or bridge circuits.

Fig. 18.27. Constant impedance mixer using three T type attenuators in parallel.

(A) Parallel type mixers

Fig. 18.27 shows a three channel mixer using T type attenuators in parallel—the same principle may be applied for any number of channels. Since the attenuators are of the constant impedance type with input and output impedances R , and the mixer output is loaded by the same impedance R , in this case $R_1 = R_2 = \frac{1}{2}R$ and the mixing loss is 9.5 db. In the general case

$R_1 = R_2 = R(n-1)/(n+1)$ and Mixing loss = $20 \log_{10} n$
where n is the number of channels. Values are tabulated below:

$n =$	2	3	4	5	6
$R_1 = R_2 =$	$(1/3)R$	$\frac{1}{2}R$	$(3/5)R$	$(2/3)R$	$(5/7)R$
Mixing loss	6.02	9.54	12.04	14.0	15.56 db.

An alternative form omits R_2 and thereby obtains lower mixing losses, but the output impedance of the mixer and hence the input impedance of the master attenuator will be R_L instead of R , the values being given below:

*Constant impedance indicates that both the input impedance and the looking-backwards output resistance are maintained constant under all conditions.

$R_1 = R(n - 1)/n$	$R_2 = 0$				
$R_L = R(2n - 1)/n^2$	Mixing loss = $10 \log_{10} (2n - 1)$				
$n = 2$	3	4	5	6	
$R_1 = 0.50R$	$0.67R$	$0.75R$	$0.80R$	$0.83R$	
$R_L = 0.75R$	$0.56R$	$0.44R$	$0.36R$	$0.31R$	
Mixing loss = 4.77	6.99	8.45	9.54	10.41 db.	

If it is desired to maintain all input and output impedances constant and equal to R , it will be necessary to insert a matching transformer or to add a matching pad, the latter introducing loss.

(B) Series type mixers

Fig. 18.28 shows a three channel mixer using T type attenuators in series. Only one of the channels can be earthed, so that there tends to be some cross-talk although this may be kept low by good design. The output impedance at terminals D is given by R_D where $R_D = Rn^2/(2n-1)$, and the mixing loss up to terminals D is $10 \log_{10}$

Fig. 18.28. Constant impedance mixer using three T type attenuators in series.

$(2n-1)$, where n is the number of channels. Values are tabulated below :

n	2	3	4	5	6
R_D	2.00	1.50	1.33	1.25	1.20
Mixing loss	4.77	6.99	8.45	9.54	10.41 db.

If this mixer is followed by a transformer there is no further loss, but if it is followed by a taper pad as in Fig. 18.28 there must be added the loss in the taper pad, the value of which is given by

$N = 20 \log_{10} (R_Z + \sqrt{R_Z^2 - 1})$ decibels
 where $R_Z^2 = \text{impedance ratio (greater than unity)}$
 $= n^2/(2n-1)$.

n	2	3	4	5	6
impedance ratio	1.33	1.80	2.29	2.78	3.27
loss in pad (N)	4.77	6.99	8.45	9.54	10.41 db.

(C) Series-parallel type mixers

Fig. 18.29 shows a four channel mixer using T type attenuators in series-parallel. The input and output are both balanced. The values of R_4 and R_0 are given by $R_4 = R(n-3)/n$ and $R_0 = 4R(2n-3)/n^2$ where n is the total number of input channels.

If n	4	6	8
then R_4	$0.25R$	$0.5R$	$0.625R$
R_0	$1.25R$	R	$0.75R$
and loss in mixer	7.0	9.5	11.1 db.

With six channels, the output resistance is equal to R and the taper pad will not be required. In other cases its loss should be added to that in the mixer.

(D) Bridge type mixers

Fig. 18.30 shows a bridge type mixer with four input channels. This can only be earthed at one point, but is otherwise satisfactory for four input sources. The output resistance is equal to R , so that no taper pad or matching transformer is required—the mixing loss is 6 db, which is less than that of any other 4 channel resistance mixer.

(E) Coil mixing (Ref. C18)

Coil mixing refers to the use of a special transformer (Fig. 18.31). The loss is the theoretical minimum and is given by $10 \log_{10} n$ where n is the number of input sources—it is 6 db when $n = 4$. The value of R_s is given by

$$R_s = \frac{1}{2}R(n-1)$$

and is equal to R when $n = 4$. The secondary transformer impedance is equal to nR .

Fig. 18.29. Constant impedance mixer using four T type attenuators in series-parallel.

Coil mixing appears to be very little used.

(F) Choice of mixer circuit

The parallel circuit has the very important advantage that one terminal of all (unbalanced) attenuators can be earthed. Other circuits in which one or more attenuators are above earth nearly always suffer from cross-talk and variation of frequency response at high attenuations. There are thus two features on which the choice of a mixer circuit must be based—the earthing of all attenuators, and minimum mixing loss. Many engineers insist on the earthing even at the expense of increased mixing loss in some cases.

Fig. 18.30. Constant impedance mixer using four T type attenuators in bridge connection.

The following comments are based solely on minimum mixing loss, and are therefore to be applied with discretion—

1. When the impedance of the input circuit is required to be higher than that of the output circuit, a parallel mixer should be used.
2. When the impedance of the output circuit is required to be higher than that of the input circuit, a series or coil type mixer should be used.
3. When the input and output circuits are required to be nearly the same impedance, a series-parallel or bridge type mixer should be used.

References to constant impedance mixers : C1, C2, C3, C12 (parts 7 and 8), C16, C18, D10, D11.

(G) Precautions with studio type mixing systems

Under any possible operating conditions, the level at any stage should be kept at least 6 db and preferably 10 db above the critical pre-amplifier level of -60 vu.

With mixer controls turned right off, and a normal level applied to each input in turn, the ratio of “leakage” at 10 000 c/s to normal programme level should be better than 70 db.

Cross-talk between two different circuits may be reduced by using twisted leads for all speech circuits with an electrostatic screen around each pair.

Fig. 18.31. Constant impedance mixer using coil mixing with four input sources.

Where there are long circuits between pre-amplifier outputs and mixer outputs, it is usually considered wise to use balanced transformer inputs to avoid the possibility of cross-talk or noise affecting the programme.

SECTION 1 : BELS AND DECIBELS

(i) Power relationships expressed in bels and decibels (ii) Voltage and current relationships expressed in decibels (iii) Absolute power and voltage expressed in decibels (iv) Microphone output expressed in decibels (v) Pickup output expressed in decibels (vi) Amplifier gain expressed in decibels (vii) Combined microphone and amplifier gain expressed in decibels (viii) Loudspeaker output expressed in decibels (ix) Sound system rating (x) Tables and charts of decibel relationships (xi) Nomogram for adding decibel-expressed quantities (xii) Decibels, slide rules and mental arithmetic.

(i) Power relationships expressed in bels and decibels

If a sound is suddenly increased in magnitude, the listener receives an impression of increased loudness which is roughly proportional to the logarithm of the ratio of the two acoustical powers. In mathematical form

$$\text{loudness} \propto \log (P_2/P_1) \quad (1)$$

This is quite general, and holds for a decrease in power as well as for an increase in power. Now the ultimate effect of any change of electrical power in a transmitter, receiver or amplifier is to produce a change of acoustical power from the loudspeaker, so that it is convenient to adopt a logarithmic basis for indicating a change of electrical power.

The common logarithm of the ratio of two powers gives their relationship in **bels**—

$$N_b = \log_{10}(P_2/P_1) \quad (2)$$

where P_1 is the reference power

and P_2 is the power which is referred back to P_1 .

The more commonly used unit is the **decibel**, which is one tenth of a bel. Thus, the difference in level between P_1 watts and P_2 watts is given by

$$N_{db} = 10 \log_{10} (P_2/P_1) \text{ decibels} \quad (3)$$

If P_2 is less than P_1 the value of N_{db} becomes negative. A negative value of N_{db} thus indicates that the power in which we are interested is less than the reference power.

Note that these relationships (1, 2 and 3) are independent of any other conditions such as impedance.

Applications and examples

Suppose for example that a power valve driving a loudspeaker is delivering 1 watt which is then increased to 2 watts. To say that the power has “increased by one

19.1 (i) POWER RELATIONSHIPS EXPRESSED IN BELS AND DECIBELS 807

watt " is misleading unless it is also stated that the original level was 1 watt. A far more satisfactory way is to state that a rise of 3 db has occurred. This may be calculated quite simply since the gain in decibels is

$$10 \log_{10} (2/1) = 10 \log_{10} 2 = 10 \times 0.301 = 3.01 \text{ db}$$

or approximately 3 db.

In a similar manner a decrease from 2 watts to 1 watt is a change of approximately - 3 db.

It has been found that a change in level of 1 db is barely perceptible to the ear, while an increase of 2 db is only a slight apparent increment. For this reason variable attenuators are frequently calibrated in steps of 1 db or slightly less. In a similar manner an increase from 3 watts to 4.75 watts is only a slight audible increment, being an increase of 2 db.

In order to simplify the understanding of **barely perceptible changes** the following table has been prepared, and it will be seen that a move from one column to the nearest on left or right is equivalent to a change of 2 db. In this table 0 db is taken as 3 watts.

db :	-10	-8	-6	-4	-2	0	+2	+4	+6	+8	+10	+12
watts :	0.30	0.47	0.75	1.2	1.9	3.0	4.75	7.5	12	19	30	47.5

In addition to the application of decibels to indicate a change in level at one point, they may also be used to indicate a difference in level between two points such as the input and output terminals of a device such as an amplifier or attenuator. For example, consider an amplifier having an input power of 0.006 watt and an output power of 6 watts. The power gain is 6/0.006 or 1000 times, and reference to the tables shows that this is equivalent to 30 db. The amplifier may therefore be described as having a gain of 30 db, this being irrespective of the input or output impedance.

References 1, 8, 9, 16 (Chap. 32).

(ii) Voltage and current relationships expressed in decibels

Since $P_1 = E_1 I_1 = E_1^2 / R_1 = I_1^2 R_1$
and $P_2 = E_2 I_2 = E_2^2 / R_2 = I_2^2 R_2$
where R_1 = resistance dissipating power P_1
and R_2 = resistance dissipating power P_2 ,

it is obvious that the decibel relationship between E_1 and E_2 or between I_1 and I_2 must involve the resistance.

If $R_1 = R_2 = R$, then $P_2/P_1 = E_2^2/E_1^2 = I_2^2/I_1^2$ and the difference in level is given by

$$N_{db} = 10 \log_{10}(E_2^2/E_1^2) = 20 \log_{10}(E_2/E_1) \text{ decibels,} \quad (4)$$

$$\text{or } N_{db} = 10 \log_{10}(I_2^2/I_1^2) = 20 \log_{10}(I_2/I_1) \text{ decibels,} \quad (5)$$

provided that R remains constant.

If R does not remain constant the difference of level is

$$N_{db} = 20 \log_{10}(E_2/E_1) + 10 \log_{10}(R_1/R_2) \quad (6)$$

$$\text{or } N_{db} = 20 \log_{10}(I_2/I_1) + 10 \log_{10}(R_2/R_1) \quad (7)$$

In the general case with an impedance $Z = R + jX$ which is the same for both P_1 and P_2 , equations (4) and (5) also hold.

When the two impedances are not identical, the difference in level in decibels is

$$N_{db} = 20 \log_{10}(E_2/E_1) + 10 \log_{10}(Z_1/Z_2) + 10 \log_{10}(k_2/k_1) \quad (8)$$

$$= 20 \log_{10}(I_2/I_1) + 10 \log_{10}(Z_2/Z_1) + 10 \log_{10}(k_2/k_1) \quad (9)$$

where k_1 = power factor of $Z_1 = R_1/Z_1 = \cos \phi_1$

and k_2 = power factor of $Z_2 = R_2/Z_2 = \cos \phi_2$.

References 7, 8, 9, 16 (Chap. 32).

(iii) Absolute power and voltage expressed in decibels

(A) Power

Although the decibel is a unit based on the ratio between two powers, it may also be used as an indication of absolute power provided that the reference level (or "zero level") is known. There have been many so-called "standard" reference levels, including 1, 6, 10, 12.5 and 50 milliwatts, but the 1 milliwatt reference level is very

widely used at the present time. As an example, a power of 1 watt may be described as

- 30 db (reference level 1 mW)
- or 30 db (0 db = 1 mW).
- or 30 dbm*.

The abbreviation db 6m is sometimes used to indicate a level in decibels with a 6 milliwatt reference level.

To convert from a reference level of 1 mW to 6 mW, add -7.78 db.

To convert from a reference level of 1 mW to 10 mW, add -10.00 db.

To convert from a reference level of 1 mW to 12.5 mW, add -10.97 db.

To convert from a reference level of 6 mW to 1 mW, add $+7.78$ db.

To convert from a reference level of 10 mW to 1 mW, add $+10.00$ db.

To convert from a reference level of 12.5 mW to 1 mW, add $+10.97$ db.

With any reference level, a power with a positive sign in front of the decibel value indicates that this is greater than the reference power, and is spoken of as so many "decibels up." A negative sign indicates less power than the reference power, and is spoken of as so many "decibels down." 0 db indicates that the power is equal to the reference power.

A statement of power expressed in decibels is meaningless unless the reference level is quoted.

References 1, 5, 8, 9, 10.

(B) Voltage

A reference level of 1 volt has been standardized in connection with high impedance microphones. The abbreviation dbv has been standardized (Ref. 38) to indicate decibels referred to 1 volt.

(iv) Microphone output expressed in decibels

The output of a microphone may be expressed either in terms of voltage or power.

(A) In terms of output voltage

The response of a microphone at a given frequency may be stated in decibels with respect to a reference level 0 db = 1 volt (open-circuit) with a sound pressure of 1 dyne per square centimetre (Ref. 36). The abbreviation dbv is used to indicate a voltage expressed in decibels, with reference level 1 volt (Ref. 38).

For example, the output of a microphone may be stated as -74 dbv with a sound pressure of 1 dyne per square centimetre. This is the open-circuit voltage developed without any loading such as would be provided by the input resistance of the amplifier. Table 1 [Section 1(x)] may be used to determine the corresponding open-circuit voltage, which for the example above is approximately 0.0002 volt r.m.s. (Column 1). If the input resistance of the amplifier is equal to the internal impedance of the microphone (here assumed to be resistive as the worst possible case) the voltage across the input terminals will be only half the generated voltage, giving a loss of 6 db or an effective input voltage of -80 dbv.

FIG. 19.1

Fig. 19.1. Amplifier with source of input voltage E having internal resistance R .

In the general case, the input voltage to the amplifier will be (Fig. 19.1):

$$E_1 = ER_1/(R + R_1)$$

where E = open-circuit voltage developed by the microphone

R_1 = input resistance of amplifier

and R = internal resistance of microphone (here assumed purely resistive).

(B) In terms of output power

Alternatively the output of a microphone may be given in terms of output power for a stated sound pressure.

*dbm indicates a power expressed in decibels with a reference level 1 mW.

For example, the output of a microphone may be stated as -65 dbm into a load of 150 ohms, with an input sound pressure of 1 dyne per square centimetre. From Table 3—Sect. 1(x)—the power is 3.2×10^{-7} milliwatt. If desired this may be converted into voltage across 150 ohms.

(C) In terms of effective output level

When a microphone is connected to an unloaded input transformer, its output cannot be expressed in terms of power delivered, as no appreciable power is delivered by the microphone. For this reason, microphone output ratings are sometimes given in terms of effective output level, expressed in dbm. The effective output level is so calculated that when the amplifier power gain in db is added to the microphone effective output level in dbm the correct output level from the amplifier (in dbm) will be obtained. The effective output level rating is based upon the assumption that the microphone works into a load impedance equal to its own rated impedance. The voltage corresponding to this effective output level is actually 6 decibels below that which is actually obtained when the microphone is worked into a high impedance pre-amplifier input. This 6 db difference is a function of the pre-amplifier input termination and not of the microphone itself. The "power gain" ratings of pre-amplifiers take into account this 6 db increase in gain where it occurs, so that it is not necessary to apply any coupling factor.

If the effective output level of a microphone is not known, it may be derived from available data:

- (1) The output power may be converted to dbm, or
- (2) Where the microphone open-circuit voltage output is known in dbv (0 db = 1 volt), this may be converted to volts (E_G) and the effective output level in milliwatts is given by

$$1000 E_G^2 / (4R_M) \text{ milliwatts}$$

where R_M is the nominal microphone impedance. The power in milliwatts may then be converted into dbm.

(D) R.M.A. microphone system rating (RMA Standard SE-105)

This is particularly useful when it is desired to calculate the combined "system gain" of a microphone, amplifier and loudspeaker. The R.M.A. microphone system rating is defined as the ratio in db relative to 0.001 watt and 0.0002 dyne per square centimetre of the electric power available from the microphone to the square of the undisturbed sound field pressure in a plane progressive wave at the microphone position.

The R.M.A. microphone system rating (Ref. 35) is given by

$$G_M = \left(10 \log_{10} \frac{E^2 / 4R_{MR}}{p^2} \right) - 44 \text{ db} \quad (10)$$

which reduces for practical applications to

$$G_M = (20 \log_{10} (E/p) - 10 \log_{10} R_{MR}) - 50 \text{ db} \quad (11)$$

where G_M = microphone system rating

E = open-circuit voltage generated by the microphone

p = sound pressure in dynes per sq. cm.

R_{MR} = microphone rating impedance—see Chapter 18 Sect. 1(xiv). This may differ from the actual microphone impedance.

The R.M.A. Microphone System Rating is essentially the same as expressing the microphone output in terms of Effective Output Level, except that the acoustical pressure at the microphone is 0.0002 dyne/cm² (the limit of audibility). To convert from R.M.A. Microphone System Rating to the Effective Output Level Rating, it is only necessary to allow for the change of acoustical pressure. For example, if a microphone has an R.M.A. Microphone System Rating of -154 db, the Effective Output-Level Rating for an acoustical pressure of 10 dynes/cm² will be -60 dbm, and for 1 dyne/cm² will be -80 dbm.

* An amplifier is normally tested as described in Chapter 37 Sect. 3(ii)C with an input voltage from a generator applied through a constant impedance attenuator, which combination effectively applies a constant voltage through a resistance equal to the rated source impedance of the amplifier as in Fig. 19.3.

Microphone system ratings are most commonly used in a complete sound system—sound, microphone, amplifier, loudspeaker, sound—see (ix) below.

See Chapter 18 Sect. 1 for the relationships between various forms of microphone ratings.

(v) Pickup output expressed in decibels

Although many pickups are rated on the basis of output voltage, some are rated on a power basis with respect to a specified reference level. The procedure is the same as for microphones.

Reference 9.

(vi) Amplifier gain expressed in decibels

Much confusion has been caused by the incorrect or careless use of decibels to indicate the gain of a voltage amplifier. Decibels may be used in various ways to indicate the gain of an amplifier—

(A) In terms of voltage gain (Fig. 19.4)

This is really an arbitrary use of decibels, but it is so convenient that it cannot be suppressed.

$$\text{Gain in decibels of voltage gain} = 20 \log E_2/E_1 \quad (12)$$

where E_2 = voltage across output terminals of voltage amplifier
and E_1 = voltage across input terminals of amplifier.

It is important to distinguish these decibels from decibels of power, which have an entirely different meaning. The abbreviation dbvg is suggested as indicating decibels of voltage gain.

Some engineers express the gain of an amplifier in terms of voltage by taking E_1 (eqn. 12) as the open circuit generator voltage (E in Fig. 19.1). If the load resistance (R_1 in Fig. 19.1) is equal to the generator resistance (R), the indicated gain by this method will be 6 db less than that given by eqn. (12). If R_1 is greater than $10R$, both methods give approximately the same result. If the generator impedance has an appreciable reactive component, the difference between the two methods will be less than indicated above.

(B) Amplifier gain in terms of power

Amplifier gain is defined as the ratio expressed in db of the power delivered to the load, to the power which would be delivered to the same load if the amplifier were replaced by an ideal transformer which matches both the load and source impedances (R.M.A. Standard SE-101-A, Amplifiers for sound equipment—Ref. 35).

In Fig. 19.1 the power delivered to the load is

$$P_2 = E_2^2/R_2 \quad (13)$$

The power which would be delivered to the same load if the amplifier were replaced by an ideal transformer which matches both the load and source impedances is

$$P_1 = E_1^2/R_1 \quad (14)$$

Therefore gain in decibels = $10 \log_{10}(P_2/P_1)$. (15)

If the input resistance of the amplifier is made equal to the internal resistance of the source,

$$\text{i.e. } R_1 = R,$$

then $E_1 = E/2$ and $P_1 = E^2/4R_1 = E^2/4R$.

Gain in decibels = $10 \log_{10} (4RE_2^2/R_2E^2)$

$$= 20 \log_{10} \frac{2E_2}{E} \sqrt{\frac{R}{R_2}} = 6 + 20 \log_{10} \frac{E_2}{E} \sqrt{\frac{R}{R_2}} \quad (16)$$

If, in addition, $R_2 = R_1 = R$, then

gain in decibels = $6 + 20 \log_{10} (E_2/E)$ (17)

(C) Gain of a bridging amplifier

A bridging amplifier is one whose internal input impedance is such that it may be connected across a circuit without appreciably affecting the circuit performance in any respect. Its function is to operate into programme circuits or similar loads (Ref. 33).

Bridging gain is the ratio, expressed in db, of the power delivered to the bridging amplifier load to the power in the load across which the input of the amplifier is bridged (Ref. 33).

The commonest case is that of the input to an amplifier having a load of 600 ohms, with the input terminals of the bridging amplifier connected across it. The output load of the bridging amplifier is most commonly 600 ohms.

(vii) Combined microphone and amplifier gain expressed in decibels

(A) When a microphone, rated in terms of voltage, is connected to a voltage amplifier which is rated in decibels of voltage gain (dbvg), the output may be calculated as under :

Output in dbv* = microphone rating in dbv* + coupling factor + amplifier gain in decibels of voltage gain (dbvg). (18)

The coupling factor = $20 \log [R_1/(R + R_1)]$ (Fig. 19.1). (19)

Typical values of the coupling factor are tabulated below :

$R_1/(R + R_1)$	=	0.5	0.56	0.63	0.71	0.79	0.89
Coupling factor	=	-6	-5	-4	-3	-2	-1 db

Example : Microphone -54 dbv*

Amplifier + 80 dbvg

$R_1/(R + R_1) = 0.5$

Output = $-54 - 6 + 80 = +20$ dbv* = 10 volts.

It should be noted that the calculated output applies for the rated sound pressure, for example 1 dyne per square centimetre. At other sound pressures the voltage will be proportional to the sound pressure.

(B) When a microphone, rated in terms of effective output level, is connected to an amplifier having its gain expressed in terms of power in accordance with R.M.A. Standard SE-101-A :

The amplifier power gain is measured effectively with a constant input voltage in series with a resistance equal to the rated source impedance of the amplifier as in Fig. 19.3. Under these conditions no correction factor is necessary and the output from the amplifier in dbm is equal to the sum of the microphone effective output level in dbm and the amplifier power gain in decibels. This output level will only be attained when the pressure at the microphone is equal to the rated pressure—e.g. 10 dynes/sq. cm.

FIG. 19.3

Fig. 19.3. Method of testing amplifier for gain.

FIG. 19.4

Fig. 19.4. Voltage amplifier showing input and output voltages.

For example, a ribbon microphone has an effective output level of -59 dbm with an acoustical pressure of 10 dynes/cm². If this is connected to an amplifier with a power gain of 40 db, the output level will be $-59 + 40 = -19$ dbm with an acoustical pressure of 10 dynes/cm².

(C) When a microphone, rated in accordance with the R.M.A. microphone system rating is connected to an amplifier having its gain expressed in terms of power in accordance with R.M.A. Standard SE-101-A :

For general remarks see (B) above.

The output from the amplifier in dbm is equal to the sum of the R.M.A. microphone system rating, the amplifier power gain in decibels, and the sound pressure in decibels.

For example, a ribbon microphone with a R.M.A. system rating (G_M) of -153 db, operating with a sound pressure of 10 dynes/sq. cm. (i.e. +94 db) and connected to

*0 db = 1 volt

an amplifier with a power gain of 40 db will give an output level $-153 + 40 + 94 = -19$ dbm. The microphone amplifier and sound pressure in this example are the same as for (B) above.

(viii) Loudspeaker output expressed in decibels, in terms of acoustical pressure

In accordance with the American R.M.A. Standard SE-103 (Ref. 29) the loudspeaker pressure rating is the difference between the axial sound pressure level (referred to a distance of 30 feet) and the available input power level, and is expressed in db.

It is expressed by the following forms (equations 20, 21, 22, 23) :

$$G_{SP} = 10 \log_{10} [(p_S/p_0)^2 / (W_{AS}/W_0)] \quad (20)$$

$$G_{SP} = 44 + 20 \log_{10} p_S - 10 \log_{10} W_{AS} \quad (21)$$

$$G_{SP} = 44 + 20 \log_{10} p_S - 20 \log_{10} E_G + 10 \log_{10} R_{SR} + 20 \log_{10} [1 + (R_{SG}/R_{SR})] \quad (22)$$

$$(\text{pressure in db above } p_0) = G_{SP} + (\text{power in dbm}) \quad (23)$$

where G_{SP} = loudspeaker pressure rating in db

p_S = axial, free-space, r.m.s. sound pressure at 30 feet, in dynes/cm²

p_0 = reference r.m.s. sound pressure = 0.0002 dyne/cm²

W_{AS} = electrical power available to the speaker, in watts, and is equal to $E_G^2 R_{SR} / (R_{SG} + R_{SR})^2$ (Fig. 19.5)

W_0 = reference power = 0.001 watt

E_G = r.m.s. value of the constant voltage of the source, in volts

R_{SR} = loudspeaker rating impedance, in ohms*

R_{SG} = speaker measurement source impedance, in ohms*

and dbm = power in decibels referred to 1 milliwatt.

Fig. 19.5. Loudspeaker testing conditions (R.M.A. Standard SE-103).

The sound pressure (p_d) at any distance d feet may be used to compute the pressure p_s at 30 feet by the relation

$$p_s = (d/30)p_d \quad (24)$$

See also Ref. 34.

Example : If the loudspeaker pressure rating (G_{SP}) is 46 db, what is the axial sound pressure level at 30 feet, with an available power input of 10 watts, using a standard test signal?

$$G_{SP} = 46 \text{ db} \quad W_{AS} = 10 \text{ watts} = 40 \text{ dbm}$$

From equation (21),

$$20 \log_{10} p_S = 46 - 44 + 10 \log_{10} 10 = 12 \text{ db.}$$

Therefore $p_S = 4$ dynes/cm² (i.e. 86 db above p_0).

The same result may be derived more directly from equation (23), pressure = 46 + 40 = 86 db above p_0 .

(ix) Sound system rating

The total gain of a system from sound, through microphone, amplifier and loudspeaker to sound again may be calculated by adding the system ratings of the several sections and coupling factors (if any).

(A) **Using the American R.M.A. system ratings** for microphone, amplifier and loudspeaker we may put

$$SR = G_M + G + G_{SP} \quad (25)$$

where SR = sound system rating (gain in db)

G_M = R.M.A. microphone system rating (equations 10 and 11)

G = amplifier power gain (equation 15)

and G_{SP} = loudspeaker pressure rating in db (equations 20, 21 and 22).

*See Chapter 20 Sect. 6(x)B for definitions of R_{SR} and R_{SG} .

A system rating of 0 db indicates that the sound pressure 30 feet from the loudspeaker is the same as that at the microphone. Similarly a system gain of x db indicates that the sound pressure 30 feet from the loudspeaker is x db greater than that at the microphone.

(B) Proposed method of rating microphones and loudspeakers for systems use by Romanow and Hawley (Ref. 11)

This proposed method has not been adopted generally in the precise form expounded, but the article gives a most valuable analysis of the whole subject of system gain. This method is also described in Ref. 34.

(x) Tables and charts of decibel relationships

Table 1 : Decibels expressed as power and voltage or current ratios

Note that the Power Ratio columns give power values in milliwatts when the reference level is 1 mW. The Power Ratio columns also give power values in milliwatts when the centre column represents dbm*.

The Voltage Ratio columns also give values in volts when the centre column represents dbv.†

Fig. 19.6. Gain ratio plotted against decibel gain. This chart may also be used for attenuation by inverting the ratio and making the decibels negative.

Interpolation : If it is required to find the power ratio corresponding to 22.5 db, or any other value which is not included in the table, the following procedure may be adopted :—

1. Take the next lowest multiple of 20 db (in this case 20 db), and note the corresponding power ratio (in this case 100).

*dbm is unit of power expressed in decibels with 0 db = 1 mW.

†dbv is unit of voltage expressed in decibels with 0 db = 1 volt.

2. Take the difference between the specified level and the multiple of 20 db (in this case $22.5 - 20 = 2.5$ db) and note the corresponding power ratio (in this case 1.778).
3. Multiply the two power ratios so determined (in this case $100 \times 1.778 = 177.8$).

*Or Current Ratio.

To find the decibels corresponding to ratios above 10, break the ratio into two factors and add the decibels of each. For example—

Voltage ratio = 400 = 4×100 . Decibels = 12.041 + 40 = 52.041.

TABLE 3 : DECIBELS ABOVE AND BELOW REFERENCE LEVEL 6 mW
INTO 500 OHMS

Note that the power in watts holds for any impedance, but the voltage holds only for 500 ohms.

(xi) Nomogram for adding decibel-expressed quantities

Two or more sounds combine to give a total sound whose acoustical power is the sum of the powers of the individual components. This nomogram* (Fig. 19.6A) may be used to determine the resultant level in db when the two component sound levels are also expressed in db, or for adding any decibel-expressed quantities.

The difference between the two component values in decibels is first determined by algebraic subtraction, and this difference value is found on Scale A. The corresponding figure on Scale B then indicates the number of decibels to be added to the greater original quantity to give the required resultant.

For example take two sound levels of 35.2 db and 37.0 db. The difference is 1.8 db which, when located on Scale A, indicates 2.2 db on Scale B. This value is then added to 37.0 db to give the resultant sound level of 39.2 db.

When the difference in level exceeds 20 db, disregarding the smaller quantity produces an error of less than 1%.

The nomograph scales are based on the formula :

$$B = \left[10 \log_{10} \left(1 + \log_{10}^{-1} \frac{A}{10} \right) \right] - A \quad (26)$$

where A and B correspond to points on the respective scales. Ref. 37.

* For Nomogram see page 822.

(xii) Decibels, slide rules and mental arithmetic

The following holds for power calculations under all conditions, and for voltage and current calculations when the impedance is constant.

Use of log-log slide rule

For voltage ratios, set the cursor to 10 on the log-log scale, and set the C scale to 20 on the cursor. Then set the cursor to the required voltage ratio on the log-log scale and read the decibels on the C scale. To obtain good accuracy it is advisable to use the section of the log-log scale between 3 and 100, dealing with powers of 10 separately.

For power ratios, set cursor to 10 on the log-log scale, set the C scale to 10 on the cursor and then proceed as before.

Decibel calculations by mental arithmetic

For occasions when a rule is not available, it is useful to be able to perform conversions mentally. It is possible to memorize a conversion table, but this is unnecessary because, starting with the knowledge that an increase of two times in a voltage ratio is equivalent to 6 db, and 10 times to 20 db, it is comparatively simple to build up such a table mentally as required. The backbone of the table is as follows—

db	0	2	6	8	12	14	18	20
factor	1	1.25	2	2.5	4	5	8	10

This is built up simply by adding 6 db for each two times increase from a ratio of unity, i.e. 2, 4 and 8 times represent 6, 12 and 18 db, and by subtracting 6 db for each halving of a multiplying factor of 10 times i.e. 10, 5, $2\frac{1}{2}$ and $1\frac{1}{4}$ times are represented by 20, 14, 8 and 2 db.

The next step in the table can be built up from noticing that a 2 db decrease represents a multiplying factor of 0.8 times. From this fact we can add the values for 4, 10 and 16 db—

db	4	10	16
factor	$1.6(2 \times 0.8)$	$3.2(4 \times 0.8)$	$6.4(8 \times 0.8)$

To complete the table we need values for each of the odd numbers of db. Noticing that 2 db down is equivalent to multiplying by 0.8 we can assume that the error in taking 1 db down as 0.9 is small, and the table can then be written in full.

Fig. 19.6A.

Accurate values are recorded in the third line for comparison.

db—										
0	1	2	3	4	5	6	7	8	9	10
factor—										
1	1.12	1.25	1.4	1.6	1.8	2	2.3	2.5	2.9	3.2
true factor—										
1.00	1.12	1.26	1.41	1.59	1.78	2.00	2.24	2.51	2.82	3.16

db—										
11	12	13	14	15	16	17	18	19	20	
factor—										
3.6	4	4.5	5	5.8	6.4	7.2	8	9	10	
true factor—										
3.55	3.98	4.47	5.01	5.62	6.31	7.08	7.94	8.91	10.0	

Comparing the multiplying factors computed in this manner with the true factors it will be seen that the greatest error (at 15 db) is just over 3% which is negligible for the type of calculation intended to be performed by this method.

When working with “db down,” the number of db can be subtracted from 20 and the multiplying factor from the table can be divided by 10, e.g. 7 db (20-13) down is equivalent to a multiplying factor of 0.45. A small amount of practice at such mental conversions soon results in many of the factors being memorized (or else becoming immediately obvious) without any conscious effort in this direction.

SECTION 2: VOLUME INDICATORS AND VOLUME UNITS

(i) *Volume indicators* (ii) *Volume units.*

(i) Volume indicators

When an instrument is required merely to measure power under steady conditions, no particular difficulties are encountered and the scale may be calibrated in decibels with respect to any desired reference level. In studio programmes, however, the power is constantly fluctuating and the indication of the instrument will depend upon its speed of response and damping.

Volume is here applied to the indications of a device known as a Volume Indicator, which is calibrated and read in a prescribed manner.

The **Volume Indicator** is a standardized instrument (Ref. 19) which has been developed primarily for the control and monitoring of radio programmes. The Volume Indicator is a root-mean-square type of instrument with a full-wave copper-oxide type of rectifier. The rectifier law is intermediate between linear and square-law, having an exponential of 1.2 ± 0.2 . Its dynamic characteristics are such that, if a sinusoidal voltage of frequency between 35 and 10 000 c/s and of such amplitude as to give reference deflection under steady-state conditions is suddenly applied, the pointer will reach 99% of reference deflection in 0.3 second ($\pm 10\%$) and should then overswing reference deflection by at least 1.0% and not more than 1.5% (Ref. 19). It will give a reading of 80% on an impulse of sine wave form as short as 0.025 second (Ref. 18).

It is fitted with two scales, a vu scale marked 0 (“reference deflection”) at about 71% maximum scale reading, extending to + 3 (maximum) and – 20 (minimum) and a percentage voltage scale with 100% corresponding to 0 vu reading, calibrated downwards to 0%.

The instrument is available with the scales marked differently: With “Scale A” the vu scale is made more prominent, being situated above the percentage scale—

this is for use in measuring instruments etc. where the reading of the meter together with the reading of an associated attenuator (where necessary) give the actual power level. With "Scale B" the percentage scale is made more prominent being situated above the vu scale—this is for use in studio controls etc. where the operator is non-technical and is not interested in actual levels.

The sensitivity shall not depart from that at 1000 c/s by more than 0.2 db between 35 and 10 000 c/s at an input level of 0 vu, nor more than 0.5 db between 25 and 16 000 c/s (Ref. 19).

The instrument is calibrated by connecting it in shunt with a resistance of 600 ohms through which is flowing 1 milliwatt of sine-wave power at 1000 c/s, when a reading shall be 0 vu (or n vu when the calibrating power is n db above 1 milliwatt).

If the instrument is connected across any impedance other than 600 ohms, the volume indicated must be corrected by adding $10 \log_{10} (600/Z)$, where Z is the actual impedance in ohms.

The total impedance of the volume indicator is usually about 7500 ohms, of which about 3600 ohms is external to the instrument.

The Volume Indicator is intended to be read as deviations from the reference volume (0 vu), after making allowance for the sensitivity control (attenuator) which is also calibrated in 'vu'. The reading is determined by the greatest deflections occurring in a period of about a minute for programme waves, or a shorter period (e.g. 5 to 10 seconds) for message telephone speech waves, excluding not more than one or two occasional deflections of unusual amplitude.

References 18, 19, 39, 49.

(ii) Volume units

The **volume unit** (abbreviated vu and pronounced "vee-you") is a unit to express the level of a complex wave in terms of decibels above or below a reference volume as defined below. A level referred to as x vu means a complex wave power reading on a standard vu meter. Volume units should never be used to indicate the level of a sine-wave signal—the latter should always be referred to as so many dbm. Even if a vu meter is used to read the level of a steady single-frequency sine-wave signal, which is quite permissible, the reading should be referred to as so many dbm.

A volume unit implies a complex wave—a programme waveform with high peaks. The usual convention is to assume that the peak value is 10 db above the sine-wave peak.* For this reason an amplifier for radio broadcasting systems is tested with sine-wave input at a level 10 db above the maximum vu level at which it is intended to be used. For example, a system working at a level of + 12 vu would be tested for distortion at a level of + 22 dbm sine-wave.

Reference volume is defined as that strength of electrical speech or programme waves which gives a reading of 0 vu on a volume indicator as described above, and which is calibrated to read 0 vu on a steady 1000 c/s wave whose power is 1 milliwatt in 600 ohms. Care should be taken to distinguish between this definition of reference volume, which is arbitrary and not definable in fundamental terms, and a reference level of 1 milliwatt used for power measurements under steady conditions with a single frequency.

References 18, 19, 39, 49.

*Occasional peaks under certain conditions may be somewhat higher.

SECTION 3 : INDICATING INSTRUMENTS

(i) *Decibel meters* (ii) *Power output meters* (iii) *Volume indicators* (iv) *Acoustical instruments*.

(i) Decibel meters

A decibel meter is usually a rectifier type of instrument calibrated in decibels, with 0 db situated somewhere near the centre of the scale. The scale is usually marked to indicate the reference level and the line impedance, e.g. "0 db = 6 mW ; calibrated for 500 ohm lines."

These instruments are frequently provided with attenuators to extend their range and are then sometimes called **power-level indicators**. They are actually voltmeters intended to be connected across a line of known impedance.

If a decibel meter is connected across a resistance other than the correct value the error will be

$$\text{error in db} = 10 \log_{10} (R_x/R) \quad (1)$$

where R_x = resistance across which the meter is connected
and R = correct resistance for which the meter is calibrated.

A chart of corrections based on equation (1) is given in Ref. 4.

(ii) Power output meters

These differ from decibel meters in that the instrument dissipates and measures power. The input impedance is usually variable by means of a selector switch, and the scale of the instrument may be calibrated both in milliwatts and decibels.

(iii) Volume indicators

See Section 2 above.

(iv) Acoustical instruments

Sound level meters—see Section 5 below.

Noise meters—see Section 6 below.

References to indicating instruments—1, 4, 9, 17, 18, 19, 20, 21, 23, 25, 26, 27, 39.

SECTION 4 : NEPERS AND TRANSMISSION UNITS

(i) *Nepers* (ii) *Transmission units*.

(i) Nepers

Just as there are two systems of logarithms in general use, so there are two logarithmic units for the measurement of difference of power levels. The bel and the decibel are based on the system of Common Logarithms (to the base 10).

The neper is based on the system of Napierian Logarithms (to the base e).

Nepers are not commonly used in English-speaking countries, but are used by some European countries.

Equation (1) below should be compared with Section 1, equation (2) above :

$$N_n = \frac{1}{2} \log_e (P_2/P_1) \quad (1)$$

where N_n is the ratio of two powers expressed in nepers

P_1 = reference power

and P_2 = power which is referred back to P_1 .

When the impedances relating to P_1 and P_2 are the same,

$$N_n = \log_e (E_2/E_1) = \log_e (I_2/I_1) \quad (2)$$

Equation (2) should be compared with equations (4) and (5) in Section 1 above.

Relationship between decibels and nepers

$$1 \text{ neper} = 8.686 \text{ db}$$

$$1 \text{ db} = 0.1151 \text{ neper}$$

Power ratio	1	1.259	1.585	3.162	10	100	10^5
db	0	1	2	5	10	20	50
nepers	0	0.1151	0.2303	0.5757	1.151	2.303	5.757

References 1, 9.

(ii) Transmission units

A transmission unit was the early name of the decibel, but is no longer used.

$$1 \text{ TU} = 1 \text{ db}$$

SECTION 5 : LOUDNESS

(i) Introduction to loudness (ii) The phon (iii) Loudness units.

(i) Introduction to loudness

The loudness of any tone is a function, not only of its intensity, but also of its frequency. This is indicated by the contour curves of equal loudness as shown in Fig. 19.7.

FIG. 19.7

Fig. 19.7. Contours of equal loudness level ($0 \text{ db} = 10^{-16} \text{ watt/cm}^2$)—Ref. 28, after Fletcher and Munson (Ref. 40).

(ii) The Phon

The phon is the unit of loudness level. The loudness level, in phons, of a sound is numerically equal to the intensity level in decibels of the 1000 c/s pure tone which is judged by the listeners to be equally loud. The reference intensity is $10^{-16} \text{ watt per square centimetre}^*$, which is near the value of the threshold of audibility for a 1000 c/s pure tone (Ref. 22).

When listening to a 1000 c/s pure tone, the loudness level in phons is equal to the number of decibels above the reference intensity, but with any other frequency the loudness level in phons will normally differ from the intensity in decibels (Fig. 19.7).

*The equivalent reference pressure for sound pressure measurements is 0.0002 dyne per square centimetre. The equivalent reference velocity for sound velocity measurements is 0.000 005 centimetre per second.

(iii) Loudness units

For purposes of noise measurement, the **loudness unit** has been standardized (Ref. 28), and is based on the principle that doubling the number of loudness units is equivalent to a sensation of twice the loudness. The relation between loudness level in phons and loudness in loudness units is given in Fig. 19.8.

References 40, 41, 28.

See also Supplement.

Fig. 19.8. Relation between loudness and loudness level ; reference frequency 1000 c/s—Ref. 28, after Fletcher and Munson (Ref. 41).

SECTION 6 : THE MEASUREMENT OF SOUND LEVEL AND NOISE

(i) Introduction (ii) The sound level meter (iii) The measurement of noise in amplifiers (iv) The measurement of radio noise.

(i) Introduction

Sound includes wanted sound—music or speech—and also unwanted sound—noise. Noise may be measured acoustically, as for example by a sound level meter, or electrically. Acoustical methods of measuring noise and other sounds are described in (ii) below. Electrical noise may be measured either with or without a weighting network. If a weighting network is used, there will be appreciable attenuation of the lower frequencies, including hum frequencies. It is normally assumed in good engineering practice that the hum components have negligible effect on the noise reading ; if this is not so, they should be filtered out before the noise voltage is applied to the measuring equipment.

(ii) The sound level meter

Sound measurements, when made with an American standard sound level meter (Ref. 23) are determinations of sound intensity levels and are expressed in decibels—the reference sound pressure level is 0.0002 dyne/cm^2 at 1000 c/s. The standard sound level meter has a scale calibrated in decibels, and the readings should be referred to as e.g. “60 decibels sound level” or “sound level of 60 decibels.” A sound level meter may provide a choice of frequency response characteristics:

- (A) The 40 decibel equal loudness contour*
- (B) The 70 decibel equal loudness contour*
- (C) Flat frequency response.

In all cases the frequency response should be stated in connection with any measurements. If only one frequency response is provided, this should be (A) above. Curve (A) is recommended for measurements up to 55 db, curve (B) for measurements from 55 to 85 db, and curve (C) for very loud sounds (85 to 140 db).

Within certain tolerances the sound level meter will indicate the sum of the equivalent 1000 c/s intensities of the different single frequency components in a complex wave—that is the power indicated for a complex wave will be the sum of the powers which would be indicated for each of the single frequency components of the complex wave acting alone.

The dynamic characteristics of the indicating instrument are specified in detail (Ref. 23).

The American sound level meter is a very simple instrument giving only approximate indications of loudness levels. However the ear does not judge the loudness of wide-band noises in the same way that it judges the loudness of pure tones. Consequently the use of the equal-loudness contours based on pure tones introduces errors which may be as great as 22 phons between the readings of an American sound level meter and subjectively measured loudness levels in phons (Ref. 42).

British objective noise meter

A more accurate acoustical noise meter has been designed by King and associates (Ref. 42) which includes a phase-shifting network, a peak-indicating meter and a larger number of weighting networks. See also Ref. 34 (pp. 894-896).

(iii) The measurement of noise in amplifiers*

(A) Amplifiers for sound equipment

(based on R.M.A. Standard SE-101-A—Ref. 35).

This is an interim standard for the measurement of steady-state noise, and of pulse noise waves having a peak factor (ratio of peak to r.m.s.) approximating the maximum obtainable in speech (20 db).

Noise level is the level of any noise signals appearing at the output terminals with no signal applied to the input.

The weighted noise level is the noise level weighted in accordance with the 70 decibel equal-loudness contour of the human ear and expressed in dbm. The weighted noise level shall be measured under test conditions specified in Ref. 35. The measuring amplifier shall be one whose a-f response is weighted with the 70 db equal-loudness contour in accordance with Curve B of A.S.A. Specification Z24.3-1944 (Ref. 23) with a standard vu meter as defined by A.S.A. Specification C16.5-1942 (Ref. 19) as an indicator.

A properly weighted amplifier may be obtained by applying a r.c. network with a 1 millisecond time constant to an amplifier having a frequency response of ± 1 db from 50 to 15 000 c/s. This will give an attenuation of 1 db at 300 c/s, 5.7 db at 100 c/s and 9 db at 60 c/s.

(B) Audio facilities for radio broadcasting systems

(Based on R.M.A. Standard TR-105-B—Ref. 33).

Measurement of **steady state noise** shall be made with a device having an a-f response flat within ± 2 db from 50 to 15 000 c/s and having the ballistic characteristics of the standard vu meter (Ref. 19) but reading the r.m.s. value of a complex wave. Measurement of pulse noise conditions has not been included because of lack of definition and equipment.

Measurement made on those instruments incorporating average rather than r.m.s. rectifiers will give indications differing in general less than 1 db from the latter due to this difference. This is within the overall accuracy ordinarily obtained on this type of measurement.

Audio frequency signal to noise ratio—definition

The a-f signal to noise ratio is the numerical ratio between the sine-wave signal power required for standard output and the noise power measured with zero applied signal, received by the rated load impedance from the output of the equipment under test, expressed as a power ratio in decibels (Ref. 33).

(iv) The measurement of radio noise

Radio noise is any electrical disturbance which excites a radio receiver in such a way as to produce acoustical noise.

"A major objective of radio-noise-meter design is to provide an instrument which will give, for all kinds of radio noise, indications which are proportional to the annoyance factor or nuisance capability of the noise." Instruments complying with the specification of the Joint Co-ordination Committee (Ref. 25) are stated to be very satisfactory in this regard (Ref. 21). A useful review of the progress made up to 1941

* For noise audibility test for radio receivers see Chapter 37 Sec. 1 (vi) K.

is given in Reference 26 with an extensive bibliography. The equivalent British Standard is described in Ref. 27.

SECTION 1 : INTRODUCTION

(i) *Types of loudspeakers* (ii) *Direct-radiator loudspeakers* (iii) *Horn loudspeakers*
 (iv) *Headphones* (v) *Loudspeaker characteristics* (vi) *Amplitude of cone movement*
 (vii) *Good qualities of loudspeakers* (viii) *Loudspeaker grilles.*

(i) Types of loudspeakers

In this chapter the point of view is that of the receiver or amplifier designer, not that of the loudspeaker designer.

Loudspeakers are in three principal groups :

1. Direct radiators—where the cone or diaphragm is directly coupled to the air.
2. Horn loudspeakers—where the diaphragm is coupled to the air by means of a horn.
3. Ionic loudspeakers—in which no diaphragm is used. See Refs. 212, 227.

(ii) Direct radiator loudspeakers

(A) **The moving coil or electro-dynamic** type is by far the most popular for radio receivers. It has a voice-coil mounted in a strong magnetic field ; the a-f output power from the amplifier is passed through a suitable matching transformer (see Chapter 21) to the voice coil, and the a-f currents in the coil cause a force to be exerted in the direction of the axis of the coil. If the voice coil is free, it will move in the direction of the force. The voice coil is loaded by the cone which is (normally) firmly fixed to it.

The magnet may be either an electromagnet or a permanent magnet. In all cases, the higher the flux density the greater the efficiency and electro-magnetic damping. See Sect. 2 for detailed description.

(B) The electromagnetic type has two forms, the **reed armature** and the **balanced armature**. In the former there is a steel reed armature at a short distance from the pole piece wound with insulated wire carrying the a-f current, and supplied with steady magnetic flux by means of a permanent magnet. In the balanced armature type, only the a-f flux flows longitudinally through the armature. Both types require

relatively stiff springs to return the armature to the position of equilibrium, so that the bass resonance usually occurs at a frequency above 100 c/s.

Refs. 13, 14, 15.

(C) **The inductor dynamic type** differs from the older electromagnetic type in that the two iron armatures are balanced so that they lie at rest without a strong spring tension. The natural resonance frequency may be about 70 c/s, and the amplitude of movement is about the same as that of a moving-coil type. Ref. 15.

(D) **The piezo-electric ("crystal") type** generally uses Rochelle salt for the bimorph elements. It takes two forms, in which the elements either bend or twist with the voltage applied between the two electrodes. The crystal has a predominately capacitive impedance, the capacitance being of the order of 0.02 μF .

The impedance varies considerably with frequency in both scalar value and phase angle, so that it is difficult to provide a correct load impedance for the output valve. This is not very important with a triode or if another loudspeaker is connected in parallel.

The crystal loudspeaker naturally responds to the higher frequencies, and is sometimes used as a "tweeter" in a dual or triple speaker system (Sect. 5). In this case the response may be maintained roughly constant over the desired band of frequencies by a small inductance in series with the primary of the transformer. Crystal loudspeakers are not normally used alone.

Refs. 13, 14, 24, 60.

(E) **The condenser type** of loudspeaker usually takes the form of one large solid electrode, and a thin movable electrode which is mounted in such a way that it can vibrate (usually in sections) without touching the solid electrode.

Either the solid or the movable electrode may be corrugated; the movable electrode may be of insulating material with a metal foil coating. An alternative form has both electrodes flexible (Ref. 22).

The sensitivity is dependent upon the total area; with 300 to 500 square inches the sensitivity may approximate that of an electro-dynamic type.

The Kyle speaker (Ref. 58) has a capacitance of 0.004 μF for an area of 96 square inches. The impedance is predominately capacitive. A high polarizing voltage is required for high efficiency and good performance—500 to 600 volts is usual.

Condenser loudspeakers are little used at the present time.

Refs. 13, 14, 15, 22, 58.

(F) **Throttled air-flow loudspeaker**—this consists of a mechanical valve, actuated by an electrical system, which controls a steady air stream, the air flow being made proportional to the a-f input current. It is normally limited to very large sizes.

Ref. 14.

(iii) Horn loudspeakers

Any type of driving unit actuating a cone or diaphragm may be given greater acoustical loading by means of a horn, thereby improving the efficiency and power output. The horn ceases to have any beneficial effect below a frequency whose value depends on the law of expansion and the size of the horn. Horn loudspeakers have considerably greater efficiency than direct radiators. For further information see Sect. 4.

(iv) Headphones

Headphones (telephone receivers) make use of a diaphragm which is effectively sealed to the ear by means of a cap with a central opening. The pressure of the small quantity of air enclosed between the diaphragm and the ear drum varies in accordance with the displacement of the diaphragm.

The driving mechanisms of headphones resemble those for loudspeakers.

(A) **Magnetic diaphragm**: The a-f force caused by the a-f current in the electro-magnet operates directly upon a steel diaphragm. The bipolar type is the most popular of all headphones at the present time. A permanent magnet supplies the steady flux. At frequencies above the second diaphragm resonance the response falls off rapidly. Refs. 13, 14, 59, 62.

(B) Moving armature type : The principles are the same as for loudspeakers. Ref. 14.

(C) Moving-coil type : This follows the same principles as the loudspeaker, and with careful design is capable of greater fidelity and wider frequency range than the magnetic types. One model has a response from 10 to 9000 c/s ± 2 db except for a dip of 6 db at 4000 c/s. (Ref. 63). Refs. 13, 14, 63.

(D) Crystal type : The impedance of one model is 80 000 ohms (predominately capacitive) at 10 000 c/s. A high resistance may be connected in series to raise the low frequency response relatively to the high frequency response. Refs. 13, 64.

(E) Ribbon type : The principle is the same as for a ribbon microphone. It is only used for high-fidelity reproduction. Refs. 13, 14, 65.

(F) Inductor type : This has been developed to deliver practically constant sound pressure to the ear cavity from 50 to 7000 c/s. It has a V shaped diaphragm driven by a straight conductor located in the bottom of the V. Refs. 13, 14, 66, 67.

Correction circuits for magnetic diaphragm headphones

A typical magnetic diaphragm unit has a pronounced peak slightly below 1000 c/s. A circuit for attenuating this peak and thereby giving reasonably uniform response is Fig. 20.1 (Ref. 25).

Fig. 20.1. Tone correction circuit for magnetic diaphragm headphones (d.c. resistance 4000 ohms) giving 15 db bass and treble boost. Secondary impedance roughly 500 ohms, primary load resistance 10 000 ohms (Ref. 25).

(v) Loudspeaker characteristics

The amplifier designer is mainly interested in a limited number of characteristics.

Impedance : See Sect. 2(iv) for moving-coil type, and Sect. 4(v)G for horn type.

All types of electro-magnetic loudspeakers have a somewhat similar form of impedance characteristic, although the relative values vary considerably.

Phase angle : See Sect. 2(iv) for moving-coil-type.

Frequency response characteristic

This only applies under the strict conditions of the test, particularly generator impedance, and is very often misleading. The most serious defect is the existence of sharp upward peaks extending higher than say 5 db above the smooth curve, particularly in the region from 1500 to 4000 c/s. These are not always shown by the published curves, which frequently show signs of having been smoothed.

Reflections in rooms may result in changes of 15 db or more in level at certain frequencies, and the shape of the frequency characteristic may be altered out of all recognition by variations in placement of loudspeaker and microphone, or by a change of room.

It is important to know the source impedance (i.e. the output resistance of the amplifier) used in the test. A loudspeaker should always be used with the correct source impedance—too low a source impedance may result in loss of low frequency response, while too high a source impedance will usually result in over-accentuation of a narrow band of frequencies in the vicinity of the loudspeaker bass resonance. See Sect. 9(ii) for R.M.A. Standard loudspeaker measurement source impedance. Refs. 13, 14, 15, 26 (No. 1), 42, 70.

Damping

The source impedance (i.e. the output resistance of the amplifier) also affects the damping of the loudspeaker at the bass resonant frequency. One value of source impedance will normally (in loudspeakers of high flux density) give critical damping—this being the value for no overshoot—while a slightly lower degree of damping may be considered as the optimum. Too high a resistance will give insufficient damping for good transient response. For further information see Sect. 2(x).

Directional characteristics

The usual frequency response characteristic is measured with the microphone on the axis of the loudspeaker, this being the position of maximum high frequency response. There is a serious loss of higher frequencies (4000 c/s and above) even with the microphone 30° off the axis.

See Sect. 2(vii) for further information on moving-coil types, and Sect. 4(vii) for horn types.

Refs. 13, 14, 15, 26 (No. 1), 61, 70, 133.

Non-linear distortion : see Sect. 7(i) and (v).

Efficiency versus frequency characteristic : see Sect. 2(vi).

Transient response : see Sect. 7(iii).

Matching : see Chapter 21.

Characteristics of cones : see Sect. 2(ii).

(vi) Amplitude of cone movement

The peak amplitude of a rigid disc to give an acoustical power output of 0.2 watt (equivalent to 6.7 watts amplifier power with a loudspeaker efficiency of 3%) is given by the following table. Radiation from one side only is considered (derived from Chart No. 61, Ref. 69).

Diameter of cone	Frequency (c/s)					
	1000	400	200	100	50	30
13 in.	0.0003	0.002	0.008	0.03	0.12	0.34 in.
10 in.	0.0005	0.003	0.013	0.05	0.21	0.58 in.
8 in.	0.0008	0.005	0.02	0.08	0.32	0.90 in.
5 in.	0.002	0.013	0.051	0.21	0.82	2.26 in.

(vii) Good qualities of loudspeakers

A loudspeaker should have the following good qualities—

Satisfactory sensitivity

Broad directivity

Low distortion over the whole frequency range

Smooth frequency response

Balanced response

Good transient response

Sufficient damping at the bass resonant frequency

Adequate power-handling capacity

Any loudspeaker is necessarily a compromise. It has been demonstrated by Olson (Ref. 133) that with cone type loudspeakers, increased sensitivity brought about by reducing the thickness of the cone material is accompanied by increased distortion, ragged frequency response, bad transient response, and increased "break up" effects in the cone. On the other hand, the power output for the same distortion is many times greater for the loudspeaker having the more massive vibrating system.

If increased sensitivity is required, this may be achieved, within limits, by increasing the flux density. High flux density has the additional valuable property of increasing the damping.

A prominent peak in the response characteristic at the bass resonant frequency will increase the apparent sensitivity of the loudspeaker, particularly with small speakers having the bass resonance above 150 c/s. Similarly, prominent peaks in the response characteristic above 1000 c/s will also increase the apparent sensitivity, although both are features to be avoided for good fidelity.

When loudspeakers are compared in listening tests, the sound outputs should be adjusted to the same level before a comparison is made, because sensitivity is usually of secondary importance. Refs. 150, 155, 183.

(viii) Loudspeaker grilles

If the grille cloth is not to reduce sound pressure, its resistance must be small compared with the radiation resistance of the loudspeaker. The most suitable type of cloth is one which is very loosely woven and which has hard threads—cotton or plastic. Fuzzy threads increase the resistance of the cloth. Ref. 180.

SECTION 2 : CHARACTERISTICS OF MOVING-COIL CONE LOUDSPEAKERS

(i) *Rigid (piston) cone in an infinite flat baffle* (ii) *Practical cones* (iii) *Special constructions for wide frequency range* (iv) *Impedance and phase angle* (v) *Frequency response* (vi) *Efficiency* (vii) *Directional characteristics* (viii) *Field magnet* (ix) *Hum bucking coil* (x) *Damping*.

(i) Rigid (piston) cone in an infinite flat baffle

A rigid cone is one which moves forwards and backwards like a piston—at low frequencies a loudspeaker cone approaches this ideal. The air acts as a load on the piston at all frequencies when it is set in an infinite flat baffle. The **radiation resistance per unit area** of the piston is approximately constant for frequencies above

$$f_1 = 8120/\text{diameter of piston in inches} \quad (1)$$

In tabular form :

Diameter of piston	12	10	8	6	4	inches
Frequency f_1	677	812	1015	1353	2030	c/s.

Below frequency f_1 the radiation resistance is approximately proportional to the square of the frequency.

For amplitude of cone movement see page 834.

(ii) Practical cones

In practical cones the voice coil is mounted towards the apex of the cone and the driving force is transmitted through the cone. The cone must be a compromise between strength and lightness. A cone for reproducing the low audio frequencies should be fairly rigid, and should have a large diameter. If such a loudspeaker is tested at high audio frequencies above 1000 c/s it will be found to have a poor response owing to :

1. Large mass, causing poor efficiency at the higher frequencies.
2. The vibrations tend to take the form of waves radiating from the voice-coil outwards through the cone. At the higher frequencies the outer portion of the cone may be out of phase with the inner portion, or there may be a phase difference greater or less than 180°

Cones for reproducing a wide frequency range often are designed with corrugations to reduce the effective vibrating area at the higher frequencies. Other designers achieve a somewhat similar result by a suitable choice of cone material together with changes in the thickness or compliance of the material. It is desirable that the material for the cone be no harder than is necessary to maintain response up to the highest frequency required, in order to give good reproduction of complex tones and transients.

The cone and voice-coil assembly is usually mounted at two points—an annular “surround” and a “spider” or centre mounting. Each of these introduces a restoring force which should increase linearly with the displacement. Actual mounting systems introduce a non-linear restoring force which usually increases rapidly when the displacement is fairly large. The suspension has two characteristics directly

affecting the performance of the loudspeaker—compliance and mechanical resistance. Compliance is the inverse of stiffness (e.g. the stiffness of a spring), and controls the frequency of the bass resonance. The mechanical resistance of the suspension affects the Q of the vibrating system, but usually at the bass resonant frequency the damping due to the suspension is much less than that due to the output resistance of the amplifier, except when a high output resistance is used. There appears to be an optimum relationship between the stiffness of the cone and the compliance of the rim to minimize peaks and troughs in the 1500 to 3500 c/s region.

Non-linear suspensions are sometimes used with the object of preventing damage to the cone through overloading. This procedure causes serious distortion at high amplitudes, and the quoted value of "maximum power output" is that capable of being handled without the loudspeaker suffering damage. Loudspeakers for good fidelity should be capable of handling their full power without exceeding the limits of a fairly linear restoring force. These should be rated on the maximum power (within certain frequency limits) which they are capable of handling without the distortion exceeding a predetermined value.

As one result of the suspension system, the whole cone assembly tends to resonate at the **bass resonant frequency**. Below this frequency the cone is stiffness-controlled by the suspension and the output waveform tends to have flattened peaks resulting from the non-linear suspension.

Most loudspeaker manufacturers supply at least two alternative types of cone for use with each model—one with a nearly flat response up to 6000 c/s or higher (for broadly tuned or F-M receivers or amplifiers), the other with a response peaked in the 2000 to 4000 c/s region to compensate for sideband cutting in the receiver. It is desirable, in each case, to have a choice between a cone for pentode output (without feedback), and one for triode output (or pentode with negative voltage feedback).

Cones are also available with differing bass resonant frequencies (from below 50 c/s to about 225 c/s depending on cone size and application) and differing high frequency limits (say 4500 to 8500 c/s for single cone units). Most manufacturers also supply special cones to order. It is of the utmost importance for the receiver or amplifier designer to investigate the complete range of available models and cones, and to make comparative listening tests between different makes, models and cones.

A loudspeaker using a metal cone is described in Ref. 225.

Amplitude and phase measurements on cones are described in Ref. 179.

References to cones : 1, 13, 15, 16, 19, 23, 40, 54 (Part 4), 84, 133, 179, 225.

(iii) Special constructions for wide frequency range

As mentioned above, a simple cone loudspeaker is not capable of giving satisfactory performance over a wide frequency range. One solution is to use two or more loudspeakers with each designed to cover a limited frequency range or dual or triple integral units (see Sect. 5). Another solution is to use some device to extend the effective frequency range of a single unit, as described below.

(A) **Multiple single coil, single cone** : It is possible to employ two or more identical fairly light loudspeakers with fairly small cones, all connected in parallel, series or series-parallel and correctly phased. The number to be so connected depends on the maximum power to be handled at the lowest frequency. All loudspeakers operate at all frequencies, and no filter is used.

(B) **Single coil, double cone** : This consists of an ordinary voice coil with two cones, the smaller cone being firmly fixed to the voice coil, and the larger cone being flexibly connected by means of a compliance corrugation. At low frequencies both cones move together as a whole, but at high frequencies the small cone moves while the large cone remains stationary.

Refs. 13A, 14, 71.

(C) **Double coil, single cone** : This consists of a voice coil in two parts separated by a compliance, the smaller being fixed to a single corrugated cone. The larger part of the voice coil is shunted by a capacitance to by-pass the higher frequencies. At

low frequencies the whole assembly moves together, but at high frequencies the larger part of the voice coil remains stationary, and the smaller part drives the cone. The corrugations in the cone are designed to decrease the effective cone area at the higher frequencies.

Refs. 13A, 14, 57.

(D) Double coil, double cone : This consists of a light coil coupled to a small cone, the light coil being connected by a compliance to a heavy coil which is firmly fixed to a large cone. The heavy voice coil is shunted by a capacitance to by-pass the higher frequencies. At low frequencies both voice coils are operative, and the whole assembly moves together, but at high frequencies the small cone is driven by the light coil, and the large cone and heavy coil remain stationary. This is really equivalent to two separate loudspeakers.

Refs. 13A, 71.

(E) Duode : This has a light aluminium sleeve as the voice coil former covered on the outside by a layer of rubber, over which is wound the voice coil. At high frequencies, it is claimed, the relatively heavy voice coil winding remains stationary, the aluminium sleeve acting as a one turn coil receiving its power by transformer action and driving the cone. Refs. 242, 243.

(iv) Impedance and phase angle

The impedance characteristic (e.g. Fig. 20.2) is drawn from measurements made on an electrical impedance bridge, or equivalent method, with the loudspeaker mounted on a flat baffle. The nominal value is usually taken as the impedance at 400 c/s and is reasonably constant from about 200 c/s to about 600 c/s. At lower frequencies it rises to a peak at the bass resonant frequency and then falls rapidly to the resistance of the voice coil at still lower frequencies; at higher frequencies it rises steadily throughout.

FIG. 20.2.

Fig. 20.2. Impedance versus frequency characteristic of a typical popular loudspeaker.

of the voice coil at still lower frequencies; at higher frequencies it rises steadily throughout.

The impedance at the bass resonant frequency is a function of the damping of the cone suspension, the height of the peak decreasing as the damping is made heavier (see Ref. 13A, Fig. 6.31). It is also a function of the applied voltage, owing to non-linearity of the cone suspension.

If the loudspeaker is mounted other than on a flat baffle, the impedance characteristic at frequencies in the vicinity of the bass resonant frequency may be modified. For example with a vented baffle there are normally two impedance peaks — Sect. 3(iv).

The impedance at 10 000 c/s is always greater than that at 400 c/s, the ratio varying between 1.1 and 10 times. A high ratio is most undesirable with pentode operation, with or without feedback, but is of no great consequence with triodes. The impedance at 10 000 c/s is increased by any leakage inductance in the transformer.

The equivalent electrical circuit which gives approximately the same impedance characteristic up to 400 c/s is shown in Fig. 20.3 (Refs. 15, 72). If adjustments are made in the values of L_0 , R_0 , R_1 and C_1 , the circuit may be extended to higher frequencies. The bass resonant frequency is the parallel resonance of L_1 and C_1 .

Fig. 20.3. Equivalent electrical circuit providing the same impedance characteristic up to 400 c/s as a moving-coil loudspeaker. Typical values are $L_0 = 0.0024$ H, $R_0 = 10.4$ ohms, $L_1 = 0.018$ H, $R_1 = 71.6$ ohms, $C_1 = 282$ μ F.

The impedance so far discussed is called the "free" impedance; there is also the "blocked" impedance which is measured with the voice coil prevented from moving. The "motional" impedance is found by a vector subtraction of the "blocked" from the "free" impedance. The difference between the free and blocked impedances is small except in the vicinity of the bass resonant frequency, where the motional impedance becomes the major portion of the free impedance (Refs 13, 41).

Refs. 13, 13A, 14, 15, 26 (No. 2), 36, 37, 41, 47, 70.

FIG. 20.4

Phase Angle: The phase angle versus frequency characteristic of a typical moving-coil loudspeaker is given in Fig. 20.4. The impedance is resistive at two frequencies only, being capacitive between the two points and inductive at lower and higher frequencies. The resistive and reactive components are shown in Fig. 20.5. Refs. 13, 13A, 37, 41, 61.

Fig. 20.4. Phase angle versus frequency characteristic of a typical popular loudspeaker (same as Fig. 20.2).

(v) Frequency response

When used on an adequate flat baffle, a moving-coil loudspeaker only operates satisfactorily at and above the bass resonant frequency. The upper limit of frequency response rarely extends much beyond 6000 c/s for popular 10 or 12 inch single coil, single cone loudspeakers. Any further extension adds appreciably to the cost. If wide frequency range is required, there is a choice between a complex single unit—see (iii) above—and a multiple unit (Sect. 5). Refs. 13, 13A, 14, 15, 26 (No. 1), 42, 61, 70.

Fig. 20.5. (A) Resistive and (B) Reactive components of the impedance of a typical loudspeaker. Ref. 37.

(vi) Efficiency

Loudspeaker efficiency may be regarded either as the efficiency of the loudspeaker itself, or in the form of available power efficiency.

The efficiency of the loudspeaker itself is the ratio of the radiated acoustical power to the electrical input power, and is not influenced by the regulation of the power source. The efficiency of moving-coil cone loudspeakers on large flat baffles varies from about 2% to 10% at 400 c/s, depending on the design and on the flux density, 3% being a typical average. The maximum possible electro-acoustical efficiency is given by (Fig. 20.7)

$$\eta_{max} = R_2 / (R_0 + R_2 + R_3) \quad (2)$$

and the electro-mechanical efficiency is given by

$$\eta_{em} = (R_2 + R_3) / (R_0 + R_2 + R_3) \quad (3)$$

where R_0 = blocked (d.c.) resistance of voice coil

R_2 = equivalent radiation resistance

and R_3 = equivalent frictional and eddy current loss resistance.

The electro-acoustical efficiency is always less than the electro-mechanical efficiency owing to the losses represented by R_3 . It is possible to measure the electro-mechanical efficiency fairly readily because $(R_2 + R_3)$ is the motional resistance, and

$$(R_2 + R_3) = \text{free resistance} - R_0 \quad (4)$$

but the accuracy is very poor except at frequencies in the region of the bass resonant frequency.

The available power efficiency is usually defined as the electrical power available to the load when the loudspeaker is replaced by a resistance equal to the rated load impedance with a constant voltage applied in series with the loudspeaker measurement source impedance (see pp. 812, 874-876). The electrical power W_{AS} available to the loudspeaker is

$$W_{AS} = E_G^2 R_{SR} / (R_{SG} + R_{SR})^2$$

where E_G = r.m.s. value of constant source voltage

R_{SR} = loudspeaker rating impedance

and R_{SG} = loudspeaker measurement source impedance.

If R_{SG} = 40% of R_{SR} (as in SE-103, see page 874), then the power available to the load will be half that when $R_{SG} = 0$. Maximum available power efficiency occurs at the bass resonant frequency if the baffle is sufficiently large and if the amplifier output resistance is fairly high, but if the output resistance is low, the available efficiency may be less at this frequency than at some higher frequency. The available power efficiency/frequency characteristic at low frequencies is affected by the type of baffle—see Sect. 3(iii) and (iv).

FIG. 20.7

Fig. 20.7. Equivalent circuit for power considerations, at frequencies above the bass resonance. The values of R_2 , R_3 and C_m are not constant with change of frequency.

Refs. to efficiency, 13, 13A, 14, 15, 36, 43, 54 (Part 3), 56, 70, 71, 74, 95, 121, 156.

References to equivalent circuits, 13, 13A, 15 (page 135), 41, 43, 54 (Part 3), 59, 75, 166, 188.

(vii) Directional characteristics

At low frequencies (up to 400 c/s for a 10 inch cone) a cone has only very slight directional characteristics. The angle of radiation from a flat disk 10 inches in diameter for a decrease of 4 db in sound pressure as compared with that on the axis is :

Frequency	678	1355	2710	5420	c/s
Angle (approx.)	180°	70°	35°	18°	

In practice it is possible to improve the angle of radiation by various expedients. One is to fit a deflector or diffusing lens (Ref. 120) so as to spread the higher frequency waves. Another is to use corrugations (compliances) in the cone so that only a small central area is vibrating at the higher frequencies. A further expedient is to use two co-axial loudspeakers and a frequency dividing network, the high frequency unit having some form of deflector. The ordinary popular loudspeaker is highly direc-

tional at high frequencies, but the best of the expensive designs are capable of 120° radiation up to 15 000 c/s (Refs. 36, 61).

General references : 13, 14, 15, 54 (Part 2), 70.

(viii) Field magnet

Field magnets may be either electro-magnets or permanent magnets. In either case the requirement is to provide the greatest possible flux density in the air gap. Fidelity loudspeakers should have a uniform field up to the limits of movement of the voice-coil ; cheaper models are usually lacking in this respect. Alternatively the voice coil may be longer than the gap length (Ref. 15).

Permanent magnets have advantages in that they have lower heat dissipation, leading to a lower ambient temperature for the voice coil, and the voltage drop across a suitable choke is less than that across the field coil.

Increasing the flux density increases the efficiency, the output and the damping ; it reduces the rise of impedance at the bass resonant frequency. There is an optimum value of flux density to give the most nearly uniform frequency response (Ref. 56, Fig. 3).

(ix) Hum-bucking coil

Some electro-magnetic fields are fitted with a hum-bucking coil connected in series with the voice coil such that the field coil induces equal hum voltages in the voice coil and hum-bucking coil. By connecting the hum-bucking coil and the voice coil in series opposition, the hum due to ripple in the field is minimized.

(x) Damping

Damping on a loudspeaker is partly acoustical, partly frictional, and partly electro-magnetic. The electro-magnetic damping is a function of the effective plate resistance of the power amplifier.

FIG. 20.8

Fig. 20.8. *Equivalent circuit of loudspeaker at bass resonant frequency, showing damping effect of amplifier output resistance R_G .*

effect on the Q of the tuned circuit.

At the bass resonant frequency, the Q of the tuned circuit is given by—

$$\text{Case 1—} R_G \text{ is infinite } Q = \omega_0 C_1 R_1$$

$$\text{Case 2—} R_G = 0 \quad Q = \omega_0 C_1 \frac{R_1 R_0}{R_1 + R_0}$$

$$\text{Case 3—general } Q = \omega_0 C_1 \frac{R_1(R_0 + R_G)}{R_1 + R_0 + R_G}$$

where ω_0 is angular velocity at the bass resonant frequency.

Critical damping is defined* as given by $Q = 0.5$.

Hence for critical damping,

$$R_G = \frac{R_1 + R_0 - 2\omega_0 C_1 R_1 R_0}{2\omega_0 C_1 R_1 - 1} \quad (5)$$

*See "American Standard Definitions of Electrical Terms" A.S.A. C42—1941 (05.05.365) ; also C. E. Crede "Vibration and Shock Isolation" John Wiley & Sons, Chapman & Hall Ltd. 1951, p. 171, and other textbooks on vibration. However some engineers take $Q = 1$ as critical damping.

From Fig. 20.8 it will be seen that critical damping is only possible with a positive value of R_G when R_0 is not too high, that is to say with loudspeakers having fairly high efficiencies, since the values of L , and C , are functions of the flux density. The damping of any loudspeaker may be increased by increasing the flux density.

In general, there is no advantage in using greater than critical damping.

With enclosed cabinet loudspeakers as a result of the effect on frequency response, the value of Q should not fall below 1, and the most desirable all-round condition appears to be with Q from 1.0 to 1.5—see Sect. 3(iii).

Alternatively, if the impedance is carefully measured and the impedance curve plotted over the region of the bass resonant frequency, the frequencies of the two half-power points may be noted, and the Q of the loudspeaker may be computed from the relation

$$Q \approx \left(\frac{f_0}{2\Delta f} \right) \left(\frac{R_0 + R_G}{Z_m + R_G} \right) \quad (6)$$

where f_0 = bass resonant frequency

$2\Delta f$ = band width at half power point (3 db below maximum impedance)

R_0 = voice coil resistance

Z_m = maximum value of the impedance (i.e. at f_0)

and R_G = effective plate resistance, referred to the secondary.

The measurements of frequency during this test are somewhat critical. The article by Preisman (Ref. 146) gives further details, although it does not derive eqn. (6) in this form.

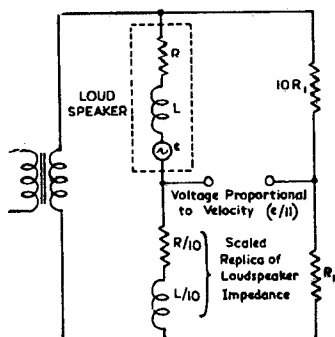

FIG. 20.9

Fig. 20.9. Bridge circuit to give a voltage proportional to the velocity of the cone, to be fed back to the input. (Ref. 184).

in the electrical damping is possible by the use of positive current feedback combined with negative voltage feedback which can make the effective plate resistance zero or negative (Refs. 157, 158, 200, 201).

Alternatively, the e.m.f. generated by the movement of the cone may be fed back degeneratively to the input of the amplifier. One method of achieving this result is to arrange a special bridge circuit (Fig. 20.9) to provide the voltage to be fed back. The amplifier must have good characteristics with very low phase shift. This has been used satisfactorily over a frequency range from 10 to 1000 c/s, using a standard 12 inch loudspeaker, whose coil velocity was made proportional to input amplitude and completely independent of frequency (Refs. 184, 186, 148B, 191, 198).

The majority of direct radiator loudspeakers have values of Q between 8 and 18 with a high valve plate resistance, although this may be decreased very considerably with a low effective plate resistance. Tests have been carried out to demonstrate the effect of a low plate resistance on the damping of a loudspeaker at the bass resonant frequency (Refs. 13A Fig. 6.30, 126, 132).

While there is no doubt that it is desirable to achieve a near approach to critical damping, the results are very much masked by the effects of the listening room which behaves as a resonant structure. In one case a room showed 8 resonances below 100 c/s, with Q values of the order of 12 to 15, and all above 8 (Ref. 155).

There are some loudspeakers in which the efficiency is too low to permit sufficient damping by reduction of the effective plate resistance. In these cases improvement

Another method is to wind a separate feedback coil of very fine wire over the existing voice coil in a conventional loudspeaker. The voltage induced in this coil by the motion of the voice coil is a pure motional voltage at most frequencies. This voltage may be used as a feedback voltage to increase the damping and to reduce distortion arising from non-linearity of the cone suspension and from fringing of the magnetic field..

At very high audio frequencies the mutual inductance between the driving voice coil and the feedback coil produces in the feedback voltage a component which is dependent on the induction between the coils rather than on the motion alone. This difficulty is overcome by incorporating additional mutual inductance equal in value but of opposite sign, between the voice coil and feedback circuits at a point external to the magnetic field (Ref. 148).

SECTION 3 : BAFFLES AND ENCLOSURES FOR DIRECT-RADIATOR LOUDSPEAKERS

(i) *Flat baffles* (ii) *Open back cabinets* (iii) *Enclosed cabinet loudspeakers* (iv) *Acoustical phase inverter ("vented baffle")* (v) *Acoustical labyrinth loudspeakers* (vi) *The R-J loudspeaker* (vii) *Design of exterior of cabinet.*

(i) Flat baffles

The baffle is intended to prevent the escape of air pressure from the front to the back of the cone, which is out of phase at low frequencies. In many theoretical calculations an infinite flat baffle is assumed, but in practice a baffle is only made just large enough to produce the desired results. When the air distance around the baffle from front to back of the cone is equal to the wavelength, there is a dip in the response. For this reason, baffles are frequently made of irregular shape or the loudspeaker is not mounted in the centre, the object being to produce air distances from front to back of the cone which vary in a ratio at least 5 : 3. For example, with a 4 ft. square baffle and a 10 in. cone, the centre of the cone may be 18 inches from each of two adjacent sides.

The size of a square baffle, with the loudspeaker mounted off-centre, for desired bass response is given approximately by the following table for a 10 inch diameter cone (Ref. 13A) :

Minimum frequency	300	170	80	c/s
Side of square	2	4	8	feet

Below this minimum frequency, and below the loudspeaker bass resonant frequency, the response falls off at the rate of 18 db/octave.

The best flat baffle is provided by mounting the loudspeaker in a hole in the wall of a room, with the rear of the cone radiating into another room.

In a very large flat baffle, a loudspeaker which has a sufficiently high Q will have a peak in the response characteristic at, or somewhat above, the bass resonant frequency ; below the peak frequency the attenuation is at the rate of 12 db/octave. Refs. 13, 13A, 14, 15 (Part 2), 75, 147, 151, 177.

(ii) Open back cabinets

An open back cabinet, as commonly used with radio receivers of the console, table or mantel type, has a resonance in the enclosure to the rear of the cone. This resonance causes a peak in the response characteristic at a frequency which is mainly a function of the cabinet although also influenced by the loudspeaker characteristics. For example, a cabinet 2 feet \times 2 feet \times 8 inches depth gave peak response at 180 c/s with a loudspeaker having a bass resonant frequency of 20 c/s, while the same cabinet gave a peak response at 110 c/s with a loudspeaker having a bass resonant frequency of 100 c/s. (Ref. 13A, Figs. 6.19B and 6.20B). The height of the peak is about 3 to 6 db for shallow cabinets or about 6 to 10 db for deep cabinets.

Open back cabinets are undesirable for good fidelity. If unavoidable, they should be as shallow as possible, with the minimum of acoustical obstruction, particularly at the back of the cabinet. Open back cabinets should be placed at least 6 inches out from the wall.

References to open back cabinets : 13A, 14, 147, 151, 188.

(iii) Enclosed cabinet loudspeakers

An enclosed loudspeaker is one which is totally enclosed so that there can be no interference between the front and back of the cone. There is no critical value for the volume of the enclosure but a large volume is desirable because it reduces the rise in resonant frequency above that on a large flat baffle. The increase in resonant frequency for Jensen speakers is shown in Fig. 20.10 and may be taken as fairly typical. There is practically no non-linear distortion caused by the suspension, since this only contributes a small part of the total stiffness.

Fig. 20.10. Increase in resonant frequency of totally enclosed cabinet loudspeaker versus cabinet volume. For each nominal speaker size, the upper limit of the shaded area corresponds to speakers with highest compliance, while the lower limit corresponds to those with least compliance. (Ref. 151).

The enclosure should be adequately damped by at least $\frac{1}{2}$ inch thickness of damping material all over (or double this thickness on one of each pair of parallel surfaces), although this is insufficient to eliminate standing waves at low frequencies.

The ineffectiveness of sound absorbent linings at low frequencies is due to the fact that all the absorbent material lies within a small fraction of a wavelength of the inner wall, which is a velocity node. Without motion of the air particles, or of the material itself, acoustical power cannot be absorbed and dissipated. Shorter (Ref. 135) has examined the problem of standing waves, and puts forward the method of damping by partitions, concentrating the absorbing material ($\frac{1}{4}$ inch carpet felt) into one or two partitions strategically placed across the cabinet. Those sections of the cabinet which are separated from the cone by one or more sound absorbing partitions receive little sound at the high frequencies and therefore require very little acoustical treatment. The loudspeaker back e.m.f. may be measured by a bridge circuit and should show a single peak without subsidiary peaks over the range from 30 to 200 c/s.

It is desirable for the enclosure to have appreciably different values of linear dimensions—typical ratios are 1 : 1.5 : 2.7. However, the longest dimension should be less than $\frac{1}{4}$ of the wavelength at the lowest working frequency. The enclosure should have rigid walls—timber at least $\frac{1}{2}$ inch thick, and braced where necessary.

One limitation of the enclosed cabinet loudspeaker is the bass attenuation which occurs with critical damping, although this only happens with high flux density and low amplifier output resistance—see below under Equivalent Circuit.

Some loudspeakers have been designed specially for use with enclosed cabinets. These usually have very low bass resonant frequencies, when measured on a flat baffle, so that when loaded by the enclosure, the resonant frequency is still sufficiently low.

The volume of the cabinet is given below for some examples :

Western Electric 755A	8 in.	70 c/s	2	cubic feet
„ „ 756A	10 in.	65 c/s	2½	„ „

Equivalent circuit

Fig. 20.11 is a simplified electrical equivalent circuit of the acoustical system of the loudspeaker (Ref. 135).

L_U represents cone mass + effect of radiation reactance.

R_U represents radiation resistance (which varies with frequency)†.

C_C represents acoustical capacitance of cabinet volume.

C_U represents equivalent capacitance of cone suspension.

R_S represents effect of electrical circuit of loudspeaker and driving amplifier reflected into acoustical circuit. The mechanical resistance of the cone suspension may be taken as being included with R_S .

E_S = constant voltage generator.

I_U = alternating air current produced by cone, which is proportional to cone velocity.

Now $R_S \propto \frac{B^2}{R_G + R_0}$ at low frequencies

where B = flux density in gap,

R_G = output impedance of amplifier referred to voice coil circuit,

and R_0 = resistance of voice coil.

The acoustical response of the loudspeaker is proportional to $I_U f$.

FIG. 20.11

Fig. 20.11. Equivalent electrical circuit of acoustical elements in an enclosed cabinet loudspeaker at low frequencies. (Ref. 135).

The voltage $E_{LU} = 2\pi f L_U I_U \propto I_U f \propto$ acoustical response. Therefore the variation with frequency of E_{LU} , for any one value of L_U , gives the frequency response of the loudspeaker. Over the frequency range for which the equivalent circuit is valid, and the wavelength is large compared with the size of the cone, the loudspeaker can be reduced—so far as frequency response is concerned—to a half-section high-pass filter working into open circuit. Small values of R_S , resulting from low flux density or high amplifier output impedance, give a resonance peak and bad transient response, while large values of R_S , corresponding to high flux density and low amplifier output impedance, can give a serious loss of bass.

Fig. 20.12 shows curves for three values of R_S and hence for three values of Q , for a resonant frequency of 45 c/s. This indicates that values of Q less than about 1 result in serious attenuation of low frequencies.

*Resonance 17 c/s on flat baffle.

†Note that R_U is small compared with other impedances in the circuit.

FIG. 20.12

Fig. 20.12. Theoretical response of enclosed cabinet loudspeaker for various values of the effective damping resistance R_s . Resonance frequency 45 c/s. (Ref. 135).

(iv) Acoustical phase inverter ("vented baffle")

Also known as a bass reflex baffle.

This has a vent* or duct in the front of the cabinet which augments the direct radiation from the cone at low frequencies (Fig. 20.13). The box should be at least partially lined with sound absorbent material to absorb the higher frequencies, but should not be too heavily damped at frequencies below about 150 c/s. The cabinet should be strongly made of heavy timber with adequate bracing to prevent vibration. Many cabinets which have been built for this purpose are partially ineffective as the

FIG. 20.13

Fig. 20.13. Typical corner cabinet with vented baffle, designed for a Goodmans Axiom 12 inch loudspeaker with a bass resonant frequency of 55 c/s, which can be used with a speaker resonant at 75 c/s by removing the tunnel. Cubic capacity about 8000 cu. ins. = 4.6 cu. ft. (Ref. 182).

*An alternative form uses several tuned resonators from the inside to the outside of the cabinet (Ref. 18).

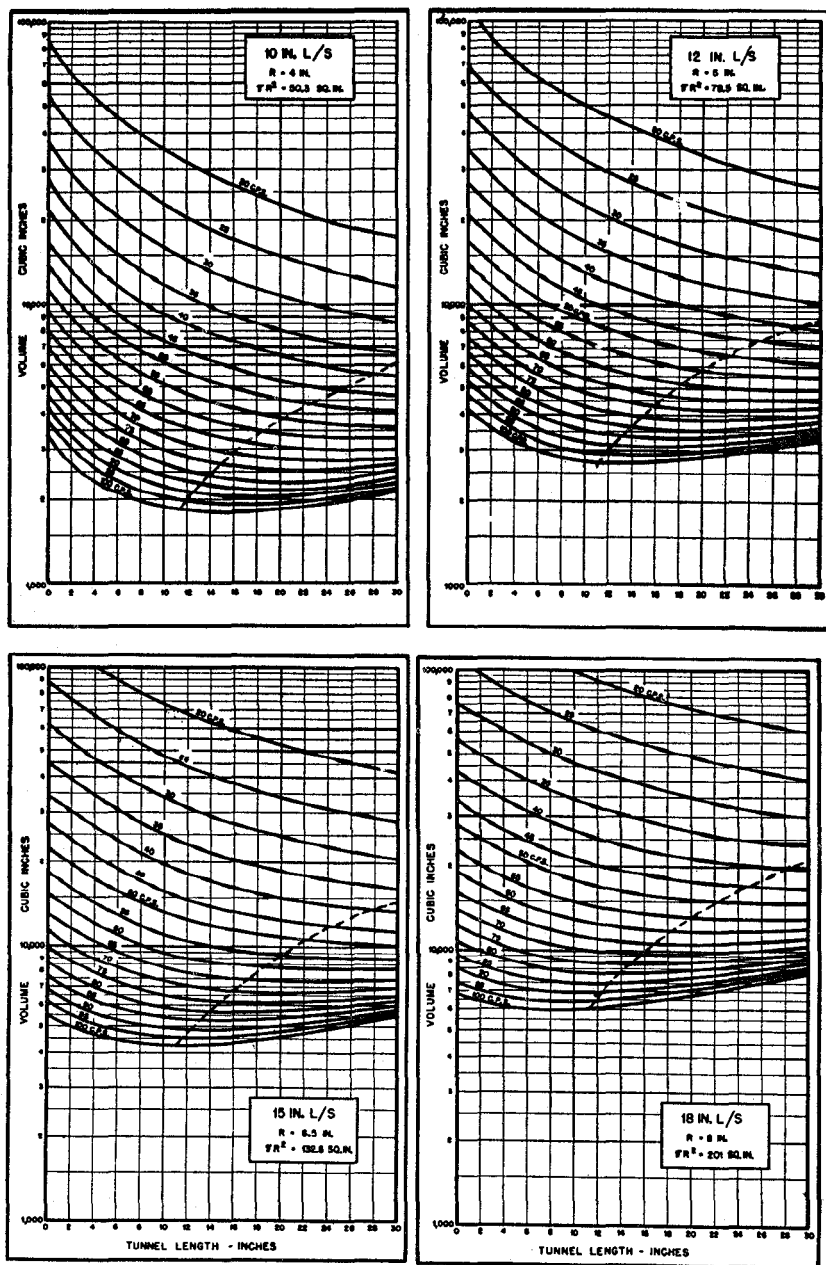

FIG. 20.14

Fig. 20.14. Curves showing tunnel length for 10, 12, 15 and 18 inch Goodmans loudspeakers with bass resonant frequencies from 20 to 100 c/s. The tunnel length should not exceed 1/12 of the wavelength of the speaker bass resonant frequency; points to the right of the broken lines should not be used (Ref. 182).

result of wall vibration under the extremely arduous conditions of operation. Other materials which have been used satisfactorily include brick and concrete.

Vented baffles are normally designed so that the loudspeaker bass resonant frequency is matched to the acoustical resonant frequency of the cabinet ; unmatched combinations are, however, also used.

(A) Matched vented baffles

The merits of the vented baffle, when correctly applied, include

- (1) improved bass response,
- (2) much reduced amplitude of movement of the cone at the resonant frequency, and hence reduced distortion at the same power output or increased power handling capacity for the same distortion,
- (3) decreased peak electrical impedance,
- (4) increased acoustical damping over a limited range of low frequencies (not including the vent resonance),
- (5) increased radiation resistance and decreased reactance of the loudspeaker at low frequencies.

The vented baffle appears to be preferred by most engineers to the acoustical labyrinth, even apart from cost.

The vent area should normally be the same as the effective radiating area of the cone, and the curves in Fig. 20.14 are based on this relationship. Thus the cross-sectional area of the tunnel is given by πR^2 where R is the radius of the piston equivalent to the speaker cone at low frequencies. The tunnel may have any length from the thickness of the timber (i.e. when no tunnel, as such, is constructed) to a maximum of approximately one twelfth wavelength, indicated by the broken curves in Fig. 20.14 ; consequently the area to the right of the broken curves should not be used.

A reasonable length of tunnel enables a smaller enclosure to be used, but the space between the end of the tunnel and the rear of the cabinet should not be less than R . The volume occupied by the loudspeaker must be added to the volume derived from the curves to obtain the volume of the enclosure. If the volume of the loudspeaker is not known, the following approximation may be used :

Volume displaced by loudspeaker :

Loudspeaker dia.	8	10	12	14	16	18	ins.
Volume (approx.)	250	400	650	1000	1600	2300	cu. ins.

Also add volume displaced by internal timber bracing.

Note that no allowance should be made for the thickness of the damping material.

The curves for the volume of the cabinet are derived from the relationship

$$V = \pi R^2 \left[\frac{1.84 \times 10^8}{\omega^2} \times \frac{1}{1.7R + L} + L \right] \quad (1)$$

where V = volume in cubic inches,

R = radius of equivalent piston in inches,

L = length of tunnel in inches

and $\omega = 2\pi \times$ frequency of vent resonance.

When correctly designed a vented baffle loudspeaker has two impedance peaks, one above and one below the vent resonance, while the same loudspeaker on a flat baffle has only one impedance peak—see Fig. 20.15. In all cases where optimum performance is desired, the electrical impedance characteristic below 150 c/s should be measured using a constant current source and a voltmeter. The ratio of the two peak frequencies should not exceed about 2.4 : 1 nor be less than about 1.5 : 1 and any subsidiary peaks caused by standing waves should be removed by the addition of damping material (as for the enclosed cabinet above ; see also Fig. 20.17).

Tests for acoustical output should not be made until the cabinet dimensions and damping have been adjusted to give the correct impedance characteristic. In general, with a vented baffle the bass range over an octave or more is increased by several decibels over either a very large baffle or an enclosed cabinet loudspeaker.

The power gain may be greater than 3 db since the air loading of the cone may be increased appreciably over the lower octave of the frequency range. For about one third of an octave above and below the resonant frequency of the system, the greater

FIG. 20.15

Fig. 20.15. Impedance versus frequency characteristics of a 12 inch loudspeaker (1) in free air (2) on a flat baffle and (3) in a vented baffle. Curve (4) shows two "staggered" vented baffle loudspeakers in parallel (measured).

part of the energy is radiated by the port. Phase shift occurs suddenly at the resonant frequency, so that the radiation below this frequency is reduced, being the vector difference between the two sources.

At the resonant frequency, the air in the vent or tunnel moves vigorously while the acoustical impedance on the rear of the cone is resistive and reaches a maximum.

At the frequency of the vent resonance, the motion of the speech coil is so small that no appreciable electrical damping can take place and there is no danger of bass attenuation such as may occur with the enclosed cabinet or flat baffle. The energy dissipated by mechanical resistances and by the radiation of sound is generally small, so that the vent resonance on which the maintenance of the bass response depends, is quite lightly damped. For this reason, when good fidelity is required, the vent resonance frequency should not be greater than 60 c/s. (Ref. 135).

A corner speaker cabinet for 15 inch cones is described in Ref. 100, while one for 12 inch cones is described in Ref. 105. These both employ a vented baffle arrangement with the vents on both sides of the cabinet, between the cabinet and the walls.

Equivalent circuit (Ref. 135)

The Fig. 20.16 is a simplified electrical equivalent circuit of the acoustical system and is based on Fig. 20.11 with the addition of R_V representing the radiation resistance of the vent, and L_V , the acoustical inductance of the vent plus the effects of its radiation reactance. Let f_V be the frequency of the vent resonance (i.e. the resonance of L_V and C_C) and assume that the cone resonant frequency is the same. Below f_V , the series combination $L_V C_U$ appears as a capacitance and the parallel combination $L_V C_C$ as an inductance, and the overall effect is to produce a series resonance at some frequency f_1 in this region. At frequencies above f_V , $L_U C_U$ appears inductive and $L_V C_C$ capacitive, and a second series resonance appears at some frequency f_2 . The resonances at f_1 and f_2 are responsible for the characteristic double hump in the electrical impedance frequency characteristic of a vented baffle and are subject to the circuit damping represented by R_S .

FIG. 20.16

Fig. 20.16. Equivalent electrical circuit of vented baffle loud-speaker at low frequencies. (Ref. 135).

I_U and I_V represent the alternating air current flow in the cone and vent respectively. I_U originates at the back of the cone and I_V must therefore be reversed in phase with respect to I_U if the acoustical output of the vent is to reinforce that from the front of the cone. At f_V , the frequency of the vent resonance, I_U and I_V are approximately in quadrature; above f_V the desired reinforcing condition is approached, but below f_V the two air currents oppose one another.

The performance of the system is determined by the value of f_V , which is normally made equal to the loudspeaker bass resonant frequency, and also by the ratio L_V/C_C . With a large cabinet and large vent (C_C large, L_V small) the response can rise to a peak in the bass, while a small cabinet and a small vent (C_C small, L_V large) will give much the same effect as a completely closed cabinet, i.e. there may be bass loss.

FIG. 20.17

Fig. 20.17. Free-air axial response of a vented baffle loudspeaker and corresponding impedance characteristics (a) conventional damping (b) optimum damping (c) excessive damping of partition. (Ref. 135.)

Between these two extremes, there will be a pair of values for L_V and C_C which gives the best approximation to a flat frequency response. The cabinet volume required for this last condition depends on the efficiency of the loudspeaker unit and the output impedance of the amplifier. Fig. 20.17 shows the response and impedance characteristics of a 15 inch unit in a 10.5 cu. ft. cabinet. Curves (a) are for the cabinet lined with kapok quilt and carpet felt, with internal space left free; a serious internal resonance shows at about 120 c/s. Curves (b) show how this resonance was suppressed by introducing into the cabinet a partition having a window of area about 170 sq. ins. covered with three layers of $\frac{1}{4}$ in. carpet felt. This damping does not seriously affect the frequency response but it suppresses the lower frequency impedance hump. Curve (c) shows the effect of too many layers of felt on the window. In this case the design aimed at a nearly level frequency characteristic down to 50 c/s.

See also Ref. 211 for other form of equivalent circuit.

(B) Unmatched vented baffles

Unmatched vented baffles preferably incorporate a loudspeaker having a very low bass resonant frequency. The cabinet is designed quite independently of the loudspeaker and may, if desired, be fitted with an adjustable vent. In the latter case the maximum vent area may be somewhat greater than the loudspeaker cone area, while in the other extreme the vent may be completely closed. Using a cabinet 2 ft. \times 2 ft. \times 18 ins. (volume 6 cu. ft.) and a loudspeaker with a bass resonant frequency of 30 c/s, the frequency of maximum acoustical pressure increases from 40 to 60 thence to 75 c/s as the vent area is varied from small to medium to large respectively. The height of the maximum response above that at 400 c/s rises from 4 db (small vent) to 6 db (medium vent) thence to 8 db (large vent) (Ref. 13A).

In other cases a loudspeaker is used which has a bass resonant frequency of conventional value, but here also the vent frequency is higher than the loudspeaker bass resonant frequency. This permits the use of a smaller cabinet while still retaining some of the good features of a matched vented baffle, although it is not so good on transients. In all cases an adjustable vent area is desirable. Tunnels are not generally used, since they give no flexibility of adjustment.

The vent frequency should not exceed (say) 90 c/s, otherwise the tone will be poor. This limits the reduction in cabinet volume to about $2\frac{1}{2}$ cubic feet.

The shape of the cabinet, as well as its volume, affect its frequency response and impedance characteristics. For example, a change from 30 ins. \times 15 ins. \times 8 ins. to an equivalent volume 15 ins. \times 15 ins. \times 16 ins. caused an increase from 45 to 58 c/s in the lower impedance peak and from 75 to 110 c/s in the higher peak (Ref. 117). In the cubic shape of cabinet the addition of an internal partition between loudspeaker and vent, extending approximately half-way from front to back, causes a reduction in the frequencies of both impedance peaks, and is claimed to give improved results on both speech and music (Ref. 117).

Careful attention to damping, along the lines given above for both enclosed cabinets and matched vented baffles, would be well repaid.

(c) **Special types of vented baffle loudspeakers**—see Supplement.

Refs. to vented baffles : 4, 9, 12, 13, 13A, 29, 36, 76 (Part 2), 85, 96, 113, 116, 116A, 117, 118, 135, 143, 144, 147, 150, 151, 166, 168, 175, 182, 188, 202, 209, 211, 225, 229, 230.

(v) Acoustical labyrinth* loudspeaker

The acoustical labyrinth gives a performance somewhat similar to that of a vented baffle. The rear of the cone drives a long folded tube, lined with sound absorbing materials, the mouth of which opens in front of the cabinet (Fig. 20.18). The length of the tube is approximately 7 feet (measured on the centre-line) for nearly linear response down to 70 c/s. The loudspeaker bass resonance loaded by the labyrinth is preferably at a frequency at which the wavelength is four times the length of the tube ; in the example this is 40 c/s. If this latter condition is not fulfilled, the frequency response will not be linear. The loudspeaker resonance frequency in the example was reduced from 50 to 40 c/s by the loading of the labyrinth. This is the only form of baffle which reduces the bass resonant frequency of a loudspeaker. The rise of impedance from 400 c/s down to the bass resonant frequency is reduced considerably by the acoustical labyrinth—in one case the ratio was reduced from 10 : 1 to 4.3 : 1 (Ref. 27).

References 13, 14, 27, 28, 188, 204, 225 Part 2.

(vi) The R-J loudspeaker

The R-J loudspeaker has a particularly compact bass unit, to which any desired tweeter can be added. In one design a 15 inch woofer unit is mounted in a cube with 18 inch sides and fundamental bass reproduction is claimed down to 20 c/s. Only the forward radiation is used, but both sides of the cone are loaded. The back of the speaker is completely enclosed within a small stiff cavity. The front of the woofer works into a carefully designed rectangular duct, and the sound issues from a slot extending across the base of the enclosure.

Refs. 189, 190, 219, 234. See also Supplement.

(vii) Design of exterior of cabinet

The sharp corners on the usual more-or-less box shaped cabinet, particularly those of the side in which the loudspeaker is mounted, produce diffraction effects causing a sequence of peaks and valleys up to ± 5 db in the response characteristic. The best shaped enclosure is a complete sphere, while the worst is a cube with the loud-speaker in the centre of one side. A rectangular parallelepiped (box shaped) with the loudspeaker closer to one of the short sides than to the other is an im-

provement over the symmetrical cube, but still far from the ideal. A very close approach to the ideal is given by a rectangular truncated pyramid mounted on a rectangular parallelepiped (Fig. 20.19) Ref. 193.

In all cases it is desirable that the edge of the cone should be flush with the front of the cabinet.

SECTION 4 : HORN LOUDSPEAKERS

(i) *Introduction* (ii) *Conical horns* (iii) *Exponential horns* (iv) *Hyperbolic exponential horns* (v) *Horn loudspeakers—general* (vi) *Folded horn loudspeakers* (vii) *High frequency horns* (viii) *Combination horn and phase inverter loudspeakers for personal radio receivers* (ix) *Materials for making horns.*

(i) Introduction

A horn is used in conjunction with a diaphragm or cone loudspeaker for the purposes of increasing the acoustical loading on the diaphragm (over a limited frequency range) and thereby increasing the efficiency and reducing non-linear distortion. With a horn, inside the useful frequency limits, the movement of the diaphragm is much less and the acoustical damping is much greater than on a flat baffle, for the same acoustical power output. Thus with a horn, a smaller diaphragm can radiate a given acoustical power.

A horn is essentially a device which transforms acoustical energy at high pressure and low velocity to energy at low pressure and high velocity.

Horns are of various shapes—conical, parabolic, hypex and exponential, but the exponential is most widely used.

A well designed and well executed exponential or hypex horn loudspeaker is capable of giving a flatter frequency output characteristic with less distortion than any other form of loudspeaker.

References 13A, 14, 15, 59, 82, 142, 177, 188.

(ii) Conical horns

A conical horn is one having straight sides ; it functions in a manner similar to an exponential horn but its throat resistance is less than that of an equivalent exponential horn, except at high frequencies. Conical horns are sometimes used with cone type loudspeakers to give directional characteristics ; the angle of propagation is then approximately equal to the angle of the horn.

Conical horns are sometimes used, for economy, as the first section at the throat end, with an exponential horn forming a second section at the mouth end. This device is frequently used with folded horns. Sometimes an approach to an exponential horn is made with a number of conical sections, each with a different degree of taper. All such compromises lead to inferior performance.

References 13A, 14, 15, 142, 175.

(iii) Exponential horns

In an exponential horn, the cross-sectional area (S) at any point distant x feet along the axis is given by

$$S = S_0 \epsilon^{mx} \quad (1)$$

where S_0 = cross-sectional area at throat (sq. feet)

ϵ = 2.71828 (Napierian base)

and m = flaring constant.

Equation (1) may be put into the form

$$S/S_0 = \epsilon^{mx}$$

Therefore $mx = \log_{\epsilon} (S/S_0) = \log_{10} (S/S_0) \times 2.3026$.

If $(S/S_0) = 2$ then $mx = 0.3010 \times 2.3026 = 0.6931$.

If $(S/S_0) = 4$ then $mx = 0.6020 \times 2.3026 = 2 \times 0.6931$.

We may therefore deduce that

- (1) the cross-sectional area doubles itself each time the distance along the axis is increased by $0.6931/m$.
- (2) the value of m (in inverse feet) is equal to 0.6931 divided by the distance along the axis in feet for the cross-sectional area to double itself.

This is shown more clearly below where $l' = 0.6931/m$:

Distance along axis	Cross-sectional area
$x = 0$ (at throat)	S_0
$x = l'$	$S = 2S_0$
$x = 2l'$	$S = 4S_0$
$x = 3l'$	$S = 8S_0$ etc.

The corresponding diameter and side of circular and square cross sections are :

Distance along axis	Diameter	Side of square
$x = 0$ (at throat)	d_0	a_0
$x = l'$	$1.414d_0$	$1.414a_0$
$x = 2l'$	$2d_0$	$2a_0$
$x = 3l'$	$2.818d_0$	$2.818a_0$
$x = 4l'$	$4d_0$	$4a_0$

The flare cut-off frequency for an infinite exponential horn is given by

$$f_0 = m \times 89.5 \quad (2a)$$

while the corresponding cut-off wavelength is

$$\lambda_0 = 12.6/m \quad (2b)$$

where m is expressed in inverse feet.

Fig. 20.20. Exponential horn of either circular or square cross-section.

Design on basis of minimum useful frequency

The characteristics below are given as a function of f' , the lower frequency limit for satisfactory horn loading. The value of f' is arbitrarily taken as 1.2 times the flare cut-off frequency for an infinite exponential horn; it is, of course, influenced also by the dimensions of the mouth and the length of the horn.

The value of m , the **flaring constant**, should then be equal to or less than $10.5/\lambda'$ (2c)

where λ' = wavelength (in feet) of the minimum useful frequency (f') for satisfactory horn loading.

Minimum useful frequency (f')	50	100	150	200	c/s
Maximum useful wavelength (λ')	22.6	11.3	7.52	5.65	feet
Maximum value of m	0.47	0.93	1.40	1.85	inversc feet

The **diameter of the mouth** should preferably not be less than one third of the maximum useful wavelength, while the effect of resonances at the low frequencies may be made negligible by increasing the mouth diameter to two thirds of the maximum useful wavelength (λ'). Taking the smaller mouth diameter, and referring to the minimum useful frequency:

$$\text{Minimum circumference} = 1.05\lambda' = 1200/f' \quad (3)$$

Equation (3) may be applied to any shape of mouth—see table below:

Circumference (min.)	24	12	8	6	feet
Maximum useful wavelength (λ')	22.6	11.3	7.52	5.65	feet
Minimum useful frequency (f')	50	100	150	200	c/s

Horns with circular cross-section

In this case the equation is

$$d = d_0 e^{mx/2} \quad (4)$$

where d = diameter in feet

and d_0 = throat diameter in feet.

$$\text{Diameter at mouth: } d_m = d_0 e^{m l/2} \quad (5)$$

$$\text{or } d_m = d_0 \text{ antilog}_{10} (ml/4.605) \quad (6)$$

$$\text{Length: } l = (4.605/m) \log_{10} (d_m/d_0) \quad (7)$$

For chart see Ref. 39 Chart III.

$$\text{Flaring constant: } m = (4.605/l) \log_{10} (d_m/d_0) \quad (8)$$

If the minimum useful frequency is taken as f' where $f' = 1.2f_0$, and if the minimum diameter of mouth is taken as one third of the wavelength at frequency f' , then m may have its maximum value of $10.5/\lambda'$ and

$$\text{minimum diameter of mouth} = \lambda'/3 = 380/f' \quad (9)$$

$$\text{minimum length} = (500/f') \log_{10} (380/f' d_0) \quad (10)$$

where λ' = wavelength in feet at frequency f'

$$f' = 1.2f_0 = 1.2 \times \text{flare cut-off frequency}$$

d_0 = diameter at throat in feet

and all dimensions are in feet.

Horns with square cross-section

These follow the same laws as horns of circular cross-section having diameters equal to the sides of the square, but the length and mouth dimensions are slightly less for the same minimum useful frequency f' :—

$$\text{minimum side of mouth} = 300/f' \quad (11)$$

$$\text{minimum length*} = (500/f_0) \log_{10} (300/f' a_0) \quad (12)$$

where a_0 = length of side at throat.

For cutting the side of a square horn from a sheet, see Ref. 77.

General references to horn dimensions: 39, 46, 82.

References to theory of exponential horns: 13A, 142, 175, 188.

(iv) Hyperbolic exponential horns ("hypex")

A hyperbolic exponential horn is one which follows the law

$$S = S_0 [\cosh mx + T \sinh mx]^2 \quad (13)$$

where S = cross-sectional area at distance x along the axis in sq. ft. (or in any other convenient units)

S_0 = cross-sectional area at throat in sq. ft.

m = flaring constant

x = distance along the axis in feet

and T = shape parameter (T may have any value from zero to infinity).

*For chart see Ref. 46 Figs. 1 and 2

The cut-off frequency is the same as for an exponential horn having the same flaring constant—see eqn. (2a). When $T = 1$, the horn is exponential. When $T = 1/(mx_0)$ and m is allowed to go to zero, the horn is conical. When $T = 0$ the horn is hyperbolic cosine or catenoidal (Refs. 13A, 123, 140, 142, 188). The name “hypex” is usually applied when T is greater than zero and less than unity.

The value of T in “hypex” horns is usually between 0.5 and 0.7, and within these limits the throat resistance of an infinite horn is more nearly constant than that of an exponential horn, at frequencies slightly above the cut-off frequency. These comparisons are for constant throat, mouth and length of horn; under these conditions a “hypex” horn with T of the order of 0.6 has improved low frequency characteristics as compared with those of an exponential horn. Consequently, for equivalent performance, a “hypex” horn may be made more compact than an exponential horn. A further useful feature of the “hypex” characteristic is that it makes possible a gradual transition from conical, via “hypex” with varying T , to exponential (Ref. 123).

An analysis of the response peaks in finite hyperbolic horns, and design procedure for horns to have peaks at pre-determined frequencies, is given in Ref. 139.

(v) Horn loudspeakers—general

(A) Frequency limitations

The resistive component of the throat impedance drops rapidly below about 1.2 times the flare cut-off frequency. Some output is obtained with finite horns at, and even below, the flare cut-off frequency (Ref. 45), but at frequencies below the flare cut-off frequency there is a strong tendency towards the production of harmonics. Care should therefore be taken to eliminate from the amplifier any appreciable output power below about 1.2 times the flare cut-off frequency, unless the loudspeaker is known to be capable of handling such frequencies without damage or distortion.

The resonant frequency of the diaphragm should not be less than the flare cut-off frequency, and preferably not less than 1.2 times this value, in order to ensure sufficient loading at the resonant frequency.

The only known method for handling frequencies below the flare cut-off frequency of an exponential horn, with good fidelity, is the use of an enclosed air-chamber behind the diaphragm, resonant at a frequency in the vicinity of the flare cut-off frequency, as used with the Klipsch loudspeaker. This air-chamber is designed to provide a capacitive reactance approximately equal to the inductive reactance (inertance) of the horn at the flare cut-off frequency. The volume of the air-chamber is given by eqn. (15) in Sect. 4(vi) below—see also Ref. 31.

(B) Diaphragm and throat

Some horns are designed with the throat area the same as the diaphragm area. Greater acoustical loading is obtained by the use of a larger diaphragm and a sound chamber. The maximum size is limited by the high frequency response—the distances from any parts of the diaphragm to the throat opening should vary by less than one quarter of the wavelength of the highest frequency to be reproduced. The simplest form of sound chamber is Fig. 20.21A, with a single hole in the centre. Better high frequency performance is obtained with the more complex forms of Figs. 20.21 B, C.

Relatively large throats are necessary for high efficiency at low frequencies, and relatively small throats are necessary for high efficiency at high frequencies. Consequently any loudspeaker must be a compromise, and **the highest efficiencies are obtained with limited frequency ranges.**

Second harmonic distortion is generated in the throat and follows approximately the theoretical relationship

$$\text{Percentage second harmonic} = (\sqrt{W}/81) (f_1/f_0) \times 100 \quad (14)$$

where W = acoustical watts per square centimetre of throat area

f_1 = frequency being radiated

and f_0 = cut-off frequency due to flaring (eqn. 2).

FIG. 20.21

Fig. 20.21. Different forms of sound chambers in horn loudspeakers.

For example if a horn with a 40 c/s cut-off is to reproduce a 4000 c/s note, there will theoretically be 8% second harmonic distortion for an acoustical power of 0.01 watt per square inch of horn throat. The actual distortion appears to be about half the theoretical value.

Thus for reasons of both efficiency and distortion, a horn should only be designed to cover a limited frequency range.

(C) Driving units

The simplest driving mechanism is the electro-magnetic type with an iron diaphragm as the armature (Fig. 20.21A).

All modern driving units are of the moving-coil type and may have a diaphragm of aluminium alloy or some form of paper or a cloth base impregnated with synthetic resin.

Well designed direct-radiator loudspeakers may be used as the driving mechanisms for horns. The most suitable size is from 8 to 12 inches diameter for medium power requirements. Some loudspeakers are designed specially for this application.

Where high power output at very low frequencies is required, a 15 inch unit may be used, as in the Klipsch corner horn described below.

(D) Distortion

In addition to the distortion caused by the throat, there is also **distortion due to the sound chamber**. The acoustical capacitance is a function of the position of the diaphragm, and the effect is most apparent at low frequencies where the amplitude is large. This distortion may be reduced by the use of a large sound chamber, thus limiting this unit to low frequencies only. A separate high frequency unit with a small sound chamber may be used, since it will not be required to handle large amplitudes.

Distortion is also caused by a non-linear suspension; this is only serious at low frequencies (Ref. 14, Fig. 8.21). **Distortion at low frequencies due to non-linear suspension** may be reduced by

- (1) the use of a large dynamic driver,
- (2) increased compliance in the suspension,
- (3) an enclosed air-chamber at the rear of the diaphragm as in the Klipsch corner horn.

Another cause of distortion is **frequency modulation** through the Doppler Effect—see Sect. 7(ii)—which can be reduced to small proportions by the use of separate high and low frequency units.

It is impossible to design a horn loudspeaker that covers a wide frequency band and is simultaneously free from non-linear distortion. Thus two separate units for low and high frequencies are essential for fidelity. This is a limitation peculiar to horn loudspeakers.

(E) Efficiency

With horn loudspeakers efficiencies as high as 80% can be achieved over a limited frequency range. A typical horn of the type used in cinema theatres has an efficiency from 30% to 45% over its useful range. The Klipsch corner horn has an efficiency around 50% over its useful range.

(F) Directional characteristics

For wavelengths larger than the mouth diameter, the directional characteristics are approximately the same as for a cone the same size as the mouth. At frequencies above 3000 c/s the directional characteristics are only slightly affected by the flare or length. At intermediate frequencies the directional characteristics are broader than those obtained from a piston (cone) the size of the mouth.

When a number of horns are arranged in a line, a sharp beam will be obtained when the horns are parallel to one another, while a broader beam will be obtained when they are arranged radially.

(G) Electrical impedance

A rise in electrical impedance normally occurs at the diaphragm resonance, although less than that with a direct radiator, with a rise at the higher frequencies as with a moving-coil direct radiator.

On account of the variation in impedance, triode power valves (preferably with negative voltage feedback) are highly desirable for fidelity.

(H) Damping and transients

With a well designed horn of sufficient mouth area, or with a smaller horn in which the resistive loading has a peak in the vicinity of the bass resonant frequency, the acoustical damping at that frequency will be high. The damping due to the output resistance of the amplifier will be additive.

At higher frequencies, experimental results indicate that spurious transients are much lower in horn loudspeakers than with direct radiators. For example (Ref. 155), a 12 inch direct radiator loudspeaker, when loaded by a short horn, gave 12 to 15 db less transient level than when used without the horn, using Shorter's method—see Sect. 7(iii).

(I) Horns and rooms

Horns require larger rooms than direct radiator loudspeakers, even apart from the space occupied by the speaker itself, owing to the roughness of the overlap between the low and high frequency units. The distance from loudspeaker to listener must be greater than that with cone type direct radiators (Ref. 150).

Horn loudspeakers are frequently mounted in the corner of the room, so that the angle between the walls acts as sort of continuation of the horn. Some ingenious corner horns have been developed, for example one in which the difference between the solid angle between the walls and the desired exponential flare is taken up by a suitably shaped "plug" (Ref. 130).

(vi) Folded horn loudspeakers

Owing to the large space required by a horn, much attention has been paid to folded horns. These all involve some loss of the higher frequencies, due to reflections and differences in length of path causing cancellation of some frequencies. The number of folds should be kept to the minimum—most folded horns have only one or two folds. Any increased number of folds, if unavoidable, must be accompanied by a reduction in the maximum frequency.

Concentric folded horns

In these, the high frequency loss may be made fairly small, and it is possible to cover a range from below 200 up to 8000 c/s. One popular form is the three section directional reflex (Fig. 20.22A) in which the total length of the air column is nearly three times the overall length; this gives useful radiation over an angle of 60°. A modified form is the radial type which may be suspended from the ceiling to give an angle of 360°; this gives almost the same radiation upwards as downwards. Refs. 2, 82.

Low frequency folded horns

When a folded horn is used as the low frequency unit in a dual system, the loss of higher frequencies is actually an advantage, and the inner surface of the horn is frequently covered with sound absorbent material to eliminate high frequency reflections. Some of the forms which such a horn may take are given in Figs. 20.23 (Ref. 51) and 20.24 (Ref. 52).

Fig. 20.22. Concentric folded horns (A) three section reflex (B) three section reflex radial type.

One outstanding design is the Klipsch corner type speaker which includes a folded low frequency horn.

This is notable mainly on account of the comparatively small space which it occupies—20 cubic feet in all—compared with other dual horn systems having equivalent performance. The efficiency of the low frequency woofer unit (K-3-D) is not less than 50% down to 36 c/s, and still fairly high at 32.7 c/s; it is capable of radiating a clean fundamental at reduced power down to 27 c/s. Maximum electrical power input is 15 watts, so that the maximum acoustical power output is over 7 watts.

Fig. 20.23. Folded horns for low frequencies actuated by rear of cone with area increasing in steps.

The low frequency unit has a 15 inch direct radiator loud-speaker with an enclosed cabinet baffle at the rear and a folded horn in front. The recommended driver for ordinary home and small theatre power levels is the Stephens P-52-LX-2 woofer motor; this is specially treated to increase its compliance before installation. The enclosed cabinet baffle at the rear is designed to offset the mass reactance of the throat impedance at low frequencies. The volume of the enclosed baffle is given theoretically by

$$V = 2.9 AR \quad (15)$$

where V = volume in cubic inches

A = throat area in square inches

and R = length of horn in inches within which the horn area doubles.

Fig. 20.24. Folded horns for low frequencies—as part of dual system, with conical individual sections. (Ref. 52.)

For the K-3 woofers, $A = 88$ sq. ins., $R = 16$ and the calculated volume is 5270 cubic inches. This equation presumes the suspension compliance to be infinite, which is not the case ; some experimental adjustment is therefore necessary.

The general construction is shown in Figs. 20.25 and 20.26. The voice coil impedance of two designs, the second with increased cone compliance, is shown in Fig. 20.27.

The cross-over frequency is 500 c/s, so that the **high frequency horn** has to be of unusual design, capable of handling 15 watts input down to 500 c/s. The recommended driver for home use is the Stephens P-15 HF motor, with which the response is good to 15 000 c/s. Other suitable drivers are the Jensen XP-101, Western Electric 713A, or Stephens P-30, P-40. The cell structure is contained in the region of small cross-section of the horn, so that the individual mouths of the cells are small. The construction of the high frequency horn is shown in Fig. 20.28.

(vii) High frequency horns

High frequency horns are frequently used in dual or triple systems in conjunction

FIG. 20.25

Fig. 20.25. Top and isometric view of the Klipsch bass reproducer Model K-3. (Ref. 48).

CORNER LINE

FIG. 20.26

with either horn or direct-radiator low frequency units. They are only capable of satisfactory radiation over an angle of from 20° to 40° for a single horn, but up to six similar horns may be built into one unit operated by a single driver to give good coverage over a wide horizontal angle (Refs. 76 Part 1 ; 52, 136). Alternatively the multi-cellular construction may be adopted (Ref. 33). Diffusing lenses may also be used with high frequency horns as an alternative to multi-cellular construction, to spread the sound over a wider angle. In one example the angle was increased from about 20° to over 50° at 8000 c/s by the use of such a diffusing lens. The construction appears cheaper than a multi-cellular

horn and permits greater flexibility in application (Refs. 120, 141).

(viii) Combination horn and phase inverter loudspeakers for personal radio receivers

A combination horn and phase inverter loudspeaker for personal radio receivers has been described (Ref. 124) which has an efficiency of about 25% and a frequency range from 300 to 4000 c/s. A sound level of 84 db is obtained at 3 feet from the loudspeaker with an input of 10mW—this level is somewhat higher than conversational speech. Sub-miniature valves and very small B batteries may therefore be used to give an acceptable sound output from a receiver having a cubic capacity of 41 cubic inches.

(ix) Material for making horns

The best materials are concrete, brick and masonry. The most practical material for horn construction, with many good features, is untempered 3/16 inch Masonite. It should be reasonably strutted and backed with absorbent material (Ref. 191).

SECTION 5: DUAL AND TRIPLE SYSTEM LOUSPEAKERS

- (i) *Introduction* (ii) *Choice of the cross-over frequency* (iii) *The overlap region*
(iv) *Compromise arrangements.*

(i) Introduction

When a wide frequency range has to be covered there is a choice between

1. A single unit employing some special construction to extend the frequency range—see Sect. 2(iii),
2. Two or three separate loudspeakers, each covering a limited frequency range,
3. An integral dual or triple system with two or three loudspeakers mounted (usually co-axially) in one equipment, and
4. Some compromise arrangement—see (iv) below.

If separate loudspeakers are used, they should be mounted as closely together as possible, with co-axial mounting as the ideal; this is not so important when the cross-over frequency is below 500 c/s. In addition, they should be co-planar, with the plane of horn loudspeakers taken as the plane of the diaphragm. The loudspeakers should be correctly phased, so as to be additive in the overlap region.

A frequency dividing network is used to split the output between two loudspeakers so that neither unit is called upon to handle large amplitudes of frequencies beyond its range. This has the advantage that Doppler Effect distortion (see Sect. 7) is much reduced. Other advantages are that, on account of limitations in the frequency range of each unit, the system efficiency is increased, while the directivity characteristic is improved due to the smaller diaphragm (or horn mouth) for the high frequency unit. In addition, the transient response is improved, and there is less intermodulation and reduced frequency modulation.

The loudspeakers should preferably have the same efficiency, otherwise one will have to be attenuated. The directional characteristics of the high frequency unit should receive careful attention.

Integral dual systems

One excellent arrangement employs two cones, co-axial and co-planar, with the small high-frequency cone mounted near the apex of the large cone. Both cones vibrate in unison in the overlap region. (Refs. 61, 116, 116A).

Another arrangement employs a large low-frequency cone and a co-axial high-frequency horn. This has the disadvantage that the sound sources are not co-planar, since the diaphragm of the high frequency unit is mounted to the rear of the cone.

Integral triple systems

In one design there is a large low-frequency cone, a mid-frequency horn using the flared low-frequency cone for its mouth, and a high-frequency horn mounted in front of the mid-frequency horn.

(ii) Choice of the cross-over frequency

In a dual system, that is one having a low-frequency and a high-frequency loudspeaker, the cross-over frequency is usually between 400 and 1200 c/s. The following points must be satisfied.

1. The low frequency unit ("woofer") must be capable of handling at least half an octave above the cross-over frequency, at full power. See also (4) below.
2. The high frequency unit must be capable of handling at least half an octave below the cross-over frequency at full power. See also (4) below.
3. Provided that point (2) can be satisfied, the cross-over frequency should be as low as possible, say 400 to 500 c/s.
4. If a 6 db/octave frequency dividing network is used, each unit should be capable of handling one octave beyond the cross-over frequency at full power, and about 3 octaves beyond the cross-over frequency at reduced power.

Some systems have cross-over frequencies from 1200 to 2000 c/s, in which case the high frequency unit approaches more closely to a true "tweeter," since the latter is generally limited to frequencies above 2000 c/s (Refs. 11, 45).

In a triple system there is no necessity for such a compromise regarding the cross-over frequency. The "woofer" may handle up to between 300 and 600 c/s, the middle unit up to between 2000 and 5000 c/s, and the "tweeter" will then look after the higher frequencies (e.g. Ref. 134).

The design of frequency dividing networks is covered in Chapter 21, Sect. 3

(iii) The overlap region

Serious distortion often occurs in the overlap region when both units are contributing to the total acoustical output. In a dual direct-radiator system in which the distances from each cone to the listener are not equal, the response characteristic will have pronounced peaks and valleys at frequencies where the two sources are in and out of phase. In the case of a dual horn system, particularly when one horn is folded, the acoustical paths may differ sufficiently to cause the same effect. Similar effects occur with other combinations, but the trouble is minimized in all cases by a low cross-over frequency (less than 600 c/s) and, in the case of dual horns, by a fairly steep attenuation characteristic (12 or 18 db/octave nominal). Most loudspeakers give serious distortion below the frequency of minimum rated response, even though the level is attenuated by the cross-over network—hence the desirability of an extended frequency range.

There tends to be a peak of distortion at the cross-over frequency owing to incorrect impedance matching and the partially reactive load. This is most serious with pentodes and beam power amplifiers (see Chapter 21).

(iv) Compromise arrangements

One possibility is to use a single moving-coil loudspeaker with the front acting as a direct radiator, and the rear as bass horn (Ref. 51). Another arrangement uses a single driver with a high-frequency horn facing forwards and a folded bass horn driven by the rear of the diaphragm (Ref. 52). Owing to the use of a single cone or diaphragm, the high frequency response does not extend as far as with two separate units, each specially designed.

General references to dual and triple systems : 11, 30, 33, 45, 48, 51, 52, 61, 76, 130, 134, 150, 165, 167, 194, 215.

SECTION 6 : LOUDSPEAKERS IN OPERATION

(i) *Loudness* (ii) *Power required* (iii) *Acoustics of rooms* (iv) *Loudspeaker placement* (v) *Stereophonic reproduction* (vi) *Sound reinforcing systems* (vii) *Open air Public Address* (viii) *Inter-communicating systems* (ix) *Background music in factories.*

(i) Loudness

Loudness may be measured in loudness units—see page 827 and Fig. 19.8.

(ii) Power required

(A) Direct radiation (outdoor)

Some loudspeaker manufacturers quote the intensity level on the axis at a distance of, say, 30* feet with a stated electrical input power, usually with a warble frequency (from 300 to 3300*, 500 to 2500 or 500 to 1500 c/s). The intensity level decreases by 6 db each time the distance is doubled, or increases by 6 db each time the distance is halved.

The intensity level increases by 3 db when the power input to the loudspeaker is doubled, by 6 db when the power is quadrupled, and so on.

*R.M.A. SE-103. See Sect. 6(x).

Example : At a distance of 30 feet on the axis, a certain loudspeaker is stated to produce a level of 81.5 db above 10^{-16} watt per square centimeter at 8 watts input with a warble frequency from 500 to 2500 c/s. Find the intensity level on the axis at a distance of 6 feet with 3 watts input.

Effect of change of distance = $20 \log_{10} (30/6) = +14$ db.

Effect of change of power input = $10 \log_{10} (3/8) = -4.3$ db.

Net change = +9.7 db.

Intensity level at 6 feet with 3 watts input = $81.5 + 9.7 = 91.2$ db.

In other cases loudspeaker manufacturers (such as R.C.A.) publish the curves of sound pressure versus frequency, from which it is easy to estimate the average over the frequency range of interest. In this case the reference level is 0 db = 10 dynes per square centimetre, and the microphone distance is 24 inches. In a typical case the output level is -1 db for an input of 0.1 watt to the loudspeaker. The level at a distance of 30 feet for a power input of 8 watts will therefore be

-1 + 19.03 - 23.52 = -5.49 db (0 db = 10 dynes/cm.²)

or converting to the basis of 0 db = 0.0002 dyne/cm²,

-5.49 + 93.98 = +88.5 db (0 db = 0.0002 dyne/cm²).

Alternatively the R.M.A. loudspeaker pressure rating may be quoted. For calculation and example see page 812.

FIG. 20.29

Fig. 20.29. Intensity in db versus acoustical watts output at specified distances along the axis of a loudspeaker which is considered as a small source in an infinite baffle. This holds fairly accurately at low frequencies, with an error of 1 db at 500 c/s with a cone 10 inches in diameter. The numbers on the sloping lines indicate the distance in feet from the loudspeaker (based on F. Massa, Ref. 69, but extended and modified).

Again, the loudspeaker percentage efficiency may be known, say 3%, and it is desired to calculate the intensity at a distance of, say, 30 feet with an input of 8 watts. The unknown factor is the angle of radiation, but at frequencies up to 500 c/s this may be taken as approximately 180° (assuming a direct radiator with a large flat baffle) and we may therefore make use of Fig. 20.29. In this case the acoustical output will be $8 \times 0.03 = 0.24$ watt and the intensity will be 87 db at 30 feet (Fig. 20.29).

At higher frequencies there will be an increasingly greater focusing effect, and the intensity on the axis will be somewhat greater than the value calculated above.

(B) Power required indoors

When a loudspeaker is operated indoors the direct radiation is supplemented by the reflected sound.

The **reverberation time** is the time in seconds for a sound to fall to one millionth of its original intensity (-60 db) after stopping the source. Eyring* gives

$$T = \frac{0.05 V}{-S \log_e (1 - \alpha)}$$

where T = reverberation time in seconds,

V = volume of room in cubic feet,

S = surface area of walls, ceiling and floor in square feet,

and α = average absorption coefficient per square foot, in sabins (values are less than unity).

The sabin is an absorption unit representing a surface capable of absorbing sound at the same rate as does 1 sq. ft. of perfectly absorbing surface, such as an open window.

In a typical living room, the reverberation time is about 0.5 second at 500 c/s and the absorption coefficient is about 0.25. The reverberation time falls to possibly 0.3 second at 5000 c/s and rises to possibly 0.75 second at 200 c/s. (Ref. 14, Fig. 13.26).

In a very large living room, the reverberation time would probably be about 0.8 second at 1000 c/s.

FIG. 20.30

Fig. 20.30. Acoustical power required to produce an intensity level of 80 db as a function of the volume of the auditorium for optimum reverberation times (after Olson, Ref. 13, by kind permission of the author and of the publishers and copyright holders, Messrs. D. Van Nostrand Company Inc.).

*See Ref. 13A page 399.

The "optimum reverberation time" at 1000 c/s depends on the volume of the room (Ref. 13A):

Volume	1000	2000	4000	20 000	100 000	500 000	cu. ft.
T_{opt}	0.7	0.75	0.82	1.01	1.28	1.62	secs.

In a typical room 20 ft. \times 15 ft. \times 10 ft., with a reverberation time of 0.5 second, and with the listener 6 feet from the loudspeaker, the reflected sound adds 3 db to the direct radiation at 500 c/s under steady state conditions, and 1 db when the sound only continues for 0.02 second as for speech (Ref. 14, Fig. 13.26). At higher frequencies the reflected sound becomes rapidly smaller, and may be neglected. At 200 c/s the reflected sound adds 5.5 db under steady state conditions or 2 db when the sound continues for 0.02 second. At 100 c/s the reflected sound adds 9.5 db under steady state conditions, or 6 db when the sound continues for 0.02 second. The effect of the reflected sound becomes more important as the listener moves further away from the loudspeaker.

References 13A, 14, 15, 50, 55, 175, 178.

The **acoustical power** in watts to produce an intensity level of 80 db (0 db = 0.0002 dyne/cm²) is plotted in Fig. 20.30 against the volume of the enclosure in cubic feet (after Olson, Ref. 13A). For living rooms the following information may be derived—

Volume	1000	2000	3000	4000	cu. ft.
Intensity level	Acoustical power in watts				
55 db	0.000 0051	.000 0098	.000 014	.000 019	watt
60 db	0.000 016	.000 031	.000 045	.000 059	watt
65 db	0.000 051	.000 098	.000 14	.000 19	watt
70 db	0.000 16	.000 31	.000 45	.000 59	watt
75 db	0.000 51	.000 98	.001 4	.001 9	watt
80 db	0.001 6	.003 1	.004 5	.005 9	watt
90 db	0.016	.031	.045	.059	watt
100 db	0.16	.31	.45	.59	watt
110 db	1.6	3.1	4.5	5.9	watts

These values apply to enclosures with optimum reverberation times. Living rooms may have reverberation times which are lower than the optimum values, and the acoustical power required will then be greater than indicated above.

The intensity levels for home listening under various conditions are set out in Chapter 14 Sect. 7(iii).

(iii) Acoustics of rooms

When a musical item is produced in the studio and reproduced by a loudspeaker in a living room, there are two reverberation times—that of the studio and that of the room. Good listening conditions are usually achieved by controlling the reverberation time of the studio so that the music will sound well in the average medium or large living room. Large concert halls with long reverberation times are not ideal, but there is nothing which can be done in the living room to improve matters.

The desirable and usual rise of reverberation time at low frequencies with rigid walls may be replaced by a general fall, due to the **vibration** of walls, floor and ceiling. This is one prevalent cause of loss of bass, below 150 c/s; if an attempt is made to counteract it by bass boosting, the acoustical effect is not quite natural (Ref. 53).

It is preferable to mount the loudspeaker on sound absorbing pads or thick carpet to prevent the direct transmission of vibration to the floor.

At low frequencies it is doubtful whether the reverberation time of a small or even medium sized room means much, because of **room resonances** producing standing

waves. In a typical case with a room 16 ft. 9 in. \times 11 ft. 6 in. \times 8 ft. 6 in. the first nine resonances are 36.8, 51.1, 62.9, 68.6, 73.6, 77.6, 85.5, 102.3, 137.2 (Ref. 53).

The most desirable shape for a listening room is approximately in the ratio height : width : length = 1 : 1.27 : 1.62, so as to distribute the resonances fairly uniformly.

The peaks due to these resonances are of the order of 20 db and completely mask less pronounced effects. The bad effects may be reduced by

- (1) increased acoustical damping at low frequencies, especially near the corners of the room where it is twice as effective as elsewhere (Ref. 175), and
- (2) an open door or window, or preferably both.

In addition to these room resonances, which occur over the whole room, there are other peaks of response due to focusing or interference between different paths, at middle and high frequencies, which vary from point to point. Thanks to our two ears, these sharp peaks and valleys are much less evident than they otherwise would be.

References 13A, 14, 53, 175, 192, 208, 220, 221.

(iv) Loudspeaker placement

The ideal position for a loudspeaker is in one corner of the room, either low down near the floor or in the corner between two walls and the ceiling. In either case the boundaries of the room form a triangular conical horn, and the angle of radiation is $\pi/2$ steradians. The axis of the loudspeaker may point directly at the head of one listener, say seated with his head 42 inches above the floor, but every other listener will then lose something of the high frequencies. If a ceiling-corner position is used, the maximum angle of elevation between a listener and the loudspeaker should not normally exceed 30° ; this position is therefore limited to large rooms or those with low ceilings. If a special loudspeaker is used having wide angle radiation at all frequencies, the problem disappears. In other cases the trouble may be minimized by

- (1) accentuating the high frequencies and pointing the axis of the loudspeaker away from the listeners, who should be seated at approximately the same angle to the axis, or
- (2) keeping the listeners within an angle of 15° from the axis.

Another possible position for the loudspeaker is in the corner of a room, half-way between floor and ceiling—this gives an angle of radiation of π steradians.

In all cases where a loudspeaker is mounted in the corner of a room, the adjacent walls and floor or ceiling should have reflecting surfaces so as to act as a horn. The rest of the room should have a considerable amount of damping material such as upholstered furniture, heavy drapings, carpets, books or acoustical tiles.

In all cases, no listener should be closer than 4 feet from the loudspeaker, with a greater distance for dual or triple systems and considerably greater distance for horns.

Loudspeakers with open-backed cabinets are very difficult to place satisfactorily. They should be about 9 inches out from the wall, and the wall behind them should preferably be damped by a heavy curtain or sheet of acoustical absorbent material. A corner position is desirable.

If a loudspeaker must be placed along one of the walls, it should preferably be along the shorter side, about the centre. This gives an angle of radiation of 2π steradians.

If two separate loudspeakers are used, each handling the full frequency range, they may, if desired, be placed in positions wide apart, such as the two ends of a room. In a fairly large living room some approach to a third dimensional effect may be obtained with the listener slightly nearer to one loudspeaker—this is the pseudo-stereophonic effect, see (v) below.

(v) Stereophonic reproduction

Reproduced sound normally comes from a single source—the loudspeaker—so that there can be no indication of the direction from which the sound originally came. In stereophonic reproduction with three or more channels there can be a 3 dimensional effect which enables the listener to determine the position of the source. Stereophonic reproduction in the strict sense can only be applied in large concert halls or cinemas

where the audience is situated further from the loudspeakers than the distance between any two loudspeakers. An illusion which gives a sense of spatial reproduction can be applied to a room by means of two loudspeakers each fed from a separate microphone through separate amplifiers. In radio broadcasting at least two separate transmitters and receivers are required—three channels are desirable. Some methods of recording are capable of carrying two or three channels, such as sound on film and magnetic tape (Refs. 86, 101, 226).

There are methods of obtaining an approach to stereophonic reproduction with a single channel (Ref. 87).

When there are two loudspeakers so placed with respect to the listener as to give a transit time difference from 1 to 30 milliseconds, the impression is that of more "liveliness" and "body" (Ref. 125). This is the **pseudo-stereophonic effect**, and to be fully effective requires the listener to be at least 4 feet—and preferably a greater distance—nearer to one loudspeaker than the other. With suitable positioning and relative volumes, the effect is quite surprising.

A more elaborate method for heightening sound perspective utilizes volume expansion in one of the two channels (Ref. 49).

References 6, 13, 14, 36, 49, 68, 86, 87, 97, 101, 112, 160, 161, 162, 163, 169, 195, 203, 216 (giving additional references), 226, 235, 236, 237, 238, also Supplement.

(vi) Sound-reinforcing systems

With this system there are two sources of sound, the original sound and the augmented sound from the loudspeakers. Usually the intensity of the original sound issuing from the stage will be sufficient over a limited area, but the sound energy from the loudspeakers must progressively increase towards the rear of the auditorium. The problem is to select a loudspeaker or loudspeakers with suitable directional characteristics, and to adjust the power output and orientation so that the total intensity level is constant for all parts of the listening area.

The acoustical power required to produce an intensity level of at least 80 db for ordinary speech and music is as follows (Ref. 13A):

Volume (cu. ft.)	10 000	50 000	100 000	500 000
Acoustical power (watts)	0.014	0.06	0.11	0.5

For full orchestral dynamic range, a maximum intensity level of 100 db is required, and the acoustical powers should be multiplied by 100. In noisy situations the sound level should be 10 to 16 db above steady noise or 20 to 30 db above the noise in relatively quiet intervals.

One of the problems in design is the avoidance of acoustical feedback. It is usual to adopt directional loudspeakers and sometimes also directional microphones. The microphone is mounted as close to the sound source as possible and in a position of low radiated sound intensity.

For the best illusion to the listener the loudspeaker(s) should be mounted so that the sound appears to come from the direction of the original source. The difference in path length between the original sound and the sound from the loudspeaker should not exceed 60 to 80 feet.

The overall response of the whole system should be free from peaks. When feedback occurs, it does so at the frequency at which the system has a peak.

If at all possible, low frequencies should be attenuated so as to reduce the size of the loudspeaker and of the amplifier, and to reduce acoustical feedback. A minimum frequency range for speech is 400 to 4000 c/s (Ref. 196). If orchestral music is to be amplified the whole frequency range should be provided for, although here also some compromise may be necessary.

In small or medium halls a single loudspeaker or bunch of loudspeakers may be mounted 20 to 30 feet above the microphone and somewhat more forward than the microphone. The loudspeakers should be pointed downwards to the audience (Ref. 196).

In larger halls one or more **line-source loudspeakers** may be used. A line-source consists of a number of loudspeakers mounted close together in a straight line. A vertical line-source gives directionality in the vertical plane but not in the horizontal plane. If the line-source is "tapered" in strength so that the sound from each ele-

ment varies linearly from a maximum at the centre to zero at either end, the directionality is improved. The line-source should be tilted slightly forwards so that the central loudspeaker points directly to the centre of the audience. Better results may be obtained by using two line-sources, a long one for the low frequencies and a shorter one (one quarter the length of the long one) for the high frequencies, with a cross-over network for $f_c = 1000$ c/s (Ref. 197).

In large installations, time delay may be incorporated (Ref. 145, 197).

Multiple loudspeakers

Haas (Ref. 125) has investigated the effects of a single echo on the audibility of speech. He has shown that when the time delay of the echo is from 5 to 30 milliseconds, the echo is not detectable as a separate source if the level of the echo is less than 10 db above that of the direct sound, and that the listener only has the sensation of hearing from the nearer loudspeaker. At greater time delays he determined how loud such an echo could be before interfering with speech (e.g. echo 0 db, 50 msec, path difference 56 ft.). For echoes at lower levels see Ref. 308. See also Refs. 308, 326, 327.

A typical reflex horn, with an input of 1 watt to the voice coil, gives the following sound levels on the axis (Ref. 73):

Distance	10	20	40	80	160	320	feet
Sound level	100	94	88	82	76	70	db

With a single horn, the axis should point directly to the farthest part of the audience. Horns may be arranged radially to cover a larger audience, allowing 30° for each horn.

For speech reproduction only, a 10 watt amplifier with two horn loudspeakers is sufficient for a crowd of 5000 people in quiet surroundings. For musical reproduction a power of 40 watts with four loudspeakers will be required. It is usual to allow from 5 to 10 watts for each horn loudspeaker. Alternatively a large number of any convenient type of loudspeaker may be used, with the spacing between loudspeakers not greater than 70 feet. When a wider frequency range is required, some dual horn system is frequently used, particularly with open-air orchestral sound reinforcing.

For large crowds, several line-source loudspeakers—see (vi) above—may be used at the centre of the crowd.

References 13A (pp. 292-296), 14 (pp. 406-409), 73, 104, 125, 176.

(viii) Intercommunicating systems

Only speech is to be reproduced, and the usual requirement is merely to have sufficient articulation to be understood. A reduced frequency range is almost universal, while a very restricted range is used in noisy surroundings (see Chapter 14 Sect. 11).

References 1, 13 (pp. 297, 299), 13A (p. 426).

(ix) Background music in factories

If the noise level is comparatively low, the system may be quite conventional, with a frequency range from say 100 to at least 6000 c/s. Loudspeakers should be placed fairly close together to give good coverage of high frequencies. The spacing should be adjusted so that, with the prevailing noise level, the range of each is slightly over half the distance between them.

If the noise level is high, the highest noise intensity is often limited in frequency range at both extremes. In such a case, as an alternative to over-riding the noise, the full frequency range up to 8000 c/s may be used for the music; which may be at the same level as the mid-frequency noise. The low-frequency music range may either be used or attenuated as desired. Careful choice of the source of music is required to give the full frequency range without distortion. A conventional A-M receiver is unsuitable, owing to sideband cutting. Many shellac discs, especially the older ones, are unsuitable on account of limited frequency range.

In all cases some form of volume compressor or limiter is required to reduce the volume range, and the music should be selected to avoid sudden large changes in volume.

SECTION 7: DISTORTION IN LOUDSPEAKERS

(i) *Non-linearity* (ii) *Frequency-modulation distortion in loudspeakers* (iii) *Transient distortion* (iv) *Sub-harmonics and sub-frequencies* (v) *Intermodulation distortion*.

(i) Non-linearity

Non-linearity in a cone occurs when the force versus displacement characteristic deviates from a straight line. The principal causes of non-linearity are—

1. Insufficient rigidity in the cone,
2. Non-linear suspension, and
3. Non-uniform flux density.

Lack of rigidity in the cone is usually the result of reduction in the mass of the cone to achieve high sensitivity. In addition to the other defects—ragged response and poor reproduction of transients—this has a marked effect in increasing the harmonic distortion over the whole frequency range (Ref. 15 Fig. 3).

All cone or diaphragm suspensions are non-linear to a greater or less extent—their stiffness usually increases with larger amplitudes. The total harmonic distortion of any such loudspeaker is fairly low (of the order of 1%) at frequencies of about 300 c/s and above, and is not appreciably affected by non-linearity in the suspension. As the frequency is decreased, however, the distortion rapidly rises in loudspeakers having non-linear suspension. For example, one 10 inch dynamic loudspeaker with a non-linear suspension gives 10% total harmonic distortion with an input of 2 watts at 60 c/s, and 30% distortion with an input of 10 watts at the same frequency (Ref. 13A Fig. 6.34). On the other hand a good quality loudspeaker is capable of handling an input of 10 watts at 60 c/s with only 3% total harmonic distortion, or an input of 2 watts at 60 c/s with less than 1% distortion (Ref. 36 Fig. 25).

When a loudspeaker is used in a well designed vented baffle, or in a suitable horn, the maximum amplitude of the cone will be decreased and the distortion arising from a non-linear suspension will also be decreased.

Non-uniform flux density up to the maximum amplitude of operation is another source of harmonic distortion. This distortion is usually less than 1% so long as the amplitude of movement is small, consisting of odd harmonics only unless the field is not symmetrical about the voice coil. However at high input levels the distortion is usually severe. In one case total distortion at 50 c/s with an input of 5 watts, was reduced from 9% to less than 5%, by careful design (Ref. 84).

At frequencies above 3000 c/s, the harmonic distortion with single large cone loudspeakers is negligibly small compared with the frequency-modulation distortion—see (ii) below.

With dual loudspeakers, or a dual cone loudspeaker, the total harmonic distortion tends to reach a peak in the vicinity of the cross-over frequency—see Sect 5(iii), also Refs. 36, 116. In one example the total harmonic distortion is over 3% from 500 to 1500 c/s for a 15 inch duo-cone loudspeaker with an input of 5 watts.

The cross-over distortion, and the other forms of distortion described above, all increase rapidly as the input power is increased.

The harmonic distortion below the bass resonant frequency is selective (Fig. 13.54). When the load imposes a greater impedance to the harmonic than to the fundamental, the measured harmonic distortion increases. At a frequency equal to one-half of the bass resonant frequency the second harmonic rises to a peak since the second harmonic frequency is equal to that of the bass resonance. Similarly at a frequency equal to one-third the frequency of the bass resonance, the third harmonic rises to a peak, and so with higher harmonics.

At frequencies above about 1000 c/s all harmonics tend to increase since the impedance of the load to the harmonics is greater than the impedance to the fundamental. This is offset to some extent by the fact that with a triode valve or with most of the commonly used negative feedback circuits, as the load impedance is increased, so the distortion decreases. The net effect is found by the combination of these separate effects.

A system has been developed (Ref. 152) for automatically recording the total harmonic distortion of a loudspeaker over the a-f range. This is particularly helpful in detecting narrow frequency bands where the distortion is high.

One method of recording the performance of a loudspeaker with regard to non-linear distortion is to measure on the axis the maximum sound level before a certain amount of harmonic distortion is produced. This may be plotted as a curve of maximum undistorted sound pressure as a function of frequency (Ref. 153). Alternatively the distortion may be plotted as a function of frequency for constant electrical input. In all cases the loudspeaker must be tested in the enclosure for which it has been designed.

References 13A (pp. 163-173), 20, 21, 23, 36, 61, 106, 108, 109, 133, 152.

(ii) Frequency-modulation distortion in loudspeakers

The origin of this form of distortion is the **Doppler effect** whereby the pitch rises when the source of sound is advancing towards the listener and falls when it is receding (Refs. 3, 13A p. 18). The effect in loudspeakers is entirely independent of non-linearity. If a loudspeaker has two input frequencies, say 50 and 5000 c/s, the acoustical output can be resolved, like a frequency-modulated wave, into a carrier frequency (the 5000 c/s input) and sidebands (intermodulation frequencies) plus the 50 c/s input. The distortion may be measured in terms of the distortion factor, and so made comparable with the total harmonic distortion when a single input frequency is applied. The distortion factor on the axis is given by

$$d.f. = 0.33 A_1 f_2 \text{ per cent} \quad (1)$$

where A_1 = amplitude of cone motion (each side of the mean position) in inches at the modulating frequency—say 50 or 100 c/s

f_2 = modulated frequency (variable frequency),

and $d.f.$ = distortion factor in per cent, defined as the square root of the ratio of the power in the sidebands to the total power in the wave.

The distortion factor is proportional to the variable modulated frequency f_2 , and is quite small below 1000 c/s. As a typical example take a 12 inch loudspeaker with an equivalent single frequency power input of 0.125 watt to the voice coil—

f_2	1000	2000	5000	10 000	c/s
$d.f.$	0.65	1.3	3.2	6.4	%

This condition applies to an input of 4.2 watts with a loudspeaker efficiency of 3%.

Tests have indicated that the greater part of the distortion above 3000 c/s with single loudspeakers is due to frequency modulation distortion; this is reduced very considerably by the use of separate high and low frequency loudspeakers.

References 3, 7, 13A.

(iii) Transient distortion

A transient is a waveform, usually with a steep wavefront, which does not repeat at periodic intervals. Any sudden commencement or cessation of a periodic wave has a transient component. For reproduction without distortion the acoustical waveform must be the same as the input waveform.

It is known from the theory of linear dynamic systems of minimum phase shift type that the amplitude response, the phase characteristic and the transient response to various applied waveforms are merely equivalent ways of observing the same inherent performance of the circuit (Ref. 131). Poor transient response leads to fuzzy reproduction with poor definition. Some requirements for good reproduction of transients are

- (1) the loudspeaker must respond to the highest audible frequencies,
- (2) the loudspeaker frequency response characteristic must be smooth and uniform, and free from sharp peaks and dips,
- (3) the loudspeaker must be sufficiently damped, particularly near the bass resonant frequency,
- (4) the bass resonant frequency should be as low as possible, and
- (5) the phase-shift characteristics of the loudspeaker should be good.

Reasonably good response to transients is obtainable with loudspeakers having a **frequency response** to 10 000 c/s, but better response is achieved with an increase to 15 000 c/s. Generally speaking it is safe to say that a loudspeaker with a smooth response characteristic has a better transient response than one having sharp resonances, but considerable skill is required for an accurate interpretation of the response characteristic (see Ref. 131 for assistance in this direction).

Loudspeaker damping at the bass resonant frequency has been dealt with in Sect. 2(x). With a suitable choice of loudspeaker and enclosure, and with a sufficiently low amplifier output resistance, critical damping or any desired lesser degree is obtainable. There are differences of opinion as to the amount of damping to be used for good fidelity. Some prefer critical damping without any overshoot, others prefer a slight overshoot with its more rapid uptake (e.g. Ref. 174).

At frequencies above 400 c/s, the cone of a direct radiator loudspeaker ceases to act as a piston, and the effective damping at any point on the cone, at any frequency within this range, is likely to be less, and may be very much less than that with a true piston cone.

Horns provide acoustical damping over a wide frequency range, and well designed horn loudspeakers have better transient response than direct radiators.

The **phase-shift characteristics** of loudspeakers are not readily evaluated. Above 1000 c/s the smoothness of the response characteristic appears to be the best available guide to good phase-shift characteristics; below 1000 c/s the "envelope delay" may be used to supplement the information which can be derived from the response characteristic (Ref. 138).

When a tone burst* is applied, some of the frequencies generated are not harmonically related to the applied signal, and they cause an annoying type of distortion somewhat similar to intermodulation. The ear is very sensitive to this type of inharmonic distortion (Ref. 131).

Ringing at the frequency of the bass resonance becomes progressively less pronounced as the frequency of the applied tone burst is increased away from the resonant frequency.

Testing loudspeakers for transients

There are four methods of testing loudspeakers for transient response—

1. Applied unit impulse,
2. Suddenly applied square wave,
3. Suddenly applied tone burst, and
4. Shorter's method.

Applied unit impulse gives all the information at one test, but is hard to interpret because it causes all the peaks to ring simultaneously (Ref. 131).

The suddenly applied square wave is more selective, since it emphasizes the ringing of the peaks of nearly the same frequency as the applied wave (Refs. 13A, 15, 36, 126, 131).

The suddenly applied tone burst method is capable of giving much valuable information. Ref. 131 gives a theory of ringing and interpretation of results. It seems that those loudspeakers that sound best generally reproduce tone bursts well, although this is better substantiated for the high frequencies than for the low (Refs. 131, 138, 166).

References to tone burst methods: 44, 88, 121, 131, 133, 138, 158, 166, 213.

It has been demonstrated (Refs. 44, 88) that a smooth frequency response curve means a rapid build-up of a transient. The decay characteristic, after the input voltage has ceased, requires further consideration. Each lightly-damped resonant element, when shock-excited by the sudden cessation of the applied voltage, will dissipate its stored energy by radiating sound at its own natural frequency. The method of testing by Shorter (Refs. 44, 117, 121) is to measure, at all frequencies, the response at time intervals $t = 0, 10, 20, 30$ and 40 milliseconds after the cessation of the applied voltage. Good transient response appears to be indicated by

*A tone burst is a wave-train pulse which contains a number of waves of a certain frequency.

1. Attenuation of 35 db at 1000 c/s, increasing steadily to 50 db at 3000 c/s and higher frequencies, for $t = 10$ milliseconds.
2. Further attenuation of about 10 db for $t = 20$ milliseconds.
3. Further substantial attenuations at $t = 30$ and $t = 40$ milliseconds. These should never be negative, even over narrow frequency bands. A negative value may indicate a spurious ripple frequency.

In double-unit loudspeakers, the important frequency region from the standpoint of transient response is near or below the overlap frequency band (Ref. 36).

References 5 (Part 1), 13A (pp. 159-163, 375), 15 (pp. 138-141, 202-212, 332-339), 36, 40, 44, 54 (Part 4), 88 (pp. 59-64), 117, 121, 131, 132, 133, 135, 138, 150, 155, 158, 166, 172, 174, 179.

(iv) Sub-harmonics and sub-frequencies

In addition to harmonic frequencies, a direct radiator loudspeaker produces sub-harmonics, that is frequencies one half, one third, one quarter, etc., of the applied frequency. Of these, the one half frequency is the only one of consequence. It occurs only in limited frequency regions, and it does not occur below a moderate, critical, level. However when this level is reached, it increases rapidly at first, and is accompanied by frequencies of $3/2$, $5/2$, $7/2$, and $9/2$ of the applied frequency (Ref. 188). Sub-harmonics are more objectionable to the listener than harmonics of the same percentage, but they require a relatively long time to "build up" and are generally assumed to be not very obvious in ordinary sound reproduction. However one authority states that a good correlation has been found between the number of sub-harmonics produced by the speaker and the quality rating of the speaker as determined by listening tests (Ref. 153).

References 13A (pp. 167-168), 19, 21, 133, 153, 171, 188 (pp. 751-752).

(v) Intermodulation distortion

Tests on the intermodulation distortion of loudspeakers have been described but no general conclusions can yet be derived (Refs. 108, 109, 171).

SECTION 8 : SUMMARY OF ACOUSTICAL DATA

- (i) *Definitions in acoustics* (ii) *Electrical, mechanical and acoustical equivalent*
(iii) *Velocity and wavelength of sound* (iv) *Musical scales.*

(i) Definitions in acoustics

Sound energy density is the sound energy per unit volume. The unit is the erg per cubic centimetre.

Sound energy flux is the average rate of flow of sound energy through any specified area. The unit is the erg per second.

The sound intensity (or sound energy flux density) in a specified direction at a point, is the sound energy transmitted per second in the specified direction through unit area normal to this direction at the point. It may be expressed either in ergs per second per square centimetre or in watts per square centimetre.

Sound pressure is exerted by sound waves on any surface area. It is measured in dynes per square centimetre as the r.m.s. value over one cycle. The sound pressure is proportional to the square root of the sound energy density.

The pressure level, in decibels, of a sound is 20 times the logarithm to the base 10 of the ratio of the pressure P of this sound to the reference pressure P_0 . Unless otherwise specified, the reference pressure is understood to be 0.0002 dyne per square centimetre.

The velocity level, in decibels, of a sound is 20 times the logarithm to the base 10 of the ratio of the particle velocity of the sound to the reference particle velocity. Unless otherwise specified, the reference particle velocity is understood to be 5×10^{-6} centimetre per second effective value.

The intensity level, in decibels, of a sound is 10 times the logarithm to the base 10 of the ratio of the intensity I of this sound to the reference intensity I_0 . Unless otherwise specified, the reference intensity I_0 shall be 10^{-16} watt per square centimetre.

Compliance is ease in bending. It is the reciprocal of stiffness.

See Chapter 14 Sect. 7 for volume range and peak dynamic range.

See Chapter 19 Sect. 5 for loudness and Sect. 7 for sound level and noise.

See also I.R.E. Standards on Acoustics : Definitions of Terms, 1951, Proc. I.R.E. 39.5 (May 1951) 509; "American Standard of Acoustical Terminology", A.S.A. Z24.1—1951.

(ii) Electrical, mechanical and acoustical equivalents

Electrical	Acoustical	Acoustical unit
Capacitance	acoustical capacitance	cm^5/dyne
Inductance	inertance	$\text{grams}/\text{cm}^2/\text{cm}^2$
Resistance	acoustical resistance	acoustical ohms
E.M.F.	pressure	dynes/cm^2
Impedance	acoustical impedance	acoustical ohms
Electrical	Mechanical	Mechanical unit
Capacitance	Compliance	cm/dyne

(iii) Velocity and wavelength of sound

The velocity of sound in a medium varies according to the relation $V = \sqrt{E/\rho}$ where E is the elasticity and ρ the density of the medium. For any particular medium, the velocity depends also on the temperature (because of its effect on the density of the medium) and the intensity of the sound. In the audible range, velocity decreases with decreasing intensity; but in the ultrasonic range, velocity increases with decreasing intensity.

Ref. Kaye, G. W. C., and T. H. Laby, "Physical and Chemical Constants" (ninth edition, Longmans, Green and Co. London).

Velocity of Sound in Some Common Media

Medium	metres/sec.	Medium	metres/sec.
Air (dry)	342 (at 18° C)	Steel	4700—5200
Hydrogen	130	Nickel	4970
Water vapour (sat'd)	413	Glass	4000—5300
Water (sea)	1540	Brass	3650
Alcohol	1260	Wood	3300—5000
Aluminium	5100	Rubber	50—70
Copper	3970		

Sound transmission in air at 20°C and 760 m.m.

Frequency	30	50	100	200	400	1000	4000	c/s
Wavelength	452	271	136	67.7	33.9	13.6	3.39	inches
	37.7	22.6	11.3	5.65	2.82	1.13	0.282	feet

Velocity of sound in air = 13 550 inches per second

= 1129 feet per second

= 344 metres per second.

$$f \times \lambda = 1129$$

where f = frequency in cycles per second

and λ = wavelength in feet.

(iv) Musical scales

Every musical tone has a frequency which is measured in cycles per second.

A **scale** is a series of tones ascending or descending in frequency by definite intervals.

The **octave** is the most important interval ; two tones are separated by one octave when the frequencies are in the ratio 2 : 1.

Each octave is subdivided into a number of smaller intervals. In the **equally tempered scale** the octave is divided into twelve equal intervals (1.0595 : 1) to allow a change of key without retuning. Thus in the equally tempered scale, if any frequency is multiplied by 1.0595 it is raised by one semi-tone ; if multiplied by 1.1225 it is raised by one tone. All normal musical instruments follow the equally tempered scale.

In addition, there are several systems of what is called the **natural scale**, or **just intonation**, in which for example C# has a different frequency from D♭ (Ref. 90 Part 1).

Table 1 gives one version of "just intonation."

TABLE 1

Tone Interval	Frequency ratio		
	Natural	(just) scale	Tempered scale
C Unison	1	= 1.000	1.000
C# Semitone	25/24	= 1.042	1.0595
D♭ Minor second	27/25	= 1.080	
D Major second (= tone)	9/8	= 1.125	1.1225
D# Augmented second	75/64	= 1.172	1.189
E♭ Minor third	6/5	= 1.200	
E Major third	5/4	= 1.250	1.260
F♭ Diminished fourth	32/25	= 1.280	
E# Augmented third	125/96	= 1.302	1.335
F Perfect fourth	4/3	= 1.333	
F# Augmented fourth	25/18	= 1.389	1.414
G♭ Diminished fifth	36/25	= 1.440	
G Perfect fifth	3/2	= 1.500	1.498
G# Augmented fifth	25/16	= 1.563	1.587
A♭ Minor sixth	8/5	= 1.600	
A Major sixth	5/3	= 1.667	1.682
A# Augmented sixth	125/72	= 1.736	1.782
E♭ Minor seventh	9/5	= 1.800	
B Major seventh	15/8	= 1.875	1.888
C♭ Diminished octave	48/25	= 1.920	
B# Augmented seventh	125/64	= 1.953	2.000
C' Octave	2	= 2.000	2.000

The frequency of all tones is determined by the "pitch." The international standard pitch is a frequency of 440 c/s for tone A (equivalent to 261.63 for C) whereas the "physical pitch" is a frequency of 256 for C.

The octaves of C in the two examples above are :

CCCC	CCC	CC	C	c ⁱ	c ⁱⁱ	c ⁱⁱⁱ	c ^{iv}	c ^v	
16.4	32.7	65.4	130.8	261.6	523.3	1046.5	2093	4186	c/s
16	32	64	128	256	512	1024	2048	4096	c/s

The frequency of any tone may be calculated by multiplying the value of C next below it by the frequency ratio of the tempered scale as given by the appropriate row in Table 1.

SECTION 9 : STANDARDS FOR LOUDSPEAKERS

(i) *Voice coil impedance for radio receivers* (ii) *Loudspeaker standard ratings for sound equipment.*

(i) Voice coil impedance for radio receivers

The American R.M.A. Standard REC-104 (Jan. 1947) "Moving coil loudspeakers for radio receivers" specifies a voice coil impedance of $3.2 \text{ ohms} \pm 10\%$ measured at the first frequency above resonance giving a minimum value tested without a baffle. This impedance differs from that specified for sound equipment (see below).

This standard (REC-104) is applied to loudspeakers having a maximum pole piece diameter not over 1 inch.

(ii) Loudspeaker standard ratings for sound equipment

The American R.M.A. Standard SE-103 "Speakers for sound equipment" (Ref. 95) lays down certain definitions and ratings which are summarized below.

The **loudspeaker impedance** (Z_s) is the complex value of the electrical impedance given as a function of frequency, and is measured at the accessible signal terminals of the speaker.

Published data to give magnitude and phase angle as function of frequency.

The **loudspeaker rating impedance** (R_{SR}) is the value of a pure resistance, specified by the manufacturer, in which the electrical power available to the speaker is measured. The value shall be 4, 8 or 16 ohms.

Loudspeakers may also be rated in terms of **power drawn from standard distribution lines**. In this case it is necessary to specify the power and the line voltage.

The **loudspeaker measurement source impedance** (R_{SG}) is the value of a pure resistance to be connected in series with the speaker and a constant voltage source to measure the speaker performance. The value of R_{SG} shall be 40% of the value of the loudspeaker rating impedance R_{SR} .^{*} This is equivalent to operating the loudspeaker from a source having voltage regulation of 3 db.

The **loudspeaker pressure rating** (or pressure "efficiency") G_{SP} is the difference between the axial sound pressure level (referred to a distance of 30 feet) and the available input power level, and is expressed in db. For further details see Chapter 19 Sect. 1(viii).

Standard Test Signal No. 1, as indicated by G_{SP1} , is a loudness weighted signal covering the frequency band from 300 to 3300 c/s. (Refs. 95, 50).

^{*}Some manufacturers (e.g. R.C.A.) apply constant voltage to the loudspeaker, so that R_{SG} is made zero.

The **loudspeaker pressure-frequency response** (L_s) is the variation of the 30 foot axial free-space pressure level as a function of frequency, and is expressed in db. The pressure level L_a at distance d feet may be used to compute the pressure level L_s at 30 feet by the relation

$$L_s = (L_a + 20 \log_{10} d) - 29.5 \text{ db} \quad (1)$$

The **loudspeaker directivity index** (K_s) is the ratio, expressed in db, of the power which would be radiated if the free-space axial sound pressure were constant over a sphere, to the actual power radiated. It is expressed in the form :

$$K_s = 10 \log_{10} \left[4\pi / \int_0^\pi \int_0^{2\pi} (p/p_a)^2 \sin \theta \, d\theta \, d\phi \right] \quad (2)$$

where p_a = axial free space sound pressure, dynes/cm²

p = general free-space sound pressure at the same distance, dynes/cm²
and θ and ϕ are the angular polar co-ordinates of the system, and the speaker axis is at $\theta = 0$.

(When standard test signal No. 1 is used, K_{s1} is the speaker loudness directivity index).

The value of the directivity index (K_s) may be calculated, over the frequency range which determines loudness, by using the following table for a rigid piston vibrating axially in an infinite baffle (based on curves in Ref. 50) :

df =	500	2000	5000	10 000	15 000	25 000	35 000	45 000
K_s =	3.0	3.0	4.0	7.0	10.5	15.0	18.2	20 db

where f = frequency in cycles per second

and d = piston diameter in inches.

When using standard test signal No. 1, the value of the **loudness directivity index** K_{s1} is tabulated for similar conditions to those above :

d =	0	4	8	12	16	20	inches
K_{s1} =	3	4.4	5.7	7.0	8.0	9.0	db

Values of K_{s1} for various types of baffles and horns are given by Ref. 50.

The loudness directivity index K_{s1} is used to evaluate the **loudness efficiency rating**, but the Standard refers to the article by Hopkins and Stryker (Ref. 50) for detailed information. Loudness efficiency rating is defined as the ratio of the total "effective" acoustical power produced by the loudspeaker to the available electrical power. The loudness efficiency rating is equal to

$$LR = 100e = 100 \times 10^{L_e/10} \quad (3)$$

where e = electroacoustical efficiency

$$L_e = 20 \log_{10} p_{ax} - 16 - k - K_{s1}$$

p_{ax} = effective sound pressure on axis of loudspeaker at distance 30 ft., in dynes/cm²,

$$k = 10 \log_{10} W_R$$

W_R = maximum available electrical power in watts

and K_{s1} = loudness directivity index (see above).

See Refs. 50, 121 (pp. 697-706).

Loudspeaker efficiency in terms of acoustical power

(Based on SE-103—Ref. 95).

The loudspeaker efficiency (G_{sw}) in terms of acoustical power is the difference between the output acoustical power level and the available input electrical power level, and is expressed in db.

The symbol G_{sw1} indicates the loudspeaker efficiency when standard test signal No. 1 is used.

$$G_{sw} = 10 \log_{10} (W_s/W_o)/(W_{AS}/W_o) \quad (4)$$

$$= 10 \log_{10} (W_s/W_{AS}) \quad (5)$$

$$= 20 \log_{10} p_s - K_s - 20 \log_{10} E_G + 10 \log_{10} R_{SR} + 20 \log_{10} (1 + R_{SG}/R_{SR}) - 16 \quad (6)$$

where G_{sw} = loudspeaker efficiency in db

W_s = total radiated acoustical power, in watts

W_{AS} = electrical power available to the speaker, in watts

W_0 = reference power = 0.001 watt
 E_G = r.m.s. value of constant voltage of source, in volts
 R_{SR} = loudspeaker rating impedance, in ohms
 R_{SG} = loudspeaker measurement source impedance, in ohms
 p_s = 30 ft. axial free space sound pressure, in dynes/cm²
 and K_s = loudspeaker directivity index, in db.

It is obvious that $(W_s/W_{AS}) \times 100$ is the loudspeaker percentage efficiency, and hence

Efficiency	2	4	6	10	20	30	100	%
G_{SW}	-17	-14	-12.2	-10	-7	-5.2	0	db

The total radiated acoustical power in dbm is given by the electrical power available to the speaker in dbm plus the speaker efficiency in db. For example, if the available electrical power is 10 watts = 40 dbm, and the speaker efficiency is -13 db, then the total radiated acoustical power will be (40 - 13) dbm = 27 dbm = 0.5 watt.

See also "American Recommended Practice for Loudness Testing" C16.4-1942 (Ref. 70).

For loudspeaker testing see also Refs. 13A (pp. 353-376), 121 (pp. 607-609, 661-706), 175 (pp. 292-295), 188 (pp. 768-773).

For Standards for multiple loudspeakers in sound systems see Chapter 21 Sect. 2(ii).

SECTION 1 : LOUDSPEAKER "MATCHING"

(i) *Loudspeaker characteristics and matching* (ii) *Optimum plate resistance* (iii) *Procedure for "matching" loudspeakers to various types of amplifiers.*

(i) Loudspeaker characteristics and matching

If the impedance of a loudspeaker were a constant resistance, the problem would be simple. In reality, the magnitude of the impedance may vary in a ratio up to 10 : 1 and the phase angle may be anything between 50° leading and 60° lagging—see Chapter 20 Sect. 1(v).

A loudspeaker, or output, transformer is an impedance changing device, with an impedance ratio approximately equal to the square of the turns ratio (see Chapter 5). The transformer by itself has no "impedance" in this sense—it merely reflects across the primary the load impedance placed across the secondary terminals, multiplied by its impedance ratio. Example : A transformer has a turns ratio 10 : 1 from primary to secondary. Its impedance ratio is therefore 100 : 1 primary to secondary. If the secondary load is 8 ohms, the reflected "primary impedance" will be 800 ohms. The only limitations on the wider use of the same transformer are the primary inductance, which will reduce the low frequency response, the maximum d.c. plate current and the maximum power output.

(ii) Optimum plate resistance

The power output of a loudspeaker is equal to the power input multiplied by the efficiency. The power input to the primary of the loudspeaker transformer, under the usual operating conditions, is equal to the square of the signal plate current multiplied by the reflected load resistance—

$$\text{Power input in watts} = I_p^2 R_L \quad (1)$$

where I_p = signal plate current in amperes, r.m.s.
and R_L = load resistance reflected on to the primary of the transformer.

The signal plate current is given by

$$I_p = \mu E_g / (r_p + R_L) \quad (2)$$

where μ = amplification factor of power output valve
 E_g = signal grid voltage, r.m.s.
and r_p = effective plate resistance of power output valve.

Consequently, at the bass resonant frequency where the resistance R_L may rise to a high value, it is possible to have maximum plate circuit efficiency and yet to have

less than the maximum electrical power output, because the signal plate current is reduced by the high load resistance. This effect is most pronounced with low values of plate resistance, and with triode valves or negative feedback the loudspeaker acoustical output may actually fall at the bass resonant frequency. With pentodes without feedback the reverse occurs, since a pentode approximates to a constant current source, and there is a high peak of output at the bass resonant frequency.

A similar effect occurs at the higher frequencies, the highest level of response occurring with pentodes, an intermediate value with triodes having $R_L = 2r_p$, and the lowest with constant voltage at all frequencies (a condition approached when a high value of negative feedback is used).

For any one loudspeaker, there is a value of plate resistance which provides most nearly constant response at all frequencies.

Reference 5.

(iii) Procedure for "matching" loudspeakers to various types of amplifiers

When the load resistance is constant, the only procedure necessary is to select a transformer ratio so that the resistance reflected into the primary is the correct load for the amplifier. When the load is a loudspeaker, the procedure is outlined below.

Class A Triodes, either singly or in push-pull, may be treated very simply by arranging for the loudspeaker impedance at 400 c/s to equal the correct load for the amplifier. Thanks to the shape of the triode characteristics, the rise of impedance at the bass resonant frequency decreases the distortion, and although the power output from the valve is lower than at 400 c/s this is counterbalanced by the rise of loudspeaker efficiency at this frequency. The rise of impedance above 400 c/s results in a tendency towards a falling response, but loudspeakers specially designed for use with triodes are capable of giving fairly uniform response up to their limiting frequency. As a result, the designer of an amplifier with a triode output stage need not consider the impedance versus frequency characteristics of the loudspeaker, but only the response.

The ratio of the nominal load resistance R_L to the output resistance R_0 of the amplifier is not unimportant. If R_L/R_0 is very high, the loudspeaker is being operated with nearly constant voltage at all frequencies. If R_L/R_0 is around 2 or 3, the voltage applied to the loudspeaker is slightly greater at frequencies where the loudspeaker impedance rises—this is generally an advantage. See also Chapter 13 Sect. 2(iv).

Pentodes without feedback are very critical with regard to load impedance [Chapter 13 Sect. 3(viii)]. Steps which may be taken to minimize the serious distortion include :

(1) The choice of a loudspeaker with a smaller variation of impedance with frequency, at least over the low frequency range [Chapter 20 Sect. 1(v)].

(2) Shunting the load by a capacitance, or a capacitance in series with a resistance, to reduce the impedance somewhat at high audio frequencies [Chapter 13 Sect. 3(viii)]. However, if the capacitance is sufficient to reduce the impedance to a more or less horizontal curve, there will inevitably be attenuation of the higher frequencies.

(3) Shunting the load by an inductance, through the use of a fairly low inductance of the transformer primary [Chapter 5 Sect. 3(iii)c ; Chapter 13 Sect. 3(vii), (viii)]. This only affects the low frequency peak, and is undesirable because of the resultant distortion.

(4) The use of a vented baffle to reduce the low frequency impedance peak [Chapter 20 Sect. 3(iv)].

(5) The selection of a loudspeaker impedance at 400 c/s rather lower than the nominal value, so that there is a variation on both sides of the nominal value instead of only on the upper side [Chapter 13 Sect. 3(viii)].

(6) The selection of an output valve capable of giving considerably more—say 3 times—the desired power output, so as to reduce the distortion with an incorrect load impedance.

(7) The use of negative voltage feedback (see below).

Fortunately, owing to the characteristics of music, the input voltage applied to the grid of the power amplifier at high frequencies will normally be less than the maximum. This somewhat reduces the distortion at high frequencies.

Pentodes with negative voltage feedback, when operated well below maximum power output, are less affected by the loudspeaker impedance variations than pentodes without feedback. If the feedback is large, the output voltage remains nearly constant irrespective of the loudspeaker. There is an optimum value of amplifier output resistance to give most nearly uniform response at all frequencies with any one loudspeaker.

When operated at maximum power output with the small degree of feedback usual in radio receivers, the load resistance is critical. Satisfactory operation with low distortion can only be obtained by reducing the grid input voltage.

With a large amount of feedback, as for a cathode follower, the impedance at 400 c/s should be the nominal value for the valve. The increase of impedance at other frequencies will not then cause distortion. See also Chapter 7 Sect. 5(iv).

SECTION 2 : MULTIPLE AND EXTENSION LOUDSPEAKERS

(i) *Multiple loudspeakers—general* (ii) *Sound systems* (iii) *Extension loudspeakers*
(iv) *Operation of loudspeakers at long distances from amplifier.*

(i) Multiple loudspeakers—general

Two or more loudspeakers may be connected to a single amplifier either to reinforce the sound in a large space, or to give a pseudo-stereophonic effect. In all normal cases the loudspeakers will each handle the whole frequency range and operate at approximately the same level. The usual arrangement is to connect the loudspeakers in parallel either on the primary or secondary side. In the former case an a-f choke may be used in the plate circuit with capacitive coupling to the transformer primaries (Fig. 21.1). If the correct load resistance is R_L , the nominal impedance of T_1 and T_2 should each be $2R_L$. If there are N loudspeakers in parallel, each should have a nominal impedance of NR_L . The value of C_1 may be calculated as a coupling condenser [Chapter 12 Sect. 2(ii)] into a resistance R_L . If $R_L = 5000$ ohms, C_1 may be $1\mu\text{F}$ for about 1 db loss at 60 c/s. The value of L_1 may be calculated as for an a-f transformer [Chapter 5 Sect. 3(iii)c and Table 2 p. 213]. The total attenuation is the sum of that due to L_1 , the coupling condenser C_1 and the transformer T_1 . A suitable value for L_1 is normally from 10 to 30 henrys.

FIG. 21.1

FIG. 21.2

Fig. 21.1. Choke-capacitance coupling to two or more loudspeakers in parallel.

Fig. 21.2. Transformer coupling to 500 ohm line, across which two or more loudspeakers are connected in parallel.

Alternatively the parallel loudspeakers may be connected across a 500 ohm (or any other convenient value) line from the secondary of transformer T_3 as in Fig. 21.2. Here T_3 will have a 500 ohm secondary and will reflect an impedance R_L into the primary. T_1 and T_2 will have nominal impedances each 1000 ohms. If there are N loudspeakers in parallel, each will have a nominal impedance of $N \times 500$ ohms.

The simplest arrangement is to connect the secondaries in parallel as for extension loudspeakers (Fig. 21.5).

Loudspeakers may also be connected in series or in series-parallel, provided that the units are identical, with identical impedances. If loudspeakers having different impedances are connected in parallel, the power output from each will be inversely proportional to its impedance—

Loudspeaker No. 1. Impedance R_1 Power output P_1

Loudspeaker No. 2 Impedance R_2 Power output P_2

Connected in parallel with applied voltage E :

$$P_1 = E^2/R_1; P_2 = E^2/R_2 \text{ etc. for any number.}$$

If it is desired to operate two loudspeakers with power outputs in the ratio A to 1, where A is greater than 1 :

$$P_1/P_2 = A; R_2/R_1 = A$$

The impedance of the two in parallel will be

$$R = R_1 R_2 / (R_1 + R_2).$$

Example : A monitor loudspeaker is to operate with an input power of 1 watt and is to be connected across a combined loudspeaker load of 30 watts with a total (line) impedance of 500 ohms. The ratio of power is 30 : 1 so that the impedance of the monitor loudspeaker (measured across the primary of its transformer) should be $30 \times 500 = 15\,000$ ohms. In this case the monitor will have negligible effect on the combined impedance.

(ii) Sound systems

In medium and large installations it is convenient to design amplifiers for a constant output voltage. The usual output voltage in U.S.A. is 70.7 volts but higher voltages 100, 141, 200 etc. are also used (R.M.A. SE-101-A, July 1949, SE-106, July 1949). Each amplifier normally has its own distribution line suitably loaded by loudspeakers. Each loudspeaker may be arranged—by the use of transformer tapplings—to take from the line any desired power, while any loudspeaker may be moved from one line to another without affecting its output level. If the loudspeaker transformers are correctly matched to the voice coil impedance and the line voltage, the matching of the whole distribution line to the amplifier will be correct when the line is loaded to the full capabilities of the amplifier.

The American Standard (R.M.A. SE-106) specifies transformer secondary impedances of 4, 8 or 16 ohms ; this does not apply to transformers which are furnished only as part of a loudspeaker. The primaries are tapped to provide output power levels of 1 watt and proceeding upwards and downwards in 3 db steps (i.e. 1, 2, 4 watts etc., 0.5, 0.25 etc.) when the standard input voltage is applied.

(iii) Extension loudspeakers

An extension loudspeaker is one which may be added to the existing loudspeaker in a radio receiver, for which provision may or may not be made by the set manufacturer.

FIG. 21.3

Fig. 21.3. Common form of extension loudspeaker.

The most common provision for an extension loudspeaker is shown in Fig. 21.3 in which the extension loudspeaker (marked "EXT") is fed through a blocking condenser connected to the plate of the power valve. It is necessary for the user to arrange for flexible leads to be taken from two terminals on the chassis, across the primary of the stepdown transformer, to the permagnetic extension speaker. If the extension speaker has the same reflected load impedance as the transformer of the original speaker,

the power output will be shared equally between the two, but the impedance of the two speaker primaries in parallel will be only half what it should be for maximum power output. If no provision is made to provide correct matching, the arrangement will be quite practical, except that the power output of both speakers together will be less than with correct matching.

An alternative arrangement, which has much to commend it, is the use of an extension speaker with an impedance of about twice that of the speaker in the set. This means that the extension speaker will operate at a lower sound level than the one in the set, but the mis-matching will be less severe and the maximum volume obtainable from the set will not be seriously affected.

If negative feedback is used in the receiver, the effect of the connection of the external speaker on the volume level of the loudspeaker in the set will not be very noticeable at low or medium levels, although the same problem arises in regard to the overload level.

Fig. 21.4. Extension loudspeaker with provision for switching either loudspeaker alone.

Fig. 21.5. Extension loudspeaker connected to the voice coil circuit.

It is possible to modify the previous arrangement by means of switches which can open-circuit the voice coil of the first speaker and at the same time close a switch in the primary circuit of the second speaker. This is illustrated in Fig. 21.4 from which it will be seen that only one speaker will be operating at the one time and there is therefore no problem with correct matching. With this arrangement, the extension speaker should have the same impedance as the one in the set and the power input to both speakers will then be equal. The two switches S_1 and S_2 could, of course, be combined into a single wafer switch.

The previous arrangements have all adopted an extension from the primary of the loud speaker transformer and therefore at a high impedance. There are advantages to be gained in using the voice-coil circuit for the extension, as illustrated in Fig. 21.5. This avoids the necessity for a step-down transformer on the extension speaker and for a blocking condenser. The set manufacturer may fit two terminals on the loudspeaker housing, connected to the voice coil, as an alternative to Fig. 21.3. To obtain the same power from both speakers, it is necessary for the voice-coil impedances to be equal. If it is required to have one speaker operating at a higher level of sound than the other, the impedance of the second (lower output) speaker should be made higher than that of the first speaker. In such a case it is possible to obtain correct matching by calculating the impedance of both voice-coils in parallel and selecting a step-down transformer to suit. Very few voice-coils have an impedance less than about 2 ohms, so that it is possible to use quite ordinary wiring in the connections of the extension speaker. If the second speaker is to be situated more than say 10 feet from the first speaker, it may be desirable to use heavy wire, such as power flex (twin plastic is very convenient). In some cases it may be desired to operate the extension speaker at a rather lower level than the first speaker, in which case losses in the extension line may be desirable.

A single-pole double-throw switch may be used to change over from one to the other voice-coil as shown in Fig. 21.6 (A). Here switch S is used to open-circuit the first voice-coil and at the same time to close the circuit to the second voice-coil. The further refinement of a series volume control R is shown in the extension speaker circuit, so that the volume may be reduced below that of the speaker in the receiver. The resistance R should have a maximum value about 20 times that of the voice-coil impedance, but even so this arrangement cannot be used to reduce the volume to zero.

In order to have a complete control over the volume from the extension loudspeaker, the arrangement of (B) may be used in which R is a potentiometer with the moving contact taken to the extension speaker.

The series resistor volume control shown in Fig. 21.6 (A) increases the effective impedance of the extension loudspeaker circuit at low volumes, but this is not a serious detriment since the volume will be low and the mis-matching of only minor importance, particularly if negative feedback is used. The potentiometer method of volume control in Fig. 21.6 (B) has to be a compromise, and is incapable of giving satisfactory matching under a wide range of conditions. A reasonable compromise for the resistance R would be about five times the impedance of the voice-coil, but this will result in appreciable loss of power even at maximum volume. For perfect matching, resistance R should be taken into account, but for many purposes the effect

Fig. 21.6. Extension loudspeaker circuits incorporating volume control of the extension speaker.

FIG. 21.6

may be neglected provided that R is not less than five times the voice-coil impedance. At low levels this arrangement has a high impedance but here again the effect will not be serious.

Another form of volume control is a tapped secondary winding, with the extension speaker connected through a rotary switch to a selected tap. Taps may be made with each one 70% of the turns of the one above it, giving roughly 3 db steps, or 80% for 2 db steps. This method causes serious mis-matching, and is not advisable unless there are several main loudspeakers and only one "extension" with volume control.

The best method of volume control is a L type level control (Fig. 21.11) which provides constant input resistance and may be continuously variable (see Chapter 18).

All the preceding arrangements are limited to the use of either of two speakers or have given a choice between one and both. **The ideal arrangement is to permit the use of one or other or both.** This is particularly helpful when the extension speaker is used in a different room and one may wish to operate the extension speaker alone. Tuning-in may be done by switching over to both speakers, adjusting the volume level to suit the extension speaker, and then switching over so that only the extension is in operation. Then, if at any time the speaker in the receiver is required to operate, this may be done simply by moving the switch without causing any interference to the extension speaker.

Fig. 21.7. Extension loudspeaker circuit incorporating switching to operate either or both speakers.

If it is desired to use a single secondary winding on the transformer it is possible to arrange two speakers as shown in Fig. 21.7 so that either or both may be operated. With this arrangement the resistor R (which should have a resistance equal to the voice-coil impedance of one of the speakers) has to be used to provide correct matching

when one speaker only is operating. Only half the full power output is available when one speaker is operating alone ; the full power output is, however, available when both speakers are operating together (switch position 1). This has the result that the switching in of the second speaker does not affect the volume level of the first speaker, the resistor R really being a dummy load to take the power which would otherwise be supplied to the second speaker. The two switches S_1 and S_2 may be made from a single wafer wave-change switch.

A preferred arrangement, which does not result in any power loss under any circumstances, is the use of a tapped secondary winding on the transformer. The full winding on the secondary is used for one or other loudspeaker, while the tap is used for both operating together ; this involves a more elaborate switching arrangement but one which may be justified in certain circumstances.

The use of an appreciable amount of negative voltage feedback results in nearly constant voltage across the load under all conditions, and minimizes changes in volume level with any form of switching.

When the loudspeaker is some distance from the transformer secondary, the power loss in the connecting wiring should not exceed 15%.

Line length for 15% line power loss in low impedance lines :

Wire size		Load Impedance (Ohms)					
A.W.G.	S.W.G.	2	4	6	8	10	15
14	16	60 ft.	120 ft.	180 ft.	240 ft.	300 ft.	450 ft.
16	18	38 ft.	75 ft.	113 ft.	150 ft.	190 ft.	285 ft.
18	19	23 ft.	47 ft.	70 ft.	95 ft.	118 ft.	177 ft.
20	21	15 ft.	30 ft.	45 ft.	60 ft.	75 ft.	112 ft.
22	23	9 ft.	18 ft.	28 ft.	37 ft.	47 ft.	70 ft.

Reference 20.

(iv) Operation of loudspeakers at long distances from amplifier

When one or more loudspeakers are to be operated at a considerable distance from the amplifier, it is usual to have at the amplifier a transformer to step-down, for example, to a 500 ohm "line" which may be in the form of ordinary electric power wiring for distances up to several thousand feet. At the far end there must be another step-down transformer from 500 ohms to the correct impedance to match the voice coil circuit impedance. In such a case the "line" does not itself impose any appreciable load ; the loudspeaker impedance is reflected back through the transformer to load the line.

Line length for 15% line power loss in 500 ohm lines :

Wire size (A.W.G.)	19	21	23	25
Wire size (S.W.G.)	20	22	24	26
Length of line (feet)	4750	2880	1780	1500

Although 500 ohms is a popular value, any lower or higher value may be used provided that the resistance of the line is not too great, and that the capacitance across the line does not seriously affect the high frequency response.

A very popular line impedance is 600 ohms.

SECTION 3: LOUDSPEAKER DIVIDER NETWORKS

When two loudspeakers are used in a 2 way system, it is necessary to have a frequency dividing network. The attenuation characteristic may have an ultimate slope of 6, 12 or 18 db per octave, but the most generally satisfactory compromise is 12 db per octave. A slope of 6 db per octave is usually insufficient to prevent overloading of the high frequency unit at frequencies below the cross-over frequency.

The theory of frequency dividing networks is covered in Chapter 4 Sect. 8(x). The simplest possible arrangement is Fig. 4.53A for which the values of L_0 and C_0 are given on page 184 for known values of R_0 and the cross-over frequency f_c . In order to obtain reasonably satisfactory performance, the high-frequency unit should be a fairly substantial 5 in. or larger loudspeaker, and the cross-over frequency should preferably be between 800 and 1200 c/s. The high frequency response will obviously be restricted. The low frequency unit should have reasonable response up to about 2000 c/s. One of the most popular arrangements for good fidelity is the series-connected constant-resistance type of Fig. 4.53B giving an ultimate attenuation of 12 db. Both inductors and both capacitors have identical values. Here $L_1 = R_0/(2\sqrt{2}\pi f_c)$ and $C_1 = 1/(\sqrt{2}\pi f_c R_0)$. For example, let the voice coil impedance R_0 be 10 ohms, and the cross-over frequency 800 c/s.

Then $L_1 = 10/(2 \times 1.41 \times \pi \times 800) = 1.41$ millihenrys
and $C_1 = 1/(1.41 \times \pi \times 800 \times 10) = 28.2 \mu\text{F}$.

The parallel-connected constant resistance type is also used (Ref. 21).

Air cored multilayer solenoids may be used for inductances up to 8 millihenrys. Suitable sizes of formers are $1\frac{1}{4}$ in. dia., with axial length $\frac{3}{4}$ in. for inductances from 0.5 to 2.0 mH and $1\frac{1}{4}$ in. for inductances from 2.0 to 8.0 mH. The winding wire may be 17 A.W.G. (18 S.W.G.) double cotton enamelled copper. The outside diameter will be less than 4 in. for the values quoted above.

FIG. 21.8

Fig. 21.8. Filter type frequency dividing network, series connection.

The number of turns may be calculated from the formulae of Chapter 10 Sect. 2(iv)A or alternatively from curves (Ref. 11 for 17 A.W.G. D.C.E.).

Iron cores introduce distortion, and are therefore undesirable. However if iron-cored inductors are used, an air gap of 0.008 in. or 0.010 in. should be provided (Ref. 6 p. 101). Ferrite cores present possibilities for this application.

In the filter type arrangement which is also popular, the two inductors and the two capacitors have different values, and the nominal attenuation is 12 db per octave (Fig. 21.8). Taking the design constant $m = 0.6$, we have

$$\begin{aligned} L_0 &= R_0/(2\pi f_c) & C_0 &= 1/(2\pi f_c R_0) \\ L_8 &= R_0/(3.2\pi f_c) & C_8 &= 0.8/(\pi f_c R_0) \end{aligned}$$

where L is in henrys and C is in farads (Refs. 6, 19).

In all cases the series connection is preferable to the parallel connection. Resistance in the inductors has a slight effect on the attenuation at the cross-over frequency, while it also introduces insertion loss (0.3 to 1 db). Care should be taken to keep the resistance as low as practicable. The usual position is between a single power amplifier valve (or two in push-pull or parallel) and the loudspeakers. The insertion loss is therefore a loss of maximum output power. The divider network may be connected either on the primary or secondary side of the output transformer, the latter being more usual—in this case the transformer must be suitable for the total frequency range of both units.

If the dividing network is placed on the primary side, each of the two output transformers is only called upon to handle a limited frequency range, and may be of cheaper construction. One interesting application is Fig. 21.9 (Refs. 9, 16). For a plate-to-plate load of 5000 ohms and a cross-over frequency of 400 c/s the component values are :

$L_1 = 2.0$ henrys (series aiding) ; inductance T_1 primary = 50 henrys min. ;
 $L_2 = 1.0$ henry (with air gap) ; T_2 primary inductance = 2.0 henrys (with air gap) ;
 $C_1 = 0.16 \mu\text{F}$; $C_2 = 0.04 \mu\text{F}$; leakage inductance of T_1 not over 1 henry ; leakage inductance of T_2 not over 0.05 henry.

Fig. 21.9. Alternative form of divider network using two stepdown transformers (Ref. 9).

It has been shown that the arrangement of Fig. 21.9 produces less distortion than the conventional circuit : this is due to two features. Firstly, the low-pass filter $L_1, 2C_1$ attenuates high frequencies propagating in either direction ; as a result the harmonic components of magnetizing current in T_1 have less effect on the high-pass channel. Secondly, the low-pass filter attenuates high frequencies on their way to T_1 so that the transformer is only called upon to handle a limited range of frequencies, thereby reducing the distortion (Ref. 9).

In the case of separate amplifiers for low and high audio frequencies, the divider network preferably precedes the amplifiers. This permits separate attenuators to be used for each channel ; these may be used for balancing the two units, or for tone control.

If the high frequency unit is more sensitive than the low frequency one, a simple form of fixed attenuator may be incorporated (Fig. 21.10). Here

$$R_1 + R_3 = R_0 \text{ and } R_1/R_3 = (E_1/E_2) - 1$$

$$\text{where } R_3 = R_2 R_0 / (R_2 + R_0).$$

For example, to give $(E_1/E_2) = 2$ (i.e. an attenuation of 6 db) :

$$R_1 = \frac{1}{2}R_0 \text{ and } R_2 = R_0.$$

Fig. 21.10. Complete circuit from valve plate to loudspeakers, incorporating the filter of Fig. 21.8 with an attenuator on the h. f. speaker.

If it is desired to use this as a variable attenuator to give tone control, it should preferably be of the constant input impedance type such as the L pad [Fig. 21.11, also see Chapter 18 Sect. 3(iii)]. If a simpler type must be used, it may be designed as for Fig. 21.10 to give the correct input impedance at the normal operating position, but with a sliding contact. It will then have an incorrect impedance at any other

setting ; the effect is only slight if the sensitivity of this unit is very much greater than the other, as happens with horn and direct-radiator assemblies.

If one loudspeaker unit has a lower impedance than the other, an auto-transformer may be used to provide correct matching. This may not be necessary if an attenuator is used on one unit.

FIG. 21.11

Fig. 21.11. *L* type level control providing constant input resistance.

It is important to check for the phasing of the two loudspeakers ; in the vicinity of the cross-over frequency both units should be in phase (aiding one another). This may be checked by the use of a single dry cell connected in series with the secondary of the transformer ; in the case of 2 ohm voice coils there may be a 5 ohm limiting resistor connected in series with the cell.

SECTION 1 : INTRODUCTION

Aerials and transmission lines differ from simple electrical networks in that their inductance, capacitance and resistance are not lumped but are distributed over distances such that the time required for electrical energy to travel from one part to another has to be taken into account. In a single chapter it is, of course, impossible to attempt to give a theoretical treatment of these devices. What will be done will be to present some useful formulae, a few physical pictures of the processes which occur and some results of practical experience with aerials and transmission lines.

SECTION 2 : THE TRANSMISSION LINE

(i) *Introduction* (ii) *The correct termination for a transmission line* (iii) *Impedance-transforming action of a transmission line.*

(i) Introduction

A transmission line consists of an arrangement of electrical conductors by means of which electromagnetic energy is conveyed, over distances comparable with the wavelength of the electromagnetic waves, from one place to another. The theory of transmission lines provides a link between circuit theory and the field theory of electromagnetic waves inasmuch as the properties of such lines may be determined either from the picture of a transmission line as a filter network with an infinite number of elements, or from the picture of electromagnetic waves guided between (usually) a pair of conducting surfaces.

Some of the properties of transmission lines will now be given.

(ii) The "correct" termination for a transmission line

A uniform transmission line has what is called a "characteristic impedance". This is the impedance that would be measured at the end of such a line if it were infinitely

long. The importance of this characteristic impedance lies in the fact that if any length of line is terminated in an impedance of this value, then all the energy flowing along the line is absorbed at the termination and none is reflected back along the line. A result of this is that the input impedance of any length of transmission line terminated in its characteristic impedance is equal to the characteristic impedance. At radio frequencies, the characteristic impedance of all normally-used types of transmission line is almost purely resistive.

The value of the characteristic impedance for a low-loss line is

$$Z_0 = \sqrt{L/C} \quad (1)$$

where L and C are the distributed inductance and capacitance per unit length of the line. The velocity of propagation of electromagnetic waves along such a line is

$$v = 1/\sqrt{LC} \quad (2)$$

With air as the dielectric, $v = 3 \times 10^8$ metres per second, which is the velocity of light*. For other dielectrics

$$v = 3 \times 10^8 / \sqrt{K} \text{ metres per second} \quad (3)$$

where K = dielectric constant.

In cables with polythene dielectric, for example, $K = 2.2$ and v is therefore 0.67 of the velocity of light. This means that the wavelength of the waves in the cable is only 67% of the wavelength in air.

For a low-loss transmission-line the characteristic impedance may be found if C and L are determined. Actually it is not necessary to determine both—one is sufficient.

If we combine (1) and (2) we obtain

$$Z_0 = 1/vC = vL. \quad (4)$$

For a transmission line consisting of a pair of parallel conductors

$$Z_0 = \frac{276}{\sqrt{K}} \log_{10} \frac{d}{r} \text{ ohms} \quad (5)$$

where d is the distance between the centres of the conductors and r is the radius of each conductor.

For a co-axial line

$$Z_0 = \frac{138}{\sqrt{K}} \log_{10} \frac{r_1}{r_2} \quad (6)$$

where r_1 is the inside radius of the outer conductor and r_2 is the outside radius of the inner conductor.

(iii) Impedance-transforming action of a transmission line

If the line is terminated in an impedance Z_L which is not equal to the characteristic impedance Z_0 of the line (or, in other words, the load is not matched to the line), then the energy is not completely absorbed at the termination, but some is reflected back along the line. As a result of this, **standing waves** are formed on the line, and the value of the input impedance to the line depends on the length of the line. The ratio of the voltage (or current) in the backward wave to that in the forward wave is called the **reflection coefficient** and has a value

$$k = \frac{Z_L - Z_0}{Z_L + Z_0} \quad (7)$$

The **standing-wave ratio** in the line is the ratio of the maximum to the minimum voltage (or current) that appears at points along the line. (The distance between a maximum and an adjacent minimum is one quarter wavelength).

The standing-wave ratio has a value—

$$\rho = \frac{1 + |k|}{1 - |k|} \quad (8)$$

If Z_L is resistive and has a value R_L , then (8) becomes

$$\rho = R_L/Z_0 \text{ or } Z_0/R_L \quad (9)$$

depending on whether R_L is greater or less than Z_0 .

*A more precise value is 2.9979×10^8 metres/sec.—see Chapter 9 Sect. 11(iii) and Ref. B1.

For a transmission-line having no dissipation, the **input impedance** Z_i is given by

$$Z_i = Z_0 \frac{Z_L \cos \beta l + j Z_0 \sin \beta l}{Z_0 \cos \beta l + j Z_L \sin \beta l} \quad (10)$$

where $\beta = 2\pi/\lambda$, λ being the wavelength of the waves in the transmission line and l the length of the transmission line.

If l is equal to any integral number of half waves, then

$$\cos \beta l = \cos n\pi = \pm 1$$

$$\sin \beta l = 0$$

$$\text{and } Z_i = Z_L, \quad (11)$$

i.e. the input impedance is equal to the load impedance irrespective of the value of Z_0 .

On the other hand, if the line has a length equal to an odd integral number of quarter-waves, then

$$Z_i = Z_0^2/Z_L \quad (12)$$

This relation is interesting, because it shows the basis of the **quarter-wave transformer**, which is used extensively. The section of line will match a generator to a load if Z_0 is chosen to be equal to the square-root of the product of the generator and load impedances.

SECTION 3: AERIALS AND POWER TRANSFER

(i) *Introduction* (ii) *Power transfer.*

(i) Introduction

The function of a receiving aerial is to collect electromagnetic energy which is passing through the space surrounding the aerial, and to pass this energy into a radio receiver.

(ii) Power transfer

We consider first the simplest case of energy transfer between a transmitter and a receiver, where **two straight dipole aerials** are placed a large number of wave-lengths apart and are far removed from any reflecting surface, such as the earth. Suppose that one aerial is energized by a transmitter, and that the other is connected to a receiver. If the power of the transmitter remains fixed, then we find that the power appearing at the receiver is dependent on a number of factors—

(a) The received power is greatest when the aerials are parallel to each other (for short aerials, the maximum occurs when the axis of each aerial is perpendicular to the line joining the centres of the two aerials; for aerials longer than one half-wave length, this is not necessarily so).

(b) The received power is inversely proportional to the square of the number of wave-lengths between transmitting and receiving aerials.

(c) For aerials less than one half-wave in length, the power received is independent of the length of either aerial, provided the aerials can be matched **without loss** to the transmitter or receiver. In practice, however, aerials very short compared with a wave-length are characterised by high ohmic losses.

Paragraphs (b) and (c) may be summarized quantitatively as follows.

If P_T is the power emitted from a dipole aerial (less than half-wave in length) and P_R is the power available for transfer from the receiving aerial to a receiver, and n is the number of wavelengths between transmitting and receiving aerials, then

$$\frac{P_R}{P_T} = \left(\frac{0.119}{n} \right)^2 \quad (13)$$

Although this formula applies only when the aerials are situated in free space (or, as is shown later, when the transmitting and receiving aerials are of the short vertical type, situated close to a flat perfectly conducting earth), the formula is useful in illustrating a very important fact, which is, that **in the transfer of power between two aerials, the number of wave-lengths, rather than the distance, is the significant parameter.** As an illustration of this we may compare the energy available

at a receiver when the frequency of the emitted wave is (a) 600 Kc/s and (b) 150 Mc/s. We assume that the energy radiated in each case is 1000 watts and the distance between transmitter and receiver is 20 kilometres.

On applying the formula (13) we find that in the medium-frequency case, the power available at the receiver is 8.8 milliwatts, while in the v-h-f case the power available is only 0.142 microwatts.

This means that if both signals are to be amplified to produce, say 1 watt at the detector then the amplification required in the first case is approximately 20 decibels while in the second, it is nearly 70 decibels.

These figures partly explain why a crystal receiver is very effective for long-wave reception, whereas a receiver required for v-h-f work usually has a large number of stages of amplification.

SECTION 4 : CHARACTERISTICS OF AERIALS

(i) *Effective area of a receiving aerial* (ii) *The power gain of an aerial* (iii) *The beam-width of an aerial.*

(i) Effective area of a receiving aerial

The radio-frequency power passing through a unit area placed at right angles to the direction from a short dipole transmitting aerial does not (in free space) depend on the frequency. Its value is given by

$$\Phi = \frac{3P_T}{8\pi d^2} \text{ watts per square metre} \quad (14)$$

if the distance d from the transmitting aerial is given in metres, and P_T is in watts. Why is the power available at the receiver dependent on the frequency? The reason is that the **effective area** for capture of energy by the receiving aerial depends on the frequency.

The power available at the receiver is

$$P_R = \Phi A \quad (15)$$

where A is defined as the "effective area" of the receiving aerial.

If we substitute values of P_R and Φ from (13) and (14) we find that the effective area for a short dipole is $0.119\lambda^2$. In the example given above, A is approximately 30 000 square metres in one case and is less than 0.5 square metre in the other. The reason for the enormous difference in the energy available at the receiver in the two cases is now clear.

In the following table, the effective areas of various types of aerial are given :

TABLE 1

Type	Effective Area
Short dipole	$3\lambda^2/8\pi$ or approx. $0.119\lambda^2$
Half-wave dipole	$0.130\lambda^2$
Half-wave dipole with reflector	$0.25\lambda^2$ to $0.50\lambda^2$ (depending on spacing)
Broadside array with reflectors	Physical area, approximately
Broadside array, without reflectors	Physical area/2, approximately
Short vertical aerial near earth	$3\lambda^2/16\pi$

It will be seen from the table that the effective area for capture of electromagnetic energy by a short dipole is approximately equal to an area bounded by a circle which is at a radial distance of $\lambda/1.6\pi$ from the dipole. The physical significance of this is that such a circle very roughly forms the boundary between the region in which the local induction field of the aerial predominates and the region in which the radiation

field is the major component. Hence we can picture the aerial as capturing the energy which falls within the region in which the induction field of the aerial is of significant magnitude.

A broadside array of dipoles with a reflecting curtain can absorb all the energy that falls on it. Without the reflectors, it absorbs only half the incident energy and radiates one quarter back towards the transmitter and one quarter in the opposite direction. A similar effect occurs with a dipole. If it absorbed all the energy available to it and reradiated none, then its effective area would be double the value given in Table 1. A reflector is required to achieve this.

(ii) The power-gain of an aerial

The power-gain of a receiving aerial is the ratio of the power appearing at the input terminals of a receiver which is attached to the aerial to the power that would appear at the receiver if the aerial were replaced by a simple type of aerial (usually a half-wave dipole).

The **power gain**, G , of an aerial, therefore, must be equal to the ratio of the effective area A of the aerial to that of the comparison aerial.

With the half-wave dipole as the comparison aerial, we have

$$G = A/0.130\lambda^2 \quad (16)$$

As an example we may consider the case of an array of N half-wave elements spaced one half-wave length and arranged in the form of a rectangular curtain. Then from Table 1 we find

$$A \approx \text{Physical area}/2 \approx (N/2)(\lambda/2)(\lambda/2) = N\lambda^2/8 \quad (17)$$

$$\text{Therefore } G \approx N\lambda^2/1.04\lambda^2 \approx N \quad (18)$$

i.e. the power-gain of a broadside array of half-wave elements is approximately equal to the number of elements in the array.

(iii) The beam-width of an aerial

For a directional aerial having one major lobe in its directivity pattern there is a rough but useful rule to determine the angular width of this lobe. If the aerial has a breadth of n wave-lengths in any particular direction and the beam-width θ of the main lobe is measured in the same plane, then

$$\theta \approx 60/n \text{ degrees} \quad (19)$$

SECTION 5 : EFFECTS OF THE EARTH ON THE PERFORMANCE OF AN AERIAL

(i) *Introduction* (ii) *A perfectly-conducting earth* (iii) *An imperfectly-conducting earth* (iv) *The attenuation of radio waves in the presence of an imperfectly-reflecting earth.*

(i) Introduction

In the previous section the effect of reflecting surfaces has been disregarded. In practice, these effects must be taken into account, except in rare cases. The two "surfaces" to be considered are the earth and the ionosphere. We deal here with the effect of the earth.

(ii) A perfectly-conducting earth

The effect of the earth on the propagation of radio-waves is complicated and no attempt will be made here to treat it at all fully. As a first approximation one can consider the earth as a perfectly conducting flat surface. This enables one to use a device which simplifies the treatment considerably. One imagines an image of the aerial in the reflecting surface, and then the problem may be treated as one in which the aerial and its image are situated in free space. (The sign of the instantaneous potentials in the image are reversed from those in the aerial).

In Fig. 22.1 are shown the effects of the earth on the field pattern of a short vertical aerial and of a short horizontal dipole. It will be seen that the earth has no effect on the field pattern of the vertical aerial apart from removing the lower half of the pattern. With the horizontal aerial, however, there is complete cancellation of the waves in the horizontal plane and the resultant effect is zero.

The conclusion may be drawn from the diagram that where waves are arriving at the aerial in directions parallel to the plane of the earth, then one would expect a vertical aerial to be very effective while a horizontal aerial would be ineffective. (This applies to a transmitting as well as to a receiving aerial). It will be seen later that this conclusion does not fit the facts, in all cases, because the earth is not a perfect conductor. At medium and low radio-frequencies, however, it is in agreement with the facts—horizontal aerials are of no use in communicating between two points both close to the earth.

When waves are arriving at the aerial in directions inclined to the horizontal (as, for example, in the case of short-wave communication via the ionosphere) then either horizontal or vertical aerials may be used. If the distance between transmitter and receiver is not great, however, then the waves will be arriving at nearly vertical incidence and the horizontal aerial will be superior, provided that it is placed at a suitable height above the earth. The height at which the aerial should be placed above the earth depends on the angle of elevation of the waves which are to be received. The height is different for horizontal and vertical aerials.

In Fig. 22.1, for an angle of elevation θ , the distance d between the path lengths of waves to the aerial and to its image should be equal to an even number of half-waves in the case of a vertical aerial, and an odd number of half-waves in the case of a horizontal aerial. Simple trigonometry shows that this corresponds to a height h given by

$$h = n\lambda / (4 \sin \theta) \quad (20)$$

where n is an even integer for a vertical aerial and an odd integer for a horizontal aerial.

FIG. 22.1

Fig. 22.1. Effects of the earth on the field pattern of a short vertical aerial (A) and of a short horizontal dipole (B). Both (A) and (B) are cross-sectional views, and in (B) the sign + indicates direction of current into the paper while the sign - indicates the opposite direction. Polar diagrams of a short vertical aerial and a short horizontal dipole, both close to earth, are shown in (C) and (D) respectively.

(iii) An imperfectly-conducting earth

The propagation of radio-waves close to the surface of a finitely conducting earth has been studied theoretically for many years. Zenneck first produced a solution to the problem, and later Sommerfeld gave a more accurate analysis. Unfortunately, the incorrectness of Zenneck's analysis combined with a small error in Sommerfeld's, created some confusion that has persisted until the present day. As a result of the errors, it appeared that a special type of wave was propagated in the vicinity of the ground-plane. This wave was called a "surface-wave." It is known now, that this Zenneck "surface-wave" does not exist, but the name still appears in the literature on wave propagation. It is applied to the waves that travel between transmitting and receiving aerials when both are close (in terms of a wavelength) to the surface of the earth, as for example, in medium-wave broadcasting. When the aerials are raised several wave-lengths above earth, then the waves travelling between them are called "space-waves." These terms are artificial, but they serve some purpose in that they indicate that the conditions of propagation between two aerials placed close to the earth, are markedly different from those between two aerials elevated several wave-lengths above the earth's surface (as in v-h-f broadcasting).

In the conditions of propagation to which the term "surface-wave" is applied, vertical aerials are superior to horizontal aerials. Thus vertical aerials are always used in medium-frequency broadcasting. (The horizontal portion of a medium-frequency receiving or transmitting aerial plays no useful part, except to increase the efficiency of coupling to the receiver or transmitter).

When the aerials are raised several wave-lengths above the earth, as is usually the case in v-h-f communication, then horizontal and vertical aerials have roughly equal effectiveness.

When waves are not arriving at the aerial in a horizontal direction, then the difference between an imperfectly conducting earth and a perfectly conducting one is not so marked. Hence for short-wave communication one can treat the earth as a perfect conductor without introducing serious error in the calculations.

(iv) The attenuation of radio-waves in the presence of an imperfectly-reflecting earth

At short distances from a transmitting aerial the resistivity of the earth does not have a major effect on the energy reaching the vicinity of the receiving aerial. The principal effect of the earth is that the energy flowing through unit area placed at right angles to the line of propagation is doubled. The reason for this is that the transmitting aerial is now emitting its energy into a hemisphere instead of into a full sphere as was the case in free-space propagation.

Instead of the relation (14) we have now

$$\Phi = 3P_T/4\pi d^2 \quad (21)$$

where the symbols have the same meaning as in formula (14).

For a similar reason the effective area for capture of radiation by the receiving aerial is half that of the free-space case. For a short vertical aerial the effective area is

$$A = 3\lambda^2/16\pi. \quad (22)$$

The effects at the transmitting and receiving aerials, however, are such that the power attenuation between the two is the same as in the free-space case, so (13) is still applicable.

As the distance between the two aerials is increased, it is found that the attenuation actually found between transmitter and receiver becomes increasingly larger than that given by (13). This is the result of both the finite conductivity and of the curvature of the earth.

For the range of frequencies used in medium-wave broadcasting, and for earth of average conductivity ($\sigma = 7 \times 10^{-14}$ e.m.u.), values of the power-flux per unit area at the receiver are shown in Fig. 22.2.

Such curves are frequently given in terms of the strength ϵ of the electric field of the wave. To convert this into power-flux per unit area, one may use the relation

$$\epsilon = \sqrt{377\Phi} \text{ volts per metre} \quad (23)$$

Fig. 22.2. Attenuation at medium frequencies of the radiation from a transmitter (1 KW radiated, short aerial, average earth conductivity, $\sigma = 7 \times 10^{-14}$ e.m.u., $\epsilon = 15$).

where Φ is expressed in watts/metre².

Sometimes it is required to know the strength H of the magnetic field of the wave. This is related to the electric field by the expression

$$H = (\epsilon/377) \text{ ampere-turn/metre}^* \quad (24)$$

As a matter of interest, it may be noted that ϵ and H are analogous to voltage and current in electrical circuit theory. On this analogy the number 377 appears to denote a resistance, and is called the **intrinsic resistance of free space**.†

At very-high-frequencies, the attenuation of waves between two aerials close to the ground is rapid. This corresponds to the case of the so-called “surface waves” referred to in the previous section. Fortunately it is not difficult, at these frequencies, to raise the transmitting and receiving aerials several wave lengths above ground and achieve the conditions for “space-wave” propagation, where the attenuation is very much less.

For such conditions, a rough but useful formula for the attenuation is given by

$$P_R/P_T = (1.5 h_T h_R / n^2)^2 \quad (25)$$

where h_T and h_R are the heights (in wavelengths) above earth of the transmitting and receiving aerials, and the other symbols are the same as in (13).

More accurate values may be found by using Figs. 22.3, 22.4 and 22.5.

*The ampere-turn/metre is the unit of magnetic field strength in the Rationalized Meter Kilogram Second (M.K.S.) system of units.

1 ampere-turn/metre = 4×10^{-3} e.m.u. (oersted).

† Note: ϵ/H in e.m.u. = c; ϵ/H in c.s.u. = 1/c.

ϵ expressed in c.s.u. = H expressed in e.m.u. Refer to Chapter 38 Sect. 1(ii) on electrical and magnetic units.

Fig. 22.3. Effect of raising the receiving aerial above the earth (1 KW at 45 Mc/s radiated over earth with conductivity $\sigma = 10^{-13}$ e.m.u. and transmitting aerial 30 feet above the earth). The same curves also apply when the transmitting and receiving aeriels are transposed.

Fig. 22.3 shows the effect of raising the aerial above the earth* for a frequency of 45 Mc/s, and indicates that unless the aeriels are close to the earth, horizontal and vertical polarizations have practically equal effectiveness.

Fig. 22.4 and 22.5 for frequencies of 75 and 150 Mc/s were derived by T. L. Eckersley for vertically polarized waves, but may be used also for horizontally polarized waves with little error when the aeriels are at heights above earth corresponding to normal practice.

*An infinitely short dipole has been assumed.

SECTION 6 : THE EFFECT OF THE IONOSPHERE ON THE RECEPTION OF RADIO SIGNALS

Radio propagation over long distances on the earth is possible because of the presence of layers of ionized gas in the higher atmosphere of the earth. Signals reflected from the ionosphere are used exclusively in short-wave reception.

The principal reflecting layers in the ionosphere are the E and F_2 layers, situated at roughly 60 miles and 200 miles, respectively, above the surface of the earth. The E layer is a poorly reflecting surface and hence short-wave communication almost exclusively takes place via the F_2 layer. In designing a receiving aerial for short-wave communication, one must calculate the angle of elevation at which signals will arrive at the aerial, and then use the relation (20) to determine the height at which the aerial should be placed above earth. This calculation involves a knowledge of the height of the ionospheric layer, the distance between transmitting and receiving aerials, and the curvature of the earth.

The Australian reader is referred to the "Radio Propagation Handbook" and the "Monthly Ionospheric Predictions" produced by the Ionospheric Prediction Service of the Commonwealth Observatory, for information on communication by way of the ionosphere. In America the equivalent publications are the N.B.S. Circular 465 "Instructions for the use of basic radio propagation prediction" and CRPL-D publication "Basic radio propagation predictions" obtainable from the Central Radio Propagation Laboratory, National Bureau of Standards, Washington, D.C. The English reference is Bulletin A, published by Radio Research Station, National Physical Laboratory.

See also Chapter 8 References 5, 7 and 10.

In medium-wave broadcasting the ionosphere does not reflect any appreciable amount of energy during daylight hours. At night, however, waves are reflected back to the earth from what remains of the E layer (unlike the F layer, the E layer practically disappears at night) and these waves provide a secondary, or fading, service during the night hours over distances of hundreds of miles. Unfortunately, these reflected waves reach the earth also at relatively short distances (50 to 100 miles) from the transmitter and combine with the ground waves to produce a very objectionable type of fading. Hence the primary or non-fading service area of a medium-wave broadcasting station may be less at night than during the day. Aerials that favour signals which arrive horizontally and discriminate against those that arrive from high angles will diminish this undesirable effect. This normally cannot be done very effectively because the height required for the aerial is neither possible nor economical in a receiving installation. The best that can be done is to avoid types of aerials that accentuate this effect. Where night-time fading of signals is encountered, straight vertical aerials should be used. Loop aerials and inverted-L aerials with long horizontal sections should be avoided, and care should be taken that r-f coupling between the power mains and the receiver is kept to a minimum.

SECTION 7 : THE IMPEDANCE OF AN AERIAL

(i) Introduction (ii) Resistive component of impedance (iii) Reactive component of impedance (iv) Characteristic impedance of aerial (v) Examples of calculations (vi) Dipoles (vii) Loop aerials.

(i) Introduction

In the previous sections, the energy ideally available at the receiver terminals has been calculated. This energy is available, however, only if the receiver is matched to the aerial, and if there are no resistive losses associated with the aerial or aerial-earth system.

If the input circuit of a receiver is to be designed to extract the maximum energy from the radio-waves that are passing the aerial, then a knowledge of the component parts of the impedance of the aerial is required.

(ii) Resistive component of impedance

The first part of the aerial impedance to be considered is the resistive part concerned with the coupling between the aerial and the space around it. This is called the **Radiation Resistance** of the aerial and is the resistance that would be measured at the point of maximum current in a tuned aerial, in the absence of resistive losses. If a load resistance of this value is placed in the aerial at the point considered, then the aerial would extract from a passing wave an amount of power equal to the "available power" calculated in the previous sections.

The calculation of the radiation resistance of an aerial is not easy, and in most cases the calculations provide only approximate answers. The reader is referred to standard texts for these approximate methods of calculation.

If the impedance is measured at the base of an ideal vertical aerial, then the resistive component is called the **Base Radiation Resistance**. Values of this for the types of aerial commonly used in medium-frequency reception are given in Fig. 22.6.

If the r-f resistance at the base of an aerial is measured, it will be found to be greater, in general, than the calculated radiation resistance. The difference represents the loss resistance associated with the aerial-earth system. For a short aerial with small radiation resistance, the loss resistance may be many times greater than the radiation resistance. With such an aerial one can extract only a fraction of the power ideally available at the terminals of the aerial.

Fig. 22.6. Base radiation resistance of an inverted L aerial.

If we wish to calculate the power that may be extracted from the aerial in the presence of resistive losses we proceed as follows.

The power P_R ideally available at the aerial may be calculated and we can use information such as that given in Fig. 22.6 to find the radiation resistance R_R of the aerial. By measuring the base resistance and subtracting R_R from this we are left with R_L , the equivalent series loss resistance of the aerial-earth system. The equivalent circuit is shown in Fig. 22.7. It may be noted that we have not yet calculated e , the equivalent e.m.f. induced in the aerial by the radio-wave. This can be done easily however, because we know the resistance R_R and the power P_R that would be generated in a load resistance of this value if R_L were absent. Across such a load we would have a voltage of $e/2$.

FIG. 22.7

Fig. 22.7. Equivalent circuit of aerial-earth system.

$$\text{Hence } e = 2\sqrt{P_R R_R} \quad (25A)$$

When R_L is not negligible, then the load resistance R must be increased to $R_R + R_L$ for maximum power transfer. In this case, the power in the load is

$$P' = \left(\frac{e}{2}\right)^2 / (R_R + R_L) \quad (26)$$

Hence the ratio of power actually extracted from the aerial to that ideally available (or the **radiation efficiency of the aerial**) is given by

$$P'/P_R = R_R / (R_R + R_L). \quad (27)$$

To take a simple example, suppose that we have a vertical aerial of $1/16$ wavelength, and an earth resistance of 20 ohms and that we wish to calculate the radiation efficiency of the aerial.

From Fig. 22.6 we find $R_R = 1.6$ ohms, and we are given $R_L = 20$ ohms. Then $P'/P = 0.08$, which is the radiation efficiency of the aerial.

(iii) Reactive component of impedance

So far, only the resistive component of the base impedance of the aerial has been mentioned and we have assumed that the reactive part has been tuned out. It is most desirable that we should be able to calculate this reactive component, at least roughly, from the aspects of both the design of the input circuit of the receiver and the estimation of losses introduced by the tuning reactances.

A simple way to make an approximate calculation of the reactance of an aerial, is to treat it as a section of transmission line. We can simplify this treatment still further by neglecting the resistive component of the aerial impedance and by assuming that the transmission line has no loss. (This treatment breaks down when the base of the aerial is close to the point of minimum current of an aerial, but this case is very seldom met in an aerial designed for reception). Hence we can use the simple transmission line formula (10).

If the aerial is a straight wire, then this may be taken as an open circuited length of line. The terminating impedance Z_L is then infinite and (10) becomes

$$Z_i = X_i = -jZ_0 \cot \beta l \quad (28)$$

This formula can be applied also to an inverted L aerial, by neglecting the bend in the aerial and by taking l as the total length of wire in the aerial. If the aerial has a more elaborate type of capacitance top, then one can proceed as follows. Imagine the capacitance top broken at the point at which it joins the downlead of the aerial. Use (28) to calculate Z_i for each section of the capacitance top, then combine in parallel the values of Z_i . The resultant is then the terminating impedance Z_L of the aerial downlead. The impedance of this is then obtained from (10).

(iv) Characteristic impedance of aerial

As yet, we have given no indication of the value of characteristic impedance Z_0 to be assigned to the aerial. Various approximate formulae are available for this, but that of Steinmetz is possibly the best. This is

$$Z_0 = 138 \log_{10} (\lambda/d) - 104 \text{ ohms} \quad (29)$$

where λ is the wave-length

and d is the diameter of the aerial conductor (or cage) measured in the same units as λ .

(v) Example of calculations

The following worked example uses much of the work covered so far in this chapter.

Example

A receiving aerial of the inverted-L type has a horizontal top section of 50 ft. length and a 30 ft. vertical downlead. The aerial conductor is composed of 7/.029 in. copper wire. (a) What is the input impedance of the aerial at a frequency of 1000 Kc/s, if the equivalent series earth resistance is 20 ohms? (b) What voltage will appear at the input terminals of a receiver, matched to the aerial, if the receiving aerial is at

a distance of 20 miles from a transmitter? The transmitter has a short aerial (less than quarter-wave) and radiates 500 watts. The ground between transmitting and receiving aerials has a conductivity of 7×10^{-14} e.m.u.

(a) Calculation of input impedance

The length of conductor is 80 feet or 24.4 metres, therefore $l/\lambda = 24.4/300 = 0.0813$.

From (28), $X_i = -jZ_0 \cot 2\pi l/\lambda$.

We obtain Z_0 from (29):

$$Z_i = 138 \log_{10} 1.36 \times 10^5 - 104 = 603 \text{ ohms}$$

$$\text{and } 2\pi l/\lambda = 29.3^\circ.$$

Therefore $X_i = -j 603 \cot 29.3^\circ = -j 1070 \text{ ohms}$.

Next, to obtain R_R we use Fig. 22.6. For this aerial the ratio of the horizontal portion of the aerial to the total length is 0.625. By interpolation between plotted values we find that R_R is approximately 1.0 ohm. The series loss resistance is given as 20 ohms, hence the total resistance at the base is 21 ohms.

The base impedance of the aerial is then

$$Z_i = 21 - j 1070 \text{ ohms}.$$

(b) Calculation of voltage at receiver terminals

From Fig. 22.2 we see that at the given frequency and distance the power flux per unit area Φ is 2.0×10^{-8} watts/m² for a radiated power of 1 KW. Hence Φ is 1.0×10^{-8} for 500 watts radiated. The effective area of the aerial is given in Table 1 as $3\lambda^2/16\pi$. Hence the power ideally available is

$$P_R = 1.0 \times 10^{-8} \times 3 \times 300^2/16\pi$$

$$= 0.535 \times 10^{-4} \text{ watts}.$$

From (25A) we find that the e.m.f. induced in the aerial (referred to the base radiation resistance) is $e = 2\sqrt{P_R R_R} = 1.46 \times 10^{-2}$ volts or 14.6 millivolts.

FIG. 22.8

Fig. 22.8. Equivalent circuit of aerial and input circuit of the receiver.

The voltage appearing at the aerial terminals will be greater than the induced e.m.f. because of the highly reactive impedance of the aerial. The equivalent circuit of the aerial and input circuit of the receiver are shown in Fig. 22.8. We see that the aerial current is

$$i = 1.46 \times 10^{-2}/42 \text{ and the voltage at the receiver terminals is approximately}$$

$$V = i 1070 = 0.373 \text{ volt}.$$

(vi) Dipoles

The second type of aerial, the impedance of which we may wish to calculate is the dipole aerial. Dipole aerials well removed from the earth may be treated in a manner similar to that of a vertical aerial, because, at least approximately, a vertical aerial with its image forms a dipole aerial. With the vertical aerial we measure the impedance with respect to the neutral point (earth) of the equivalent dipole, so the impedance is only half that of the equivalent dipole. Hence in calculating the impedance of a dipole we can use the results obtained previously, but multiplied by a factor of two. Because a dipole aerial (remote from the earth) has no earth loss, it is in general more efficient than the equivalent vertical aerial with earth return.

The most commonly used variety of dipole aerial is the resonant, or half-wave variety. When remote from earth it has twice the impedance of a quarter-wave aerial, i.e. its impedance is resistive and has a magnitude of 73 ohms. When in the vicinity of the earth, the impedance depends on the height above earth. The variation is shown in Fig. 22.9.

Reflectors are sometimes used with half-wave aerials at very high frequencies.

In Fig. 22.10 is shown the effect, on the radiation resistance of a half-wave dipole, of the spacing between aerial and reflector, when the latter is tuned to provide maximum forward radiation. (For further information on the effects of reflectors the reader is referred to Ref. 14).

(vii) Loop aerials

Another common type of aerial used in broadcast reception is the loop aerial. With such aerials, the radiation resistance at medium frequencies is normally negligible compared with the loss resistance of the conductors. The aerial may be treated as a lumped inductance, the electrical constants of which can be calculated from well known formulae.

FIG. 22.9

Fig. 22.9. Radiation resistance of horizontal half-wave dipole aerial plotted against height of aerial above the earth.

Fig. 22.10. Radiation resistance of half-wave dipole aerial plotted against spacing between aerial and reflector (tuned to provide maximum forward radiation).

SECTION 8 : DUMMY AERIALS

When a signal generator is used in adjusting a receiver and in measuring its performance, it is necessary that the generator should present an impedance at the input terminals of the receiver which is equal to that of the aerial. At a single frequency this presents no difficulty; one may calculate the aerial impedance in the manner shown in the previous section and then add appropriate amounts of resistance and reactance in series with the generator impedance to produce an impedance equal to that of the aerial.

When the receiver is required to be used over a range of frequencies, the production of a dummy aerial that will simulate the aerial is not quite so easy. If the aerial is very short and has a radiation resistance less than the aerial-earth loss resistance, then we can assume the latter to remain constant in value. We have to produce, therefore, a reactance which changes in the same way as that of the aerial. With a very short aerial, the term $\cot \beta l$ in (28) is approximately equal to $1/\beta l$ and we have

$$X_i \approx -jZ_0/\beta l \quad (30)$$

which may be reduced to

$$X_i = \frac{-j}{2\pi f C} \quad (31)$$

where C is the total capacitance of the aerial.

Hence, for such an aerial, the dummy consists of a fixed resistor in series with a fixed capacitor. The impedance of a longer aerial may be represented moderately well over a range of frequencies by a resistor, inductor and capacitor in series, all shunted by a capacitor. For such networks we refer the reader to sources listed in the bibliography.

For standard dummy aerials to be used in receiver testing, see Chapter 37 Sections 1 and 2.

With a receiver designed to operate with a loop aerial, it is not usual to use a dummy aerial when testing the receiver. Instead the aerial is left connected to the receiver and a known e.m.f. is induced in the loop. This is effected by connecting a second loop to a signal generator, and placing the two loops at a suitable distance from each other. The e.m.f. induced in the receiving loop can be calculated if, in addition to the distance, the dimensions of the loops, the number of turns, and the current in the transmitting loop are known.

SECTION 9 : TYPES OF AERIAL USED FOR BROADCAST RECEPTION

(i) *Introduction* (ii) *Medium-frequency receiving aerials* (iii) *Short-wave receiving aerials* (iv) *V-H-F aerials*.

(i) Introduction

Only simple types of aerials, such as are employed in broadcast reception, will be described here ; no mention will be made of the more complicated aerials used in point-to-point communication services.

There are three important factors to be considered in the design of an aerial for reception.

(a) Its effective area for the capture of radio energy and its efficiency should be sufficiently great to provide a signal that will override the internal noise of the receiver.

(b) It should be placed as far as possible from sources of noise-interference and, in particular, it should be situated outside the induction field of such generators.

(c) If the radio signal should arrive at the receiver by two different paths (e.g. ground-wave and sky-wave) so that distortion of the received signal results, then the aerial should have sufficient directivity to favour the wanted signal and reject the unwanted one.

At very-high frequencies, the effective area for capture of radio-energy by an aerial becomes so small that the first factor is of great importance. In medium-frequency reception, on the other hand, the second factor is the most important. One reason for this is that at such wavelengths it is not easy to place the aerial outside the induction field of noise sources. This may be seen from the following discussion.

At a distance of several wave-lengths from an aerial the power flowing through unit area falls off as the inverse square of the distance from the aerial. This implies that the field strength of the signal falls inversely as the distance [see (23)] from the aerial. This field is called the radiation field of the aerial. An aerial has also another component of its field which is the predominating one at points close to the aerial, but falls off rapidly and becomes negligible compared with the radiation field at a distance of a few wavelengths from the aerial. This is called the "induction field." At a distance of approximately one sixth of a wavelength ($\lambda/2\pi$) from a short aerial, the components of the induction and radiation field are equal. At shorter distances the intensity of the magnetic field of the aerial increases roughly as the inverse square of the distance from the aerial while the intensity of the electric field increases roughly as the inverse cube of the distance. It is obviously desirable that a receiving aerial should be situated outside this zone around a noise source in which the field intensity increases very rapidly as the distance between receiving aerial and the generator is decreased. This is comparatively easy at very-high frequencies where one sixth of a wavelength may be only one or two feet. At medium frequencies, the corresponding distance is of the order of 50 yards and it may be difficult to place the aerial at such a distance from sources of electrical interference.

(ii) Medium-frequency receiving aerials

Aerials short compared with one half-wave length are generally used. These may be of the straight-vertical, inverted-L or T types. The characteristics of these have been discussed in previous sections.

Very small aerials of this type are sometimes used **indoors**. Such aerials are useful only when the required signals are of large intensity, because these indoor aerials do not fulfil any of the three conditions listed above, except when close to broadcast stations. Besides being inefficient because of their small size, they are also partially shielded by earthed conductors in the house-wiring. They are also very liable to pick up r-f noise carried along the power mains.

Loop aerials are sometimes used in broadcast receivers. When used indoors they have the same drawbacks as the indoor capacitance type aerial, except that if shielded, or balanced with respect to earth, they are less sensitive to inductive interference from nearby sources of r-f noise. The reason for this is that a balanced or shielded loop responds to the magnetic component of the field of an aerial, whereas the capacitance type aerial responds to the electric component. In the radiation field, these two components are equal and are mutually dependent. In the immediate vicinity of an aerial they are not equal, and the electric component increases more rapidly than does the magnetic field as one approaches the aerial. Hence in the vicinity of a radiation source of r-f noise, a loop aerial will pick up less energy than will a vertical aerial.

A loop aerial is more sensitive to waves arriving at steep angles to the plane of the earth than is a vertical aerial. Hence it should not be used where interference between ground and skywaves is experienced. In such conditions a straight vertical aerial is normally the best type of aerial that can be used. In special circumstances, such as occur sometimes in country areas, it is possible to use another type of aerial, called a wave-antenna, to reduce ground-wave - sky-wave interference.

The wave antenna consists of a horizontal wire several wave lengths long suspended a few feet from the ground and directed towards the required broadcast station.

It functions because of an effect that has not been mentioned previously, called wave-tilt. This is the production of a radial component of the electromagnetic field, when the waves are passing over imperfectly conducting ground. This component is picked up by the horizontal wire which, when a wavelength or more long, has maximum directivity along its axis.

(iii) Short-wave receiving aerials

Since short-wave reception usually is concerned with signals of low field intensity, efficient aerials placed well away from sources of interference are required. In an earlier section it was shown that the height of the aerial above ground is also important. Indoor aerials are most unsuitable for short-wave reception. A half-wave dipole placed at the correct height above earth and connected to the receiver by a transmission line provides an efficient receiving system over a restricted range of frequencies. In short-wave reception, however, one is concerned with a range of approximately 3 to 1 in frequency. If the aerial is to provide a reasonably good match to the transmission line or receiver over such a frequency range, then a more elaborate aerial than the simple half-wave type is required.

One way of doing this is to arrange a number of half-wave dipole aerials in the form of a fan and connect them in parallel. Each dipole is tuned to one of the frequency bands allotted for short-wave broadcasting. At resonance the half-wave dipole matches a 70 ohm transmission line. The dipoles that are off resonance provide high and predominately reactive impedances of both signs in parallel with the 70 ohms of the resonant dipole, and have small overall effect.

Such an aerial is connected to the receiver by a balanced transmission line. The receiver must be provided with an input circuit that is also balanced with respect to earth. Alternatively an aperiodic balance/unbalance transformer must be connected between the transmission line and the receiver.

An aerial that has similar characteristics to the one described above, but is not of the balanced type, is shown in Fig. 22.11. It is essentially half of the fan arrangement of dipoles. A common type of co-axial transmission line, having a characteristic impedance of 50 ohms, is suitable for use with this aerial. A few buried radial wires roughly half-wave (at the mid-frequency) in length provide a good earthing system for this aerial.

FIG. 22.11

(iv) V-H-F aerials

Because the effective area of an aerial at very high frequencies is small and the amount of energy that it can supply to the receiver is correspondingly small, it is essential that the efficiency of the aerial system should be high. At these frequencies the signal power per unit area at the aerial increases as the square of the height above ground, so the aerial should be placed at the maximum available height.

At very high frequencies the dimensions of the aerial are so small that rigid rods, rather than flexible wires, are used as aerial conductors. This simplifies the problem of the mechanical support for the aerial. Half-wave dipoles and quarter-wave vertical aerials with a counterpoise are the most common arrangements. The provision of a reflector is not difficult and is sometimes advantageous.

Matching the aerial to a transmission line is effected, when necessary, by means of sections of transmission line, rather than by combinations of lumped inductors and capacitors. Space does not permit a treatment to be given here of the great variety of line-sections, stubs and other impedance transforming devices that are in common use at very high frequencies. Nor can we deal with the very large number of varieties of aerial in use. A few of the common types are shown in Fig. 22.12. Of these, (a), (b), (c) and (d) are designed for reception of vertically polarized waves, and (e) and (f) are for horizontally polarized waves. The aerial (a) is the simplest type. It consists of a quarter wave radiator connected to the inner conductor of a co-axial line. Connected to the end of the outer conductor of the coaxial line is a quarter-wave "skirt," which forms, in effect, the second half of a vertical dipole. The impedance of the aerial is roughly 70-75 ohms and matches directly a common type of co-axial transmission-line. The disadvantage of this aerial is that the "skirt" is coupled to the outer conductor of the transmission-line and will pick up signals or noise that are present on this.

Type (b) consists of a vertical quarter-wave aerial with four horizontal quarter wave elements which form an artificial earth plane. The impedance of this aerial is lower than that of the normal quarter-wave aerial above a full earth plane, and it

requires a matching stub, or a quarter-wave transformer to transform its impedance to that of a usual type of co-axial transmission line. The impedance of this aerial may be increased by a factor of four, by the device shown at (c), and the necessity of providing an impedance transformer is eliminated. Type (d) is a discone aerial, useful over a wide range of frequencies.

(e) Is the most commonly used type of horizontal aerial. It consists of two quarter-wave arms, one connected to the inner, and one to the outer conductor of a co-axial line. An outer quarter-wave sheath is connected at its lower end to the outer conductor of the co-axial line. The effect of this is to isolate the latter from earth, and hence preserve the balance of the aerial with respect to earth.

FIG. 22.12

FIG. 22.12(a)

Fig. 22.12. Some varieties of v-h-f aerials.

(f) Is a modification of (e). The aerial conductors are made in the form of a conical cage to increase the frequency-range over which the aerial is effective. In this aerial another method of providing the transformation from the unbalanced transmission line to the balanced dipole is shown. It consists of splitting the outer conductor of the co-axial line into halves, for a distance of one quarter-wave. At the top of this "split" the halves of the dipole are connected directly to the outer conductor, while the inner conductor of the transmission line is connected to one of them.

One of the most easily constructed aerials is the folded half-wave dipole, which is shown in Fig. 22.12 (g). Whilst the radiation characteristic is the same as that of a conventional half-wave dipole, the folding produces an impedance transformation. When the conductors are of the same diameter throughout, the input impedance of the aerial is approximately 300 ohms. This enables the aerial to be matched directly to a 300 ohms moulded transmission line, which is commercially available. The spacing between the parallel conductors is not critical but, as in the case of a transmission line, it must be very small compared with a wavelength.

SECTION 1 : INTRODUCTION

(i) Aerial coupling (ii) Tuning methods (iii) R-F amplifiers (iv) Design considerations.

(1) Aerial coupling

In any radio receiving system it is necessary to have some means of effectively transferring the modulated carrier voltage from the aerial system to the grid of the first radio frequency voltage amplifier. The usual method of achieving this result is to use some form of aerial coupling transformer which will give the desired voltage a larger amplitude than that of any other radio frequency voltages which may also be present at the receiver input terminals.

There are many possible forms of aerial coupling arrangements, but the most common type is the inductively coupled transformer, consisting of a primary and a secondary winding. The tapped inductance, or auto-transformer, is also extensively used, particularly with receivers tuning the broadcast F-M band and in portable battery receivers using single turn loops.

The aerial coupling unit is equally applicable to either tuned radio frequency or superheterodyne receivers, since the fundamental problem of effective voltage transfer is the same in each case.

Fixed tuned and untuned aerial stages are sometimes employed. The fixed tuned arrangement is more often used where the desired frequency range to be covered is only a small percentage of the operating frequency, e.g. in a band-spread range of a multi-range receiver, or at v-h-f. The more usual practice is to tune the secondary of the transformer by means of a variable capacitor, or alternatively to make the inductance variable, since this allows the optimum operating conditions, or a close approach to them, to be obtained over the required tuning ranges. It is not generally of great importance whether the tuning is accomplished by using a variable capacitor or a variable inductor. Because of mechanical difficulties with inductance tuners the variable capacitor has been more widely used up to the present time. The inductance tuner is rapidly gaining favour, however, at frequencies around 100 Mc/s, and higher, because of the difficulties due to common metal shafts in ganged capacitors

and the inductance of the metal parts making up the capacitor. With the ganged capacitor arrangement considerable trouble is experienced due to coupling from one circuit to another, because it is not an easy matter to earth the shaft effectively between sections. The earthing wipers or leads have appreciable reactance and resistance at v-h-f and these factors are no longer negligible in comparison with the tuned circuit impedances. Insulated rotors and stators are of considerable assistance in overcoming difficulties due to common shaft coupling.

(ii) Tuning methods

Apart from ganged capacitors, many types of tuners have been used at v-h-f, including vane, guillotine, permeability, resonant line arrangements, etc., but all appear to have some disadvantages and it cannot be said that any one method is greatly superior to all others. Permeability tuning has also achieved some success on the 540 to 1600 Kc/s A-M, broadcast band, but it does not appear likely, in its present form, to supersede the variable capacitor.

(iii) R-F amplifiers

In conjunction with the aerial stage it often becomes necessary to incorporate a further stage to obtain additional radio frequency amplification and to increase further the discrimination against undesired signals, such as those from other broadcasting stations, and in the case of a superheterodyne receiver to limit the effects due to image and other spurious responses. This additional stage usually takes the form of a pentode voltage amplifier operating under class A_1 conditions and using a fixed or variable tuned circuit to act as a load impedance; an untuned stage may be used in some cases. The valve is connected between the aerial transformer and the r-f tuned circuit which is in turn coupled to a converter valve or another r-f voltage amplifier.

Whether the r-f stage carries out its various functions efficiently depends on a number of factors. Firstly it is necessary that the input resistance of the valve should not be too low at the operating frequency, as this will adversely affect the performance of the input circuit—the aerial circuit in the case of one r-f stage. In addition, the noise generated by the valve should be low, and in a superheterodyne receiver the noise voltage should be very much less than that developed by the converter valve if there is to be appreciable improvement in the signal-to-noise ratio. Also the r-f stage gain should not be too low, otherwise the converter noise will still have an appreciable effect on the signal-to-noise ratio. This last requirement calls for valves operating at v-h-f to have fairly high values of mutual conductance, since the tuned circuit impedances are low and the stage gain is the product of these two factors. Grid-to-plate capacitance should be small in conventional voltage amplifiers to avoid the necessity for neutralization. Input and output capacitances are also important as they set a limit on the possible tuning range. Further considerations of operating conditions for valves used as r-f voltage amplifiers are given in Chapter 2 Sect. 4, and in Sects. 5, 6, 7 and 8 of this chapter.

Since the fundamental principles of operation of the aerial and r-f circuits are very similar whether we use a t-r-f or superheterodyne receiver, it can be taken that the coupling methods and the stage gain and selectivity calculations will apply equally well in both cases. Each type of receiver presents its own particular problems but it is not intended to enter into a discussion of these matters here. Moreover the arguments relating to the relative merits and de-merits of the two systems are well known and details can be found in the references listed at the end of the chapter.

A question which sometimes arises is the desirability of having more than one r-f stage in a superheterodyne receiver. It should be quite clear that, provided the gain of a single r-f stage is sufficient (say 10 to 15 times) to over-ride the effects of converter noise, no appreciable improvement in signal-to-noise ratio is obtained by adding further r-f stages of the same type. The advantage of additional r-f stages lies in the improved selectivity which is possible against image and other undesired frequencies. It is generally preferable to obtain any additional amplification which may be required in the i-f and a-f stages, depending on the purpose for which the

additional gain is required. Further, a number of tuned r-f stages using ganged capacitors presents a rather difficult tracking problem, as well as giving rise to the increased possibility of unstable operation. Normally, only the transformer secondary is tuned and the overall selectivity characteristic is not as good as can be obtained with fixed-tuned i-f transformers. The gain and selectivity of the tuned r-f amplifier varies with the signal frequency, and a fixed intermediate frequency will allow more constant gain and higher gain per stage, for a given range of signal frequencies. The higher gain per stage is due to the higher dynamic impedance of the i-f transformer when the intermediate frequency is lower than the signal frequency. Even for an intermediate frequency higher than the signal frequency, larger stage gains are possible because of the better L/C ratio which can generally be obtained.

Even in cases where signal-to-noise ratio and r-f selectivity are not a problem, it is still sometimes advantageous to include a r-f stage. The r-f stage is used as a buffer to prevent the radiation of undesired signals from the receiver. A typical case of radiation occurs with a v.h.f. F-M receiver operated in conjunction with an efficient aerial system. If no r-f stage is used, radiation can occur at the oscillator frequency due to voltages at this frequency appearing at the input circuit of the frequency changer. This is serious because it opens up the possibility of interference between radio receivers which are operating in close proximity to one another.

It is not proposed, in this chapter, to deal in any great detail with grounded grid and other special types of r-f voltage amplifiers, as these are rather specialized applications which are not normally used in the design of narrow-band receivers covering limited bands of frequencies in the range from say 50 Kc/s to 150 Mc/s. However, at frequencies in excess of about 50 Mc/s, input stages using a grounded-grid triode are generally capable of giving better signal-to-noise ratios than circuits using the conventional grounded-cathode pentode voltage amplifier, but only at the expense of r-f selectivity. At the lower frequencies the input resistance of the pentode is much higher than that of the grounded grid triode, and so improved gain in the aerial coupling circuit can be used to offset the deterioration in signal-to-noise ratio due to valve noise. Clearly a better input circuit is possible using a pentode having a lower equivalent noise than with a pentode having the same input resistance but higher equivalent noise, and valve types should be selected with this in mind.

In cases where a wide range of frequencies has to be covered, and where the pass band of the receiver must be very wide (e.g. in television or multi-channel F-M link receivers), the grounded-grid triode offers considerable improvement in signal-to-noise ratio even at frequencies well below 100 Mc/s. Other applications occur in circuits where neutralization cannot be obtained by normal methods or where the circuit requirements are such that the grid must be earthed.

A special circuit (Cascode) which is of interest (see Ref. A10 Chapter 13) uses a grounded-cathode triode voltage amplifier, which is neutralized, followed by a grounded-grid triode. This circuit has high input resistance and low equivalent noise. It offers appreciable improvement in signal-to-noise ratio over the other two types of circuits, particularly at frequencies in excess of about 70 Mc/s. The combined circuit can be considered as equivalent to a single grounded-cathode triode having zero plate-grid capacitance, and a mutual conductance and noise resistance equal to that of the first triode valve (the valves used can be types 6J4 or 6J6 etc.).

Triode circuits of the types mentioned should not be used blindly, particularly at the lower frequencies, because the plate resistances of triodes are extremely low when compared with those of pentodes, and so the r-f stage gain may be insufficient, because the damping of the tuned circuits will be heavy, and also the r-f stage gain may be insufficient to make the effects of converter noise negligible. Detailed information on grounded-grid and triode r-f amplifiers can be found in Refs. B8, B18, A10 and A4.

(iv) Design considerations

The design methods to be discussed are equally applicable over any part of the range of frequencies mentioned above, but their practical application is rather more difficult as the frequency becomes greater, mainly because of the physical size of the com-

ponents (including valves) and because the circuit layout is increasingly important if satisfactory results are to be obtained. Electron transit time effects in valves become of greater importance as the frequency is raised because of the changes which occur in the valve input and output admittances*. The valve input admittance must be considered when designing an aerial or r-f circuit as it will affect the dynamic impedance of the circuit, and consequently the selectivity and gain. Valve sockets and other components will add further damping to the input circuits. The effects of valve noise will also be governed by the dynamic impedances of the input circuits and so the various valve effects must be considered in conjunction with the external circuits. This becomes of greater importance as the frequency increases.

A design difficulty with aerial and r-f stages is in obtaining satisfactory performance over a large tuning range. The three to one frequency coverage normally employed on dual wave receivers for the medium (540—1600 Kc/s) and shortwave (e.g. 6-18 Mc/s) bands presents some problems in regard to tracking, and constancy of gain and selectivity. The L/C ratios obtainable with a variable capacitor giving an incremental capacitance range of at least 9 : 1 are satisfactory on the medium wave range but are rather poor on the shortwave band. For these reasons it is common practice to limit the coverage on shortwave bands, in the better class of receiver, to enable improved all round performance to be obtained ; a frequency ratio of about 1.3 : 1 is usual in the region of 10 to 20 Mc/s, with larger ratios at the lower frequencies. An obvious advantage of multi-band receivers is the greatly improved ease of tuning, apart altogether from other considerations of better performance.

To obtain the reduced frequency coverage with variable ganged capacitors having a capacitance range of about 10-400 $\mu\mu\text{F}$, various arrangements of series and parallel fixed capacitors are used. If the circuits are arranged to use a combination of series and parallel capacitors for bandspreading, it is possible to make the tuning follow practically any desired law. Further, if the tuning range is small, the oscillator frequency in a superheterodyne receiver can be above or below the signal frequency and three point tracking can still be obtained using series padders in both the signal and oscillator circuits. These matters will receive further consideration in Chapter 25 Sect. 3 on superheterodyne tracking.

Methods for measuring the value of k , the coefficient of coupling, are given in Chapter 26 Sect. 4(ii)E and (iii)B, C. Methods for measuring the primary resonant frequency of an aerial or r-f transformer are covered in Chapter 37 Sect. 4(ii).

SECTION 2 : AERIAL STAGES

(i) *Difficulties involved* (ii) *Generalized coupling networks* (iii) *Mutual inductance coupling* (iv) *Tapped inductance* (v) *Capacitance coupling* (vi) *General summary.*

(i) Difficulties involved

The principal difficulty in the design of an aerial stage is that the type of aerial with which the receiver will eventually be used is, in general, not known. If the aerial impedance were known it would usually be a fairly simple matter to draw an equivalent circuit of the aerial and aerial input stage and to determine the complete performance by solving for the conditions existing in the circuit. When the conditions are not known, however, it is usually best to adopt constants for an aerial system which will have the most adverse effect on the receiver performance and to solve for these conditions. A compromise is then made in the circuit arrangement to minimize the effects of changes of gain, selectivity, and tracking with other circuits in the receiver.

(ii) Generalized coupling networks

Fig. 23.1 shows the generalized form for an aerial coupling unit. E_1 is the voltage induced in the aerial. E_2 is the voltage applied to the grid of the first amplifier stage.

*Valve admittances are covered in Chapter 2 Sect. 8.

Z_1 , Z_2 and Z_3 are intended to represent any possible arrangement of components for coupling the aerial to the receiver, where Z_1 includes all impedances external to the receiver input terminals and Z_L is the load impedance. This generalized T section can be made to represent all possible coupling arrangements, since it is well known from circuit theory that any complex network composed of linear bilateral impedances can be transformed, at any one frequency, into an equivalent T network

FIG. 23.1 GENERALIZED AERIAL COUPLING UNIT.

From the generalized network

$$\frac{E_2}{E_1} = \frac{Z_3 Z_L}{Z_1 Z_3 + (Z_1 + Z_3)(Z_2 + Z_L)} \quad (1)$$

This expression is of little assistance unless it is applied to the specialized networks used in radio receivers. Additional generalized expressions for this network are developed in K. R. Sturley's "Radio Receiver Design" Part 1, Chapter 3. It is proposed to deal specifically with a few of the more common types of coupling circuits.

(iii) Mutual inductance coupling

Fig. 23.2A shows one of the most widely used aerial coupling circuits. E_1 is the voltage induced in the aerial and Z_A represents the aerial constants, which may be any combination of inductance, capacitance and resistance. L_1 is the aerial coil primary winding which has a r-f resistance R_1 . L_2 is the secondary winding coupled by mutual inductance to L_1 . R_2 is the r-f resistance of L_2 . C_2 is used to tune the secondary circuit to resonance; it should be noted that the setting for C_2 when the aerial circuit is connected across the primary is different from the setting obtained when L_1 is on open circuit. Fig. 23.2B shows the T section equivalent of the aerial transformer, and Fig. 23.2C shows an alternative equivalent secondary circuit which is very helpful in understanding the idea of "reflected" impedances. For the present, the effects of valve loading will not be considered. When the secondary is tuned to resonance, the aerial circuit gain is given by

FIG. 23.2(A)

FIG. 23.2(B)

FIG. 23.2(C)

AERIAL TRANSFORMER.

$$\frac{E_2}{E_1} = \frac{M/C_2}{Z_{A1} \left[R_2 + \frac{\omega^2 M^2 R_{A1}}{|Z_{A1}|^2} \right]} \quad (2)$$

where $Z_{A1} = R_A + jX_A$
 $Z_1 = R_1 + j\omega L_1$
 $M = k\sqrt{L_1 L_2}$

$$Z_{A1} = Z_A + Z_1 = R_{A1} + jX_{A1}$$

$$\text{and } |Z_{A1}| = \sqrt{R_{A1}^2 + X_{A1}^2}.$$

It should be noted that the condition for secondary circuit resonance (partial resonance "S") is that

$$X_2 = \frac{\omega^2 M^2 X_{A1}}{|Z_{A1}|^2} \quad (3)$$

and the "reflected" resistance and reactance in the secondary are given respectively by

$$\frac{\omega^2 M^2 R_{A1}}{|Z_{A1}|^2} \quad (4)$$

$$\text{and } \frac{-\omega^2 M^2 X_{A1}}{|Z_{A1}|^2} \quad (5)$$

If the mutual inductance M is also made variable, the maximum value of secondary current (and of E_2/E_1 when the primary circuit Q is low) is obtained when

$$M = \frac{|Z_{A1}|}{\omega} \sqrt{\frac{R_2}{R_{A1}}} \quad (6)$$

$$\text{and } \frac{E_2}{E_1} = \frac{1}{2\omega C_2 \sqrt{R_2 R_{A1}}} \quad (7a)$$

$$= \frac{1}{2} \sqrt{\frac{R_D}{R_{A1}}} \quad (7b)$$

where R_D is the dynamic impedance of the secondary circuit. The approximations involved in these equations are discussed in Ref. B12.

From this it can be shown, with M and C_2 adjusted for maximum secondary current, that the selectivity of the tuned circuit is half the value it would have if considered in the absence of the primary. This condition of optimum coupling is not usual in broadcast receivers, except where matching to a transmission line, since the coupling between primary and secondary is made loose to prevent serious tracking errors due to the variable reactance "reflected" into the secondary circuit over a band of frequencies. The expression most generally required is that of eqn. (2) and the calculation of voltage gain need only be made at, say, two or three points across the tuning range.

It should be noted, however, that in some cases loose coupling can lead to a considerable reduction in signal-to-noise ratio if site noise is not predominant, e.g. at the higher frequencies on the short-wave band it is advantageous to use optimum coupling, or slightly greater, to improve the signal-to-noise ratio (see Ref. A2 Chapter 26).

The effects of valve input admittance can be included by considering an additional resistance and a capacitance shunted across C_2 . The value of the resistance component may be negative or positive depending on the type of valve and the operating conditions, e.g. some types of converter valves have a negative input resistance.

Having obtained the stage gain it is next important to find the **selectivity** of the circuit. As an approximation for ordinary types of aerial coils it is usually convenient to determine the selectivity of the secondary as for a single tuned circuit. The simplest approach is to consider the resultant Q of the secondary circuit at the resonant frequency when all the secondary resistance, including that due to reflection from the primary and valve loading, is included. The value of Q is given by $\omega L_{eff}/R_{eff}$, where L_{eff} is the resultant secondary inductance. The selectivity is then found as for a single tuned circuit, resonant at the frequency under consideration, using the universal curve given in Chapter 9 (Fig. 9.17) in conjunction with the methods detailed in Chapter 26 Sect. 4(iv)A. This method is satisfactory provided that the amount of mistuning is not too large a proportion of the central reference frequency, and that the aerial coil follows the usual practice with the primary resonated above or below the tuning range or is designed for connection to a transmission line (or aerial) of which the characteristic impedance is largely resistive; otherwise the variations in R_{eff} and L_{eff} would have to be considered. Further, in a number of practical cases it is permissible to calculate R_{eff} and use L_2 when finding the value for Q , since

the reflected reactance may not be very large. It is often sufficient to calculate selectivity at, say, the mid-frequency of the tuning range, although it should be noted that selectivity is a function of frequency and dependent on the circuit operating conditions.

It is now worth while considering three special cases for the aerial coupling transformer :

(1) Where the aerial can be represented by a capacitive reactance in series with a resistance.

(2) Where the aerial behaves like an inductive reactance in series with a resistance.

(3) Where the aerial is coupled to a transmission line which "looks" like a pure resistance at the aerial terminals ; or the aerial itself, coupled to the receiver, looks like a pure resistance.

Any aerial can be made to appear resistive if the reactance components are tuned out by a suitable arrangement of the aerial coupling network ; this is a common procedure with fixed frequency installations.

In case (1) it is usual to make the primary circuit resonate below the lowest tuning frequency, since this offers a good compromise with regard to constancy of gain, tracking, etc. This arrangement is also advantageous because the effect of the aerial is merely to move the primary resonant frequency still further away from the tuning range, thereby minimizing the effect of the aerial on the secondary without losing too much gain. In general the high impedance primary winding is resonated at 0.6 to 0.8 of the lowest tuning frequency, either with the aerial capacitance alone, or with an added capacitor. In either case the resonant frequency must not be close to the intermediate frequency in a superheterodyne receiver, and normally a broadcast band primary is resonated at a lower frequency than the i-f so that no aerial which is likely to be used will resonate the aerial primary at the intermediate frequency.

Since the gain obtained from an aerial transformer with its primary resonant outside the low frequency end of the tuning range decreases towards the high frequency end of the range, a small capacitance is often added across the top of the transformer. This capacitance increases the gain at higher frequencies and allows a substantially flat gain and noise characteristic to be obtained from the transformer over the desired range. This type of aerial transformer is fairly representative of those likely to be encountered on the medium and long wavebands. Practical values for the coefficient of coupling between primary and secondary are a compromise between various factors such as gain, tracking error and signal-to-noise ratios ; usual values are from 0.15 to 0.3, with most aerial coils using values of about 0.2 (this should include any added top capacitance coupling). The value for primary Q is of the order of 50, and the secondary Q is about 90 to 130 in typical aerial coils using the range of coupling coefficients stated, although Q values greater than 200 can readily be obtained by using special iron cores. Values of secondary Q above 100 generally call for smaller values of k than 0.2 if good tracking is to be achieved.

If for some particular reason it is necessary to use a higher coefficient of coupling than say 0.4, then the primary inductance should be small and arranged to resonate with the aerial at about $\sqrt{2}$ of the highest signal frequency. This improves the signal-to-noise ratio but may give rise to tracking difficulties.

Case (2) normally applies with untuned loop aerials but the condition can occur with some types of aerials on the shortwave bands. In this case it is usual to make the coefficient of coupling fairly high, of the order of 0.5 or more, and a useful rule is to make the value of primary inductance approximately equal to 0.4 of the loop (or aerial) inductance (see Refs. B17 and A2, p. 44).

For use with domestic type receivers operating on the short wave band, the standard dummy antenna is taken as being 400 ohms resistive, even though the aerial reactance will not be zero across the tuning range, as this gives an indication of average operating conditions. The aerial coupling transformer for this type of receiver can be designed using the procedure given in Case (3) below.

The untuned loop antenna (which should be balanced to ground for best results) finds application with portable receivers, and in some cases with ordinary A-M broadcast receivers. Loops have also been used in F-M receivers operating on the 40-50

Mc/s band, but not in receivers for the 88-108 Mc/s band because of the ease with which a half-wave dipole can be arranged inside the receiver cabinet. With loops it is necessary to keep stray capacitances to a minimum so as to avoid resonance effects within or close to the band of frequencies to be received ; this also assists in achieving good tracking because a loop that behaves like a small fixed inductance can be compensated for quite readily in the aerial coil secondary.

The number of turns used in untuned loop aerials is not very critical, since a loss in effective height by using fewer turns can be offset by the increased voltage step-up possible with the coupling transformer. To keep stray capacitances low the fewer turns used the better. The best compromise for receivers operating on the medium or short-wave bands is a single turn loop, or perhaps a few turns (say not more than four) of wire wrapped around the carrying case for medium wave portable receivers (this wire can be litz or copper braid, and even rubber covered hook-up wire is often satisfactory). The best type of single turn loop is one made out of copper tubing (or any other good conductor such as aluminium or one of its alloys) with the tube diameter not less than about 0.25 in. and preferably considerably larger than this ; the loop area should always be as large as possible. If the loop is to be used on the long-wave band it is preferable to use a few turns (about ten) of litz wire rather than a single turn loop. This is necessary because of the drop in Q which occurs with the single turn loop at the lower frequencies. However, satisfactory results have been achieved with a 0.25 in. diameter copper tube loop at a frequency of 500 Kc/s.

In many cases a two winding transformer is not used and the loop is made part of the tuned circuit (being in series with the main tuning inductance and earthed at one side). An alternative arrangement is to tap the loop across part of the main tuning inductance ; this can be made to give very satisfactory results.

Because the inductance of loops (of the type being considered) is usually very small, it is often difficult to measure the Q at the working frequencies. This difficulty arises with standard types of Q meters because the maximum capacitance is limited to about 400 μF . A useful method (suggested by J. B. Rudd) is as follows :

Couple the loop fairly tightly to an inductance which is sufficiently large to be tuned to the working frequency. Measure the Q of the inductance with the loop open circuited (call this Q_1) and then the Q (call this Q') with the loop short circuited at its terminals. The Q of the loop (Q_L) is given by

$$Q_L = \frac{yQ_1Q'}{Q_1(1 - y) - Q'}$$

where Q_1 = magnification factor for the primary inductance with the loop open circuited.

Q' = magnification factor for the primary inductance with the loop terminals short circuited.

$$y = 1 - (L'/L_1)$$

L' = inductance of primary with loop short circuited.

and L_1 = inductance of primary with loop open circuited.

See (vi) below for some discussion of directly tuned loops.

Case (3) permits of a fairly simple solution. Normally k is about 0.2 or less, and the primary winding reactance (at the geometrical mean frequency of the tuning range) is made equal to the characteristic impedance of the transmission line or aerial. A particularly simple solution has been made by Rudd (Ref. B12) to give conditions for two point matching in the tuning range. The procedure is as follows :

Geometrical mean angular frequency = $\omega_0 = \sqrt{\omega_1\omega_2}$ where ω_1 and ω_2 are the lower and upper angular frequency band limits. The primary inductance = $L_1 = Z_0/\omega_0$ where Z_0 is the characteristic impedance of the transmission line.

The required coefficient of coupling is then determined from

$$k = \sqrt{\frac{1}{Q_1} \left[\frac{1 + \alpha}{\alpha^{\frac{1}{2}}} \right]} \quad (8)$$

where $\alpha = \omega_2/\omega_1 = f_2/f_1$

and Q_s = secondary circuit Q in the absence of the primary. The value for Q_s should include the effect of valve loading, and so

$$Q_s = \frac{QR}{Q\omega_0 L_2 + R} \quad (9)$$

where Q is for the unloaded secondary and R is the valve input resistance.

A useful approximate formula for estimating the aerial coil gain under this condition is

$$\frac{E_2}{E_1} = \frac{1}{2\sqrt{Q_s \omega L_2}} \frac{1}{Z_0} \quad (10)$$

This expression gives the maximum possible value of gain and corresponds to eqn. (7a) given previously.

Although elaborate methods are available for calculating optimum signal-to-noise ratios etc., the details above should give a fairly close approximation to the required practical conditions where the aerial coupling circuit is a compromise between the various conflicting factors discussed previously. These factors of gain, selectivity etc. should be carefully considered as in nearly every case the performance of a receiver is largely governed by the aerial coupling circuit.

(iv) Tapped inductance

Another common type of aerial coupling arrangement is shown in Fig. 23.3. This arrangement has found wide application in receivers tuning the 88-108 Mc/s F-M band because of its simplicity and the ease with which the correct aerial tapping point may be found. This can also be considered as a particular case of the generalized aerial circuit. This circuit can be treated in a simplified manner due to Zepler (Ref. A2). The required tapping point on the total coil, which is usually a solenoid, can be found approximately from the turns ratio

$$\frac{n_2}{n_1} = \sqrt{\frac{Q_s \omega L_2}{Z_0}} \quad (11)$$

where n_2 = total number of turns

n_1 = number of turns across which aerial is connected

$\omega = 2\pi \times$ operating frequency

Q_s = magnification factor for complete circuit

and Z_0 = impedance of the aerial (or the characteristic impedance of a transmission line).

The gain is found from equation (10),

$$\frac{E_2}{E_1} = \frac{1}{2\sqrt{Q_s \omega L_2}} \frac{1}{Z_0}$$

The selectivity is calculated using the same methods as before, from the equivalent circuit. Whether this equivalent circuit takes the form of a series or parallel tuned circuit is usually not important, as the results obtained are substantially the same, and provided the circuit Q exceeds about 10 the Universal Selectivity Curves can be applied directly in either case.

It should be noted that the treatment is only approximate, as the exact tapping point is dependent on the coupling between the two sections of the aerial coil winding. However, for a wide variation in coupling, the correct tapping point is not very different from that obtained by the above procedure, which assumes unity coupling, and the loss in secondary voltage as compared with optimum coupling is quite small.

FIG. 23-3 TAPPED INDUCTANCE AERIAL TRANSFORMER

Valve input loading is usually a problem at v-h-f and a procedure to minimize this effect is to tap down across L_2 . This will allow a higher value of dynamic impedance for the tuned circuit with improved selectivity, and under some conditions the increase in impedance can more than offset the loss in voltage gain caused by tapping down.

(v) Capacitance coupling

A further type of coupling arrangement fairly commonly used is shown in Fig. 23.4.

FIG. 23.4

Fig. 23.4. Capacitance Coupled Aerial Transformer.

This shows a common disadvantage with the circuit of Fig. 23.3 in that the variation in gain across the tuning range is quite appreciable. The treatment is quite straightforward and is left to the reader ; a fairly complete analysis is given in the references.

(vi) General summary

From the considerations detailed above, it can be seen that the coupled circuit arrangement of Fig. 23.2 is generally most satisfactory since it readily lends itself, with minor modifications, to applications using balanced or unbalanced aerial systems. Under some conditions of receiver operation other methods are used because of the practical consideration of ease of adjustment for best operation, or for use with a particular type of aerial system.

Fixed tuned aerial stages are sometimes used with receivers covering a limited range of frequencies. A typical case would be in the range of 88-108 Mc/s where the loaded Q of the aerial coil may be less than 20. In such a case a simple arrangement is for the secondary to be resonated near the centre frequency in the band ; this introduces gain variations of about 2 : 1 across the tuning range. The gain variations can be offset by resonating the secondary at a point in the band such that the gain variations offset those in r-f or mixer stages. The overall gain variations for the band under consideration can be limited to less than 1.5 : 1 with a superheterodyne receiver using a tuned r-f stage, and as the loss in gain and signal-to-noise ratio is not very serious, the saving in the cost of a gang section is often well worth while when weighted against the other factors. If the aerial circuit loaded Q is above about 20, this method is not recommended because of the deterioration in circuit performance. In some cases it is preferable to tune the aerial circuit and use an untuned r-f stage (when this is practicable).

One type of coupling circuit which has not been mentioned previously is the directly tuned loop. In this case the loop provides the tuned circuit inductance as well as the direct signal pick-up. As for any other loop, the area and the Q should be as large as possible. This loop will probably be used, in most cases, with portable receivers. If the loop can be placed in such a position that its Q is not materially affected by the presence of the receiver and batteries, then its performance will usually be superior to that of the single turn loop (an improvement of about 6 db can be expected). However, this arrangement is seldom convenient and in many cases better results are possible with the single turn loop (or one with a few turns as discussed previously) because any effect on its Q can be offset to a large extent by the use of an aerial coupling transformer having a high Q winding in the tuned circuit. The improvement can be seen most readily by considering a low Q loop, having a small inductance, connected directly in series with an aerial coil which has a high Q and whose inductance is practically the whole of the tuned circuit inductance.

In some cases it is required to use an additional external aerial with the loop to increase signal pick-up. There are many possible arrangements but amongst the simplest is the use of a small capacitance (say 10 to 20 $\mu\mu\text{F}$) connected between the

external aerial and the top of the tuned circuit (i.e. to the grid connection) or alternatively a tap on the aerial coil secondary a few turns up from the earthy end. For a directly tuned loop the aerial is tapped into the loop in the same way as for the other coil arrangement; alternatively the series capacitor arrangement is satisfactory. The main disadvantage of both these simple arrangements is the large change in gain which occurs across the tuning range, but for medium-wave commercial portable receivers additional circuit complications are seldom justified.

The subject of aerial-to-receiver coupling is a large one and only a few of the more important design factors have been considered. For more complete information on particular systems it is necessary to consult the text books and references.

SECTION 3 : R-F AMPLIFIERS

(i) Reasons for using r-f stage (ii) Mutual-inductance-coupled stage (iii) Parallel tuned circuit (iv) Choke-capacitance coupling (v) Untuned and pre-tuned stages (vi) Grounded grid stages.

(i) Reasons for using r-f stage

The necessity for adding a r-f amplifier in a superheterodyne receiver arises from the need for

- (1) greater gain
- (2) improved rejection against undesired signals
- (3) improved image frequency rejection
- (4) reduction of the effects of spurious frequency combinations,
- (5) improved signal-to-noise ratio,
- (6) the prevention of radiation at the local oscillator frequency (under some conditions).

In the case of the t-r-f receiver, additional r-f stages are usually added for reasons (1) and (2) above.

The design of a r-f stage is quite similar for both types of receiver and so they will not be considered separately. The only point which will be mentioned is that, in the case of the t-r-f receiver the final r-f amplifier feeds into a detector stage which, if a diode is used, heavily loads the tuned circuit unless a tapping point is used. For this reason it is common practice to incorporate anode bend or linear reflex detectors which do not appreciably load the input circuit. However, a diode is convenient as a means of supplying an a.v.c. bias voltage of the correct polarity, a condition not fulfilled by the other two types of detectors mentioned without additional circuit arrangements.

(ii) Mutual-inductance-coupled stage

The most common arrangement for coupling a r-f amplifier valve to the following stage (Fig. 23.5) is by means of a transformer using a tuned secondary with the primary winding resonated either above or below the tuning range. The primary winding resonates with the valve output capacitance, winding capacitance, stray wiring capacitances and sometimes an added capacitor, these being lumped together and shown as C_p .

FIG. 23.5 TRANSFORMER COUPLED R-F STAGE.

If the winding is of the low impedance type it is made to resonate at approximately 1.2 to 1.5 times the highest tuning frequency. Under this condition the load presented to the valve is inductive and thus will give rise to regeneration by introducing a negative resistance component plus a capacitance into the r-f valve input circuit.

If the winding is of the high impedance type, then it is usual to resonate the primary at approximately 0.6 to 0.8 of the lowest tuning frequency, but the resonant frequency should not be close to the intermediate frequency in superheterodyne receivers. Under this condition the valve has a capacitive load which causes degeneration by introducing a positive resistance component plus a capacitance into the r-f valve input circuit due to the "Miller Effect." It is not usual to resonate the primary winding within the tuning range because of the very large changes in gain and selectivity which would be introduced. In addition, the problem of tracking the various tuned circuits becomes almost hopeless.

When the aerial coil primary is of the low impedance type it is usual, although not essential, for the r-f stage to be of this type also and vice-versa. This simplifies tracking problems.

The methods to be used for calculating the gain and selectivity of this arrangement are set out in detail in Chapter 9 Sect. 6(ii) under the heading "Coupled Circuits—Tuned Secondary." For the usual practical arrangement the stage gain is given approximately by $g_m Q_2 \omega M$,

where g_m = mutual conductance of r-f amplifier valve,

ω = $2\pi \times$ operating frequency,

$M = k\sqrt{L_1 L_2}$ = mutual inductance,

and Q_2 = secondary circuit Q including effect of valve input resistance, but not "reflected" resistance from the primary.

The selectivity can also be calculated, approximately, by the method suggested for aerial coils.

When designing a stage of this type it is necessary, as in the case of the aerial coil, to arrive at a compromise between gain, selectivity and tracking errors. This usually leads to a value for the coefficient of coupling of approximately 0.15 to 0.3, with the lower values preferred for good tracking between aerial, r-f, and, in the case of the superhet., the oscillator stage.

As with aerial coils, the primary Q is about 50 (or perhaps less) and the secondary Q from say 90 to 130 in typical coils using this range of k values. Higher Q generally calls for the lower values of k .

In the case of receivers working at say 50-400 Kc/s it is often inconvenient to resonate the primary winding in the manner suggested. Under these circumstances it is sometimes necessary to damp the primary winding heavily so that no pronounced resonance occurs. It is then permissible to resonate the winding within the tuning range. This procedure can lead to a severe loss in gain but is sometimes justified under practical conditions where the loss of gain is outweighed by other factors.

The addition of top capacitance coupling, i.e. a small capacitance from the plate connection to the grid connection of the following stage, is often employed to equalize gain variations across the tuning range. The value of the capacitance is usually of the order of a few micro-micro-farads and the exact value is best determined experimentally. It should be noted that the presence of this capacitance will alter the coefficient of coupling, stage gain, selectivity and the primary resonant frequency, as well as circuit tracking. There is always some capacitance coupling present with any practical transformer and this largely determines the relative physical arrangement of the primary and secondary windings, which are connected (in nearly all practical cases) so that the capacitance coupling adds to the mutual inductance coupling.

(iii) Parallel tuned circuit

A simple parallel tuned circuit is sometimes used in the r-f stage, and can be made to give higher gains than the transformer coupled arrangement. The difficulties encountered are that

- (1) large gain variations occur across a band of frequencies
- (2) the skirt selectivity is rather poor
- (3) tracking with conventional aerial circuits is difficult
- (4) the tuning capacitor has to be isolated from B+.

For these and other reasons this circuit is not in common use in broadcast receivers, but it might be incorporated in a receiver working at high frequencies covering a

restricted tuning range with some possible advantage. The gain of the stage is given by $g_m Q_{eff} \omega L$

where g_m = mutual conductance of r-f amplifier valve,

Q_{eff} = Q of r-f coil when loaded by plate resistance of r-f amplifier and input resistance of following stage,

$\omega = 2\pi \times \text{frequency}$,

and L = inductance of tuned circuit.

Selectivity is calculated as for any other single tuned stage, using the methods of Chapter 9 or Chapter 26, Sect. 4(iv)A.

(iv) Choke-capacitance coupling

Fig. 23.6 shows a common r-f coupling circuit for use at v-h-f such as on the 88-108 Mc/s F-M broadcast band. The usual arrangement takes the form of a r-f choke, resonated well below the lowest tuning frequency, coupled to a tuned circuit $L_2 C_2$ by means of a capacitor C . The choice of a suitable value for C will allow some reduction in variations of stage gain across the tuning range as it can be considered as part of a voltage divider formed with the tuned grid circuit. A further useful function of the arrangement is that when a suitable resonance frequency has been chosen for the choke, the total stray capacitance across the tuned circuit is effectively reduced, thereby reducing limitations on the tuning range; a small value for C assists in this latter regard. However, the application of the circuit is largely one of practical convenience and, as always, is a compromise.

FIG. 23-6 CAPACITANCE COUPLED R-F STAGE.

With a choke resonated at $1/\sqrt{2}$ of the lowest tuning frequency in a receiver with a low frequency limit of 87.5 Mc/s and an upper limit of 108.5 Mc/s, the values obtained for the additional capacitance shunted across the tuned circuit were 3.6 μF at 88 Mc/s and 4 μF at 108 Mc/s, excluding the input capacitance of the following stage. The value of C was 10 μF . Because of the low value of dynamic impedance for this circuit at v-h-f, the effect of the plate resistance of the r-f valve can usually be neglected (but see Ref. A8). In this case the selectivity for the circuit can readily be calculated as for a single tuned circuit, including the effects of the input resistance of the following stage, without introducing very large errors. The gain may be calculated with sufficient accuracy as for the case of the simple tuned circuit acting as the anode load and multiplying the result by a suitable factor to allow for the voltage division due to the capacitive reactances at the frequency being considered. This factor is readily found from a knowledge of the equivalent capacitance due to the choke circuit, at the working frequency, and the value selected for C .

(v) Untuned and pre-tuned stages

Untuned, or in some cases pre-tuned, r-f stages are sometimes used in receivers where economy and/or limited space are important factors, or where only a small frequency range is to be covered. Unfortunately in the case of portable battery receivers, where the application could be valuable, the use of untuned r-f stages is made difficult by the fairly low values of mutual conductance for the usual r-f amplifier valves. The gain obtained is limited and it may be preferable to use an additional i-f stage if the r-f stage cannot be tuned and gain is a prime requirement. With mains operated receivers the problem is different, as many suitable valve types are available and quite good stage gains (about 5 times or more, on the medium and short wave bands) can be obtained over a wide range of frequencies. Suitable design methods using untuned stages for the medium and short wave bands have been given in R.C.A. Application Note No. 116 (reprinted in Radiotronics No. 124) to which the reader is referred for full details. A typical coupling circuit of the type discussed in

the Application Note is shown in Fig. 23.7.

FIG. 23.7

UNTUNED R-F STAGE.

(vi) Grounded-grid stages

As previously mentioned this type of amplifier will not be discussed in detail.

However, the following equations should prove to be of assistance, and are generally a sufficiently good indication since experimental techniques usually provide the most suitable method for determining the best operating conditions for this type of amplifier.

$$\text{Voltage gain} = \frac{R_L}{r_p + R_L} (\mu + 1)$$

$$\text{Resistance loading across input circuit} \approx \frac{r_p + R_L}{\mu + 1}$$

(loading across output circuit $\approx r_p$).

For $\mu \gg 1$ the optimum load impedance is given by

$$R_L = r_p \sqrt{1 + R_1 g_m}$$

$$\text{Noise factor} = N = \sqrt{2 + \frac{R_1}{R_0 A_1^2} + \frac{R_2}{R_0 A_1^2 A_2^2}}$$

where R_L = load impedance connected between plate and B+

r_p = valve plate resistance

μ = valve amplification factor

g_m = valve mutual conductance

R_1 = valve input resistance at working frequency

R_2 = equivalent noise resistance of first valve

R_0 = generator impedance e.g. aerial resistance

A_1 = voltage gain of input circuit

and A_2 = voltage gain of first stage, excluding the voltage gain of the input circuit.

It should be noted that it is always advisable to operate the heater and cathode of the valve at the same r-f potential. This is readily achieved by using suitable chokes in the heater leads. For more detailed information on grounded-grid amplifiers see References B8, B18, A10 and A4.

SECTION 4 : IMAGE REJECTION

(i) Meaning of image rejection (ii) Image rejection due to aerial stage (iii) Other considerations.

(i) Meaning of image rejection

With the superheterodyne receiver it is necessary to consider not only adjacent channel selectivity due to the aerial and r-f stages but also whether the selectivity of these stages is sufficient to prevent signals on image frequencies from passing into the i-f amplifier. If there were no tuned circuits ahead of the converter valve a signal lower in frequency than the oscillator frequency, and which differs from the oscillator frequency by the value of the intermediate frequency, would pass into the i-f amplifier. Similarly a signal higher in frequency than the oscillator frequency, and which differs from the oscillator frequency by the value of the intermediate frequency, would also pass into the i-f amplifier.

When one of these frequencies is the desired one (it may be either the lower or the higher), the other is referred to as its image frequency. Clearly the desired and undesired signal frequencies are separated by twice the intermediate frequency. Putting this statement in symbolic form :

$$f_{image} = f_{osc} + f_{i-f} \text{ when } f_{osc} > f_{sig}$$

$$f_{image} = f_{osc} - f_{i-f} \text{ when } f_{osc} < f_{sig}$$

where f_{sig} = desired signal frequency.

As an example : On the 540-1600 Kc/s A-M broadcast band the oscillator frequency is normally above the signal frequency. If the reasons for this are not obvious, consideration of the oscillator tuning range and the values of variable capacitance required will make it so. The usual i-f is 455 Kc/s and if a signal frequency of 1000 Kc/s is taken,

$$\text{then } f_{image} = (1000 + 455) + 455 = 1910 \text{ Kc/s.}$$

Since the converter cannot discriminate between the two signals of 1000 Kc/s and 1910 Kc/s, it is necessary for the aerial circuit, and r-f circuit if this is used, to make the magnitude of the 1000 Kc/s voltage much greater than the magnitude of the 1910 Kc/s voltage. Otherwise severe interference can result when signals are being transmitted at both these frequencies.

When making calculations for image rejection the worst conditions are usually found at the high frequency end of the tuning range, provided that the selectivity of the tuned circuits does not vary appreciably with change in frequency. This is because the separation between the two frequencies is a smaller proportion of the frequency to which the receiver is tuned. It should also be clear that higher values of i-f will materially assist in reducing image effects because of the wider frequency separation between the desired and undesired signals ; it is for this reason that some v-h-f receivers use intermediate frequencies of the order of 10.7 Mc/s.

(ii) Image rejection due to aerial stage

The image rejection due to an aerial stage alone is calculated from

$$\sqrt{1 + Q^2 \left(\frac{f}{f_0} - \frac{f_0}{f} \right)^2}$$

where $Q = \omega L_{eff} / R_{eff}$ (i.e. loaded value for secondary circuit),

$L_{eff} \approx L_2$, the secondary circuit inductance,

R_{eff} = total secondary circuit series resistance including that due to reflection from primary circuit and valve input resistance (Valve input admittance is discussed in detail in Chapter 2 Sect. 8, and further comments are given in Sect. 5 of this chapter),

f = image frequency when oscillator frequency is higher than signal frequency,

and f_0 = signal frequency under oscillator conditions as for f .

If the oscillator is lower in frequency than the signal frequency then f and f_0 should be interchanged.

Exactly the same expression and procedure are used to calculate the image protection afforded by a r-f stage. Since the calculated image rejection is a voltage ratio, the ratios obtained for the various stages are multiplied together, or the ratios expressed in decibels can be added to give the total image protection provided by the input circuits to the converter.

(iii) Other considerations

The image protection due to the r-f stage may be greater than that due to the aerial stage. A typical example occurs when the loading on the aerial stage due to the r-f amplifier valve has a positive value of input resistance and the loading on the r-f stage due to a pentagrid converter, using inner grid oscillator voltage injection, has a negative value of input resistance. The resultant Q , simply from these considerations, may then be higher in the case of the r-f coil. Also, since the resultant Q of the aerial

coil is halved, under some conditions of operation, by using two point matching to an aerial transmission line, the greater part of the image protection may here again be due to the r-f stage. These considerations are particularly important at the higher frequencies. On the long and medium wave bands sufficient image protection can often be obtained from the discrimination afforded by the aerial coil alone, but on the shortwave bands deterioration in image rejection is serious (and rapid) unless the intermediate frequency is increased above the usual value of about 455 Kc/s.

It is important to note that a good image rejection ratio is desirable since this also indicates the selectivity of the signal circuits and the degree of rejection against spurious frequency combinations. A high degree of selectivity preceding the first r-f amplifier valve has obvious advantages in reducing cross-modulation effects.

SECTION 5 : EFFECTS OF VALVE INPUT ADMITTANCE

(i) *Important general considerations* (ii) *Input loading of receiving valves at radio frequencies* (A) *Input conductance* (B) *Cold input conductance* (C) *Hot input conductance* (D) *Change in input capacitance* (E) *Reduction of detuning effect.*

(i) Important general considerations

A fairly complete discussion of some of the factors relating to valve input admittance has been given in Chapter 2 Sect. 8. These considerations are additional to the following details which take into account electron transit time effects at frequencies up to about 100-150 Mc/s, where conventional receiver design techniques begin to fail.

From the receiver designer's point of view the main factors (if we neglect changes in valve output admittance—but see Ref. A8) are

(1) A knowledge of the actual values of input resistance and capacitance (neither of which is constant with changes in valve operating conditions) with which he will have to contend when these are shunted across the tuned circuit (this must include the effects of feedback etc.), and

(2) A knowledge of the effects on input capacitance, in particular, when the signal voltage changes, giving rise to an alteration in a.v.c. bias. From this information the amount of detuning of the circuits can be determined. As the input components are in parallel with the tuned circuits, it is often more convenient to discuss the values of conductance, susceptance, and admittance rather than resistance, reactance, and impedance. Several extremely useful lists of values of conductance and capacitance for some common types of receiving valves are given in Chapter 2 Sect. 8, and further details of some additional types are set out later in this section. In cases where the value of short circuit input conductance at a required frequency is not given, then a close approximation can be found by multiplying the conductance value by

$\left(\frac{\text{Frequency required}}{\text{Frequency stated}} \right)^2$; but extrapolation should not be carried too far e.g. a conductance value at 100 Mc/s should not be used to find a conductance at 455 Kc/s, but will give a reasonable approximation at, say, 10 Mc/s.

A **figure of merit**, which forms a useful basis for comparing various types of r-f voltage amplifier valves, is given by

$$\frac{g_m}{\sqrt{g_i}} \text{ (or } g_m \sqrt{R_i} \text{)}$$

where g_m = control grid to plate transconductance (mutual conductance)

g_i = short circuit grid input conductance

and R_i = short circuit grid input resistance.

At the higher frequencies cathode lead inductance is important.

If the valve types on which information regarding short circuit input admittance is required are not listed, experimental techniques can always be resorted to and reason-

ably accurate results are possible using a high frequency Q meter to determine the capacitive and resistive loading effects. The usual precautions as to length of leads, earthing etc. must be carefully observed when making these measurements, if the results are to be of any practical value. Something of this nature is usually required when considering the effects of the converter valve on its input circuit, since the published information is rather meagre. In this regard it is well to remember that some types of converter valves, such as those using inner grid injection, e.g. types 6A8, 6K8, 6SA7, 6BE6 etc., give negative loading whilst other types such as X61M, X79, 6J8-G, 6L7, etc. (which use outer grid oscillator injection) give positive loading. Increasing the negative bias on the signal grid will reduce the loading effect with all types, but at very high values of bias the negative loading may reverse its polarity and become positive. [The reasons for these effects are discussed later in this section in connection with input loading of receiving valves.] To reduce input conductance some valve types have more than one cathode connection (see Ref. A8), and typical examples are types 6AK5 and 6AG5, each having two cathode terminals. Even when the cathode terminals are directly connected to ground the length of the cathode lead is still sufficient to provide appreciable inductive reactance at frequencies of the order of 100 Mc/s. For this reason all plate and screen by-pass capacitors should be returned to one cathode lead and the grid returns to the other. The alternating voltages developed across the cathode lead inductance due to currents from the plate and screen circuits are in this way prevented from being directly impressed in series with the grid circuit, since it is the grid to cathode voltages which are of major importance. Direct current divides between the two available cathode paths, but this is not important since the path taken by this current normally does not affect the grid input admittance. To obtain grid bias the "grid" cathode lead employs the usual resistor and capacitor combination. The r-f by-pass capacitors from the plate and screen circuits connect directly to the other cathode terminal which is not directly connected to ground in this arrangement. A typical circuit is shown in Fig. 23.8.

In pentodes working at v-h-f it is advisable to connect the suppressor grid terminal directly to ground, when a separate terminal is available for this electrode, rather than to the cathode, because the suppressor lead inductance would then be connected in series with any external cathode lead inductance. If this precaution is not taken the coupling between control grid and plate is increased, because of the capacitance from control grid to suppressor and from suppressor to plate, the junction of these two capacitances having an impedance to ground depending on the total lead inductance.

Similar considerations also apply to screen grid circuits, particularly when the valve has a single cathode lead, and the shielding action of this grid can be seriously affected if proper precautions are not taken, such as directly earthing by-pass capacitors. These circuit arrangements are not very important at low frequencies where degenerative effects may be more serious, necessitating the connection of the suppressor grid and by-pass capacitors directly to the cathode.

FIG. 23.8 R-F AMPLIFIER WITH TWO CATHODE CONNECTIONS.

(ii) Input loading of receiving valves at radio frequencies*

(See also Chapter 2, Sect. 8 and R.C.A. Application Note No. 118—Ref. B25).

The input resistance of r-f amplifier valves may become low enough at high radio frequencies to have appreciable effect on the gain and selectivity of a preceding stage. Also, the input capacitance of a valve may change enough with change in a.v.c. bias to cause appreciable detuning of the grid circuit. It is the purpose of this Note to discuss these two effects and to show how the change in input capacitance can be reduced.

*From R.C.A. Application Note No. 101.

(A) Input conductance

It is convenient to discuss the input loading of a valve in terms of the valve's input conductance rather than input resistance. The input conductance g_i of commercial receiving valves can be represented approximately by the equation

$$g_i = k_c f + k_h f^2 \quad (1)$$

where f is the frequency of the input voltage. A table of values of k_c and k_h for several r-f valve types is shown below. The approximate value of a valve's input conductance in micromhos at all frequencies up to those in the order of 100 megacycles can be obtained by substituting in Eq. (1) values of k_c and k_h from the table. In some cases, input conductance can be computed for conditions other than those specified in the table. For example, when all the electrode voltages are changed by a factor n , k_h changes by a factor which is approximately $n^{-1/2}$. The value of k_c is

TABLE OF APPROXIMATE VALUES OF k_c AND k_h FOR SEVERAL VALVE TYPES

¶Denotes single ended valve type.

practically constant for all operating conditions. Also, when the transconductance of a valve is changed by a change in signal-grid bias, k_h varies directly with transconductance over a wide range. In the case of converter types, the value of k_h depends on oscillator-grid bias and oscillator voltage amplitude. In converter and mixer types, k_h is practically independent of oscillator frequency.

In eqn. (1), the term $k_c f$ is a conductance which exists when the cathode current is zero. The term $k_h f^2$ is the additional conductance which exists when cathode current flows. These two terms can be explained by a simple analysis of the input circuit of a valve.

(B) Cold input conductance

The input impedance of a valve when there is no cathode current is referred to as the cold input impedance. The principal components of this cold impedance are a resistance due to dielectric hysteresis, and a reactance due to input capacitance and cathode-lead inductance. Because these components are in a parallel combination, it is convenient to use the terms admittance, the reciprocal of impedance, and sus-

ceptance, the reciprocal of reactance. For most purposes, the effect of cathode-lead inductance is negligible when cathode current is very low. The cold input admittance is, therefore, a conductance in parallel with a capacitive susceptance. The conductance due to dielectric hysteresis increases linearly with frequency. Hence, the cold input conductance can be written as $k_e f$, where k_e is proportional to the power factor of grid insulation and is the k_e of eqn. (1).

(C) Hot input conductance

The term $k_h f^2$, the input conductance due to the flow of electron current in a valve, has two principal components, one due to electron transit time and the other due to inductance in the cathode lead. These two components can be analysed with the aid of Fig. 23.9. In this circuit, C_h is the capacitance between grid and cathode when cathode current flows, C_g is the input capacitance due to capacitance between grid and all other electrodes, except cathode, g_t is the conductance due to electron transit time, and L is the cathode-lead inductance. Inductance L represents the inductance of the lead between the cathode and its base pin, together with the effect of mutual inductances between the cathode lead and other leads near it. Analysis of the circuit of Fig. 23.9 shows that, with L small as it generally is, the input conductance, g_h , due to the presence of cathode current in the valve, is approximately

$$g_h = g_m \omega^2 L C_h + g_t \quad (2)$$

where $\omega = 2\pi f$. The term $g_m \omega^2 L C_h$ is the conductance due to cathode-lead inductance. It can be seen that this term varies with the square of the frequency. In this term, g_m is the grid-cathode transconductance because the term is concerned with the effect of cathode current flowing through L . In a pentode, and in the 6L7, this transconductance is approximately equal to the signal-grid-to-plate transconductance multiplied by the ratio of direct cathode current to direct plate current. In the converter types 6A8, 6K8 and 6SA7, the signal-grid-to-cathode transconductance is small. Cathode circuit impedance, therefore, has little effect on input conductance in these types.

For an explanation of the conductance, g_t , due to electron transit time, it is helpful to consider the concept of current flow to an electrode in a valve. It is customary to consider that the electron current flows to an electrode only when electrons strike the surface of the electrode. This concept, while valid for static conditions, fails to account for observed high-frequency phenomena. A better concept is that, in a diode for example, plate current starts to flow as soon as electrons leave the cathode. Every electron in the space between cathode and plate of a diode induces a charge on the plate; the magnitude of the charge induced by each electron depends on the proximity of the electron to the plate. Because the proximity changes with electron motion, there is a current flow to the plate through the external circuit due to the motion of electrons in the space between cathode and plate.

Consider the action of a conventional space-charge-limited triode as shown in Fig. 23.10. In this triode, the plate is positive with respect to cathode and the grid is negatively biased. Due to the motion of electrons between cathode and grid, there is a current I_a flowing into the grid. In addition, there is another current I_b flowing out of the grid due to the motion of electrons between grid and plate receding from the grid. When no alternating voltage is applied to the grid, I_a and I_b are equal and the net grid current I_g is zero.

Suppose, now, that a small alternating voltage (e_g) is applied to the grid. Because the cathode has a plentiful supply of electrons, the charge represented by the number of electrons released by the cathode (Q_k) is in phase with the grid voltage, as shown in Figs. 23.11(a) and 23.11(b). The charge induced on the grid (Q_g) by these electrons would also be in phase with the grid voltage if the charges released by the cathode were to reach the plane of the grid in zero time, as shown in Fig. 23.11(c). In this hypothetical case, the grid current due to this induced charge (Fig. 23.11(d)) leads the grid voltage by 90 degrees, because by definition, current is the time rate at which charge passes a given point. However, the charge released by the cathode actually propagates towards the plate with finite velocity; therefore, maximum charge is induced on the grid at a time later than that corresponding to maximum grid voltage,

as shown in Fig. 23.11(e). This condition corresponds to a shift in phase by an angle θ of Q_g with respect to e_g ; hence, the grid current lags behind the capacitive current of Fig. 23.11(d) by an angle θ , as shown in Fig. 23.11(f). Clearly, the angle θ increases with frequency and with the time of transit τ . Expressed in radians, $\theta = \omega\tau$.

FIGURES 23.9 TO 23.14 INCLUSIVE

The amplitude of Q_g is proportional to the amplitude of the grid voltage; the grid current, which is the time rate of change Q_g , is thus proportional to the time rate of change of grid voltage. For a sinusoidal grid voltage, $e_g = E_g \sin \omega t$, the time rate of change of grid voltage is $\omega E_g \cos \omega t$. Therefore, for a given valve type and operating point, the amplitude of grid current is

$$I_g = KE_g \omega$$

and the absolute value of grid-cathode admittance due to induced charge on the grid is

$$Y_t = I_g/E_g = K\omega \quad (3)$$

The conductive component (g_t) of this admittance is

$$g_t = Y_t \sin \theta = Y_t \theta = K\omega \theta \quad (\text{for small values of } \theta).$$

Because $\theta = \omega\tau$, this conductance becomes, for a given operating point,

$$g_t = K\omega^2 \tau. \quad (4)$$

Thus, the conductance due to electron transit time also varies with the square of the frequency. This conductance and the input conductance, $g_m \omega^2 L C_h$, due to cathode-lead inductance, are the principal components of the term $k_h f^2$ of eqn. (1).

This explanation of input admittance due to induced grid charge is based on a space-charge-limited valve, and shows how a positive input admittance can result from the induced charge. The input admittance due to induced grid charge is negative in a valve which operates as a temperature-limited valve, that is, as a valve where cathode emission does not increase when the potential of other electrodes in the valve is increased. The emission of a valve operating with reduced filament voltage is temperature limited; a valve with a screen interposed between cathode and grid acts as a temperature-limited valve when the screen potential is reasonably high. The existence of a negative input admittance in such a valve can be explained with the aid of Fig. 23.12.

When the value of E_{c2} in Fig. 23.12 is sufficiently high, the current drawn from the cathode divides between g_2 and plate; any change in one branch of this current is accompanied by an opposite change in the other. As a first approximation, therefore, it is assumed that the current entering the space between g_2 and g_3 is constant

and equal to ρv , where ρ is the density of electrons and v is their velocity. g_2 may now be considered as the source of all electrons passing to subsequent electrodes.

Suppose now, that a small alternating voltage is connected in series with grid g_3 , as shown in Fig. 23.12. During the part of the cycle when e_g is increasing, the electrons in the space between g_2 and g_3 are accelerated and their velocities are increased. Because the current ρv is a constant, the density of electrons (ρ) must decrease. In this case, therefore, the charge at g_2 is 180 degrees out of phase with the grid voltage, as shown at a and b of Fig. 23.13. This diminution in charge propagates toward the plate with finite velocity and induces a decreasing charge on the grid. Because of the finite velocity of propagation, the maximum decrease in grid charge occurs at a time later than that corresponding to the maximum positive value of e_g , as shown in Fig. 23.13(c). The current, which is the derivative of Q_g with respect to time, is shown in Fig. 23.13(d). If there were no phase displacement ($\theta = 0$), this current would correspond to a negative capacitance; the existence of a transit angle θ , therefore, corresponds to a negative conductance. By reasoning similar to that used in the derivation of eqns. 3 and 4, it can be shown that the absolute value of negative admittance due to induced grid charge is proportional to ω , and that the negative conductance is proportional to ω^2 . These relations are the same as those shown in eqns. 3 and 4 for the positive admittance and positive conductance of the space-charge-limited case.

A negative value of input conductance due to transit time signifies that the input circuit is receiving energy from the "B" supply. This negative value may increase the gain and selectivity of a preceding stage. If this negative value becomes too large, it can cause oscillation. A positive value of input conductance due to transit time signifies that the signal source is supplying energy to the grid. This energy is used in accelerating electrons toward the plate and manifests itself as additional heating of the plate. A positive input conductance can decrease the gain and selectivity of a preceding stage.

It should be noted that, in this discussion of admittance due to induced grid charge, no mention has been made of input admittance due to electrons between grid and plate. The effect of these electrons is similar to that of electrons between grid and cathode. The admittance due to electrons between grid and plate, therefore, can be considered as being included in eqn. (3).

(D) Change in input capacitance

The hot grid-cathode capacitance of a valve is the sum of two components, the cold grid-cathode capacitance, C_c , which exists when no cathode current flows, and a capacitance, C_t , due to the charge induced on the grid by electrons from the cathode. The capacitance C_t can be derived from eqn. (3), where it is shown that the grid-cathode admittance due to induced grid-charge is

$$Y_t = K\omega.$$

The susceptive part of this admittance is $Y_t \cos \theta$. Since this susceptance is equal to ωC_t , the capacitance C_t is

$$C_t = K \cos \theta = K \quad (\text{for small values of } \theta).$$

Hence, the hot grid-cathode capacitance C_h is

$$C_h = C_c + K.$$

The total input capacitance of the circuit of Fig. 23.9 when the valve is in operation, includes the capacitance C_h and a term due to inductance in the cathode lead. This total input capacitance, C_i , can be shown to be approximately

$$C_i = C_g + C_h - g_m g_t L \quad (5)$$

where the last term shows the effect of cathode-lead inductance. This last term is usually very small. It can be seen that if this last term were made equal in magnitude to $C_g + C_h$, the total input capacitance would be made zero. However, the practical application of this fact is limited because g_m and g_t change with change in electrode voltages, and g_t changes with change in frequency.

When cathode current is zero, the total input capacitance is practically equal to $C_g + C_c$. Subtracting this cold input capacitance from the hot input capacitance given by eqn. (5), we obtain the difference, which is $K - g_m g_t L$. In general, K is

greater than $g_m g_p L$. Therefore, in a space-charge-limited valve, where K is positive, the hot input capacitance is greater than the cold input capacitance. In a temperature-limited valve, where K is negative, the hot input capacitance is less than the cold input capacitance. In both valves K changes with change in transconductance. Because of this change, the input capacitance changes somewhat with change in a.v.c. bias. In many receivers, this change in input capacitance is negligible because it is small compared with the tuning capacitances connected in the grid circuits of the high-frequency stages. However, in high-frequency stages where the tuning capacitance is small, and the resonance peak of the tuned circuit is sharp, change in a.v.c. bias can cause appreciable detuning effect.

(E) Reduction of detuning effect

The difference between the hot and the cold input admittances of a space-charge-limited valve can be reduced by means of an unbypassed cathode resistor, R_k in Fig.

23.14. The total hot input admittance of this circuit is made up of a conductance and a capacitive susceptance C_i' . Analysis of Fig. 23.14 shows that, if cathode-lead inductance is neglected, the total hot input capacitance, C_i' , is approximately

$$C_i' = C_g + C_c \frac{1 + K/C_c}{1 + g_m R_k} \quad (6)$$

Inspection of this equation shows that if K is positive and varies in proportion with g_m , the use of the proper value of R_k will make C_i independent of g_m . In a space-charge-limited valve, K is positive and is found by experiment to be approximately proportional to g_m . It follows that the proper value of R_k will minimize the detuning effect of a.v.c. in a space-charge-limited valve. Eqn. (6) is useful for illustrating the effect of R_k but is not sufficiently precise for computation of the proper value of R_k

to use in practice. This value can be determined by experiment. It will be found that this value, in addition to minimizing capacitance change, also reduces the change in input conductance caused by change in a.v.c. bias. The effect of unbypassed cathode resistance on the change in input capacitance and input conductance of types 6AC7/1852 and 6AB7/1853 is shown in Figs. 23.15 and 23.16. These curves were taken at a frequency of 40 megacycles. The curves for the 6AC7/1852 also hold good for the 1851.

It should be noted that, because of degeneration in an unbypassed cathode resistor, the use of the resistor reduces gain. The reduced gain is $1/(1 + g_m R_k)$ times the gain with the same electrode voltages but with no unbypassed cathode resistance.

The hot input conductance of a valve with an unbypassed cathode resistor can be determined by modification of the values of k_h in the table. The value of k_h in the table should be multiplied by $g_m/(1 + g_m R_k)$. The resultant value of k_h , when substituted in eqn. (1), with k_e from the table, gives the input conductance of a valve with an unbypassed cathode resistor. In the factor $(1 + g_m R_k)$, g_m is the grid-cathode transconductance when R_k is by-passed.

When an unbypassed cathode resistor is used, circuit parts should be so arranged that grid-cathode and plate-cathode capacitances are as small as possible. These capacitances form a feedback path between plate and grid when there is appreciable impedance between cathode and ground. To minimize plate-cathode capacitance, the suppressor and the screen by-pass condenser should be connected to ground rather than to cathode.

SECTION 6 : VALVE AND CIRCUIT NOISE*

(i) *Thermal agitation noise* (ii) *Shot noise* (iii) *Induced grid noise* (iv) *Total noise calculations* (v) *Sample circuit calculations* (vi) *Conclusions.*

Maximum receiver sensitivity is not, in most cases, determined by the gain of the particular receiver but by the magnitude of the input circuit noise, which is generated by the antenna, the tuned input circuit, and the first tube. This is true of A-M, F-M and television except that in F-M and television the random noise effect assumes a far greater degree of importance than in the standard broadcast band. The reason for this is twofold :

(1) At the frequencies where these two services operate, 50 to 250 Mc/s, the relative values of the several different noise sources assume entirely new proportions and the heretofore unimportant and little known **induced grid noise** becomes one of the predominant components of the total.

(2) Most random input and tube noise is proportional to the square root of the bandwidth. Both television, with a 4 Mc/s band, and F-M, with a 200 Kc/s band, occupy much wider sections of the frequency spectrum than anything previously encountered by the commercial receiver engineer.

(i) Thermal agitation noise

When an alternating electric current flows through a conductor, electrons do not actually move along the conductor but they are displaced, an infinitesimal amount, first in one direction and then in the other. A voltage is built up across the conductor equal to the magnitude of the current times its resistance. Applying heat to the conducting material agitates the molecules of the conductor and, consequently, varies the instantaneous position in space of the electrons. This random electron motion is, in a sense, a minute noise current flowing through the material and is known as **thermal agitation noise**. That is, the application of heat agitates the electron distribution of the substance thereby creating the noise.

The magnitude of the short-circuit noise current is given by

$$i_n^2 = \frac{4KT\Delta F}{R} \quad (1)$$

where i_n^2 = mean squared noise current (amperes²)

K = Boltzmann's Constant (Joules per degree Kelvin), 1.38×10^{-23}

T = temperature (degrees Kelvin)

ΔF = bandwidth (c/s)

and R = resistance (ohms).

All noise currents and voltages are random fluctuations and occupy an infinite frequency band. Because of the random effect, the most convenient terminology to use in expressing their magnitude is average noise-power output. Mean-squared noise current or mean-squared noise voltage, either of which is proportional to average power, is generally used.

In the expression for various noise components the term ΔF refers to the effective bandwidth of the circuit. This is determined from a curve of power output versus frequency by dividing the area under the curve by the amplitude of the power at the noise frequency in question. For most calculations, however, where only approximate values are desired, the bandwidth between half power points, or 0.707 voltage points, will give sufficient accuracy.

The equation below expresses thermal agitation noise as a voltage in series with a given resistor ;

$$e_n^2 = 4KT\Delta FR. \quad (2)$$

Both the above forms are true of all resistive circuit elements or combination of elements including parallel and series-tuned circuits.

*This section is taken directly from an article "Input Circuit Noise Calculations for FM and Television Receivers" by W. J. Stolze, published in Communications, Feb. 1947, and reprinted by special permission.

Referring to Fig. 23.17(a), let us suppose a resistance of 10 000 ohms were connected to the input of an amplifier with a 5 Kc/s bandwidth, i.e., 5 Kc/s between half power points or an audio band of 2.5 Kc/s. At room temperature, 20°C or 293°K, the term $4KT$ in the expressions for noise simplifies to 1.6×10^{-20} , which may be used in most receiver calculations. The noise in Fig. 23.17(a) is therefore :

$$e_n^2 = 1.6 \times 10^{-20} \Delta FR$$

$$e_n = \sqrt{1.6 \times 10^{-20} \times 5000 \times 10000}$$

$$e_n = 0.89 \text{ microvolt.}$$

The noise bandwidth is generally determined by the narrowest element in the entire circuit under consideration. In the example for Fig. 23.17(b) the bandwidth of the amplifier is narrower than the tuned circuit and therefore its ΔF is used in the calculations.

FIG. 23.17

Fig. 23.17. Sample thermal noise circuits :
Frequency = 1000 Kc/s ; $Q = 100$;
 $L = 300$ microhenries (Ref. B33).

Fig. 23.17(b) is a simple parallel-tuned circuit where the noise generating resistance is equal to the tuned circuit impedance. Again let us assume the bandwidth to be five Kc per second.

$$R = Q(\omega L) = 100 \times 1900 = 190000 \text{ ohms}$$

$$e_n^2 = 1.6 \times 10^{-20} \Delta FR$$

$$e_n = \sqrt{1.6 \times 10^{-20} \times 5000 \times 190000}$$

$$e_n = 3.9 \text{ microvolts.}$$

Thermal agitation noise voltage may be calculated easily with eqn. (2) but by using the graph shown in Fig. 23.18 the room temperature values may be found directly.

FIG. 23.18

Fig. 23.18. Thermal agitation noise voltage versus resistance and band-width (Ref B33).

(ii) Shot noise

Another important component of the total receiver noise is shot noise. This noise is generated inside the vacuum tube and is due to the random fluctuations in the plate current of the tube, or, to state it in another manner, random variations in the rate of

arrival of electrons at the plate. When amplified, this noise sounds as if the plate were being bombarded with pebbles or as if a shower of shot were falling upon a metal surface, hence the name shot noise.

Although generated essentially in the plate circuit of the tube, which is not a convenient reference point for sensitivity or signal-to-noise ratio calculations, the shot noise is nearly always referred to as a noise voltage in series with the grid. Since the following equation is true,

$$e_g = i_p / g_m \quad (3)$$

where e_g = a.c. grid voltage

i_p = a.c. plate current,

and g_m = transconductance,

by simply dividing the noise current in the plate circuit by the transconductance of the tube, the shot noise may be referred to the grid and expressed in terms of grid voltage.

Another step is taken, however, to simplify the noise nomenclature. Suppose a given tube has a shot noise equal to e_n microvolts in series with its grid. It is perfectly valid to imagine that this voltage could be replaced by a resistance whose thermal agitation noise is equal to e_n (the shot noise) and to consider the tube to be free of noise. This imaginary resistance, which when placed in the grid of the tube generates a voltage equal to the shot noise of the tube, is known as the shot noise equivalent resistance or just as the equivalent noise of the tube. The advantage of this terminology is that when the equivalent noise resistance of the particular tube is known, the noise voltage may be calculated directly for any given bandwidth by substituting values in the following formula :

$$e_n^2 = 4KT\Delta FR_{eq} \quad (4)$$

where R_{eq} = equivalent noise resistance,

or at room temperature

$$e_n^2 = 1.6 \times 10^{-20} \Delta FR_{eq} \quad (5)$$

If the noise were expressed as a voltage or current its value would be correct only for one particular bandwidth.

TRIODE AMPLIFIER	$R_{eq} = \frac{2.5}{G_m}$
PENTODE AMPLIFIER	$R_{eq} = \frac{I_B}{I_B + I_{G2}} \left(\frac{2.5}{G_m} + \frac{20I_{G2}}{G_m^2} \right)$
TRIODE MIXER	$R_{eq} = \frac{4}{G_c} \quad G_c = \frac{G_m}{4}$
PENTODE MIXER	$R_{eq} = \frac{I_B}{I_B + I_{G2}} \left(\frac{4}{G_c} + \frac{20I_{G2}}{G_c^2} \right)$
MULTIGRID CONVERTER OR MIXER	$R_{eq} = 20 \frac{I_B(I_n - I_B)}{I_n G_c^2}$
R_{eq} = EQUIVALENT SHOT NOISE RESISTANCE G_m = GRID PLATE TRANSCONDUCTANCE I_B = AVERAGE PLATE CURRENT I_{G2} = AVERAGE SCREEN CURRENT G_c = CONVERSION TRANSCONDUCTANCE I_n = AVERAGE CATHODE CURRENT	

FIG. 23.19

Fig. 23.19. Approximate calculated equivalent noise resistance of various receiving-type tubes (Ref. B33). the expressions presented in the chart, Fig. 23.19*.

When the term converter is used it refers to a tube that is used for frequency conversion where the single tube acts as the local oscillator and the mixer (6SA7); the term mixer where two tubes are used, one as the mixer (6SG7), and one as the local oscillator (6C4).

By knowing the R_{eq} of any two given tubes their relative shot noise merit is also known regardless of what bandwidth they are to operate at, while if the noise voltages were given alone the operating bandwidth at which the calculation was made would also have to be noted if the relative merits of the two tubes were to be defined.

Noise-equivalent resistance values for a number of different tube types (triodes, pentodes, and converters) and for various circuit applications (amplifiers and mixers) can be calculated by applying

FIG. 23.20

After the equivalent noise resistance is known the value of r.m.s. noise voltage at the grid of this tube can be calculated by applying the same expression that is used for thermal agitation noise,

$$e_n^2 = 1.6 \times 10^{-20} \Delta F R$$

or, by using the graph of Fig. 23.18.

Fig. 23.20 presents calculated equivalent noise resistance values for a number of commonly used tubes acting as various types of circuit elements. These are, of course, approximate figures.

It can be seen from Figs. 23.19 and 23.20 that the noise resistance or voltage is at a minimum for a triode, increasing for the pentode and the multigrid tube, following in that order.

Shot noise is unique among the noise sources in the sense that the shot-noise voltage should be considered to exist in series with the grid inside the tube. The reason for this is that nothing can be done to the external grid circuit that will alter the magnitude of this component. Even though the shot noise must be tolerated, its effect can be minimized by designing the input circuit for maximum signal at the grid. This does not reduce the magnitude of the noise but does improve the signal-to-noise-ratio of the receiver.

(iii) Induced grid noise

Also present in the receiving tube is a third source of noise which is generated internally in the tube but whose magnitude and effect are determined partially by the external input circuit. Known as induced grid noise, this minute current is induced in the grid wires of the tube by random fluctuations in the plate current. It is known that a varying electron beam will induce a current in any nearby conductor. Therefore, the fluctuating plate current which is in a sense a varying electron beam, will induce a noise current in the nearby grid conductors.

The input impedance of a vacuum tube has a reactive and a resistive component. At relatively low frequencies the resistive component is very high (below about 30 Mc/s); as the frequency is increased the resistive component decreases and its magnitude eventually becomes comparable to or even lower than the external grid circuit impedance. The resistive component is composed of two parts, the portion due to transit time effect, and the portion due to the inductance of the cathode lead.

An expression for induced-grid-noise* for tubes

FIG. 23.21

FIG. 23.22

Fig. 23.22. Approximate electronic input resistance versus frequency (Ref. B33).

ance to be electronic would not introduce too great an error. Another factor in favour of this approximation is that it would be the case for maximum induced grid noise and any error introduced would more than likely be on the safe side.

*D. O. North "Fluctuations induced in vacuum-tube grids at high frequencies" Proc. I.R.E. Feb. 1941.

with control grid adjacent to the cathode follows :

$$i_{i.g.}^2 = 1.4 \times 4KT_k \Delta F G_{elect}$$

or when expressed in the form of a voltage generator,

$$e_{i.g.}^2 = 1.4 \times 4KT_k \Delta F R_{elect} (6)$$

where : T_k = cathode temperature (degrees Kelvin)

G_{elect} = electronic (transit time) component of input conductance

and R_{elect} = electronic component of input resistance.

From eqn. (6) it can be seen that the induced grid noise is proportional to the electronic or transit time component of the input resistance. Measurement of the total input resistance is a comparatively simple matter with the use of a high frequency Q meter, but the separation of the electronic and the cathode inductance components, which are essentially two resistances in parallel between the grid and ground, is a very difficult matter. Since most high-frequency tubes are constructed with either two cathode leads or one very short lead, assuming the total measured input resistance

Cathode temperature in most receiving tubes, which almost exclusively use oxide-coated cathodes, is approximately 3.6 times the normal room temperature in degrees K. Eqn. (6) can be rewritten therefore as

$$e_{i.o.}^2 = 5 \times 4KT\Delta FR_{elect} \quad (7)$$

where T = room temperature (degrees Kelvin),

or, when $T = 300$ degrees Kelvin,

$$e_{i.o.}^2 = 8 \times 10^{-20} \Delta FR_{elect} \quad (8)$$

In circuit calculations this noise is essentially in series with a resistance equal to R_{elect} located between the grid and ground—Fig. 23.21.

The approximate input resistance for a number of common receiving tubes in the frequency range of F-M and television is given in Fig. 23.22. This chart can be used to find approximate input resistance values for induced grid-noise calculations.

(iv) Total noise calculations

Calculations of total input noise are made by using the grid of the input tube as a reference point. There are many sources of noise and each must be calculated and referred to the grid reference point before a summation is made. Since noise is a random effect and calculated on a power basis, the separate components cannot be added directly but as the square root of the sum of the squares.

$$\text{Total Noise} = \sqrt{e_1^2 + e_2^2 + e_3^2 + \text{etc.}} \quad (9)$$

The various noise voltages that must be referred to the first grid are :

- (1) Thermal agitation noise of the antenna radiation resistance.
- (2) Thermal agitation noise of the tuned grid circuit.
- (3) Shot noise of the input tube.
- (4) Induced grid noise of the input tube.
- (5) Grid circuit noise of the following stages referred back to the first grid.

In Fig. 23.23(a) appears a diagram of a practical input circuit and the location of all the circuit parameters and noise voltages. Fig. 23.23(b) is essentially the same except that the antenna circuit is reflected through the transformer and considered to exist at the grid. This is the diagram that is most useful in calculating the total input circuit noise.

- e_{shot} = Valve Shot Noise
- N = Turns Ratio of Coupling Transformer

Fig. 23.23. Position of various noise sources in input circuit (Ref. B33).

The steps necessary to find specific values for each of these factors are shown in Fig. 23.24. Antenna radiation resistance varies widely with the type of antenna chosen, but for F-M and television work it is generally in the order of 75 to 300 ohms. When the noise is known in terms of an equivalent resistance, as is the case here for the antenna, tuned circuit, and shot noise, the equivalent voltage can be either calculated or obtained directly from Fig. 23.18.

In order to add the antenna, tuned circuit, and induced grid noise to the shot noise the effective voltage of these three components at the grid, or between the points A and B, must be known. Each must go through what is essentially a resistive divider and may be calculated as shown in Fig. 23.25.

After knowing the magnitude of the separate sources that exist between A-B, the total noise voltage is

Fig. 23.24. Procedure for calculating various noise voltages (Ref. B33).

$$e_{total} = \sqrt{(e_{shot})^2 + (e_{ant} \text{ at A-B})^2 + (e_{i-g} \text{ at A-B})^2 + (e_{ckt} \text{ at A-B})^2} \quad (10)$$

One other factor may affect this total, however. If the total noise of the following stages, which is calculated similarly, ignoring the antenna of course, is appreciable, it must be added to the constants of Fig. 23.25. In reflecting it to the first grid the second stage noise should be divided by the gain of the first tube. When the gain is about ten or more this factor may usually be neglected.

Effective signal voltage across A-B is calculated in the same way as the antenna noise in Fig. 23.25. The signal-to-noise ratio is now also known.

Since the signal-to-noise ratio is determined by the signal strength and the total noise at the grid of the input tube, for a receiver that has a mixer, such as 6SK7, for the input tube, the signal-to-noise ratio may be considerably improved by the addition of an r-f tube, such as a 6SG7, which has considerably less total noise. By adding additional r-f tubes (6SG7's), however, since the total noise and signal at the grid will be the same, the signal-to-noise ratio will not be improved.

FIG. 23.25

Fig. 23.25. Circuit for reflecting various voltages to the grid (Ref. B33). To find the effective voltage of the antenna, the tuned circuit, and the induced grid noise at the grid of the tube let R_1 equal one of the above noise resistances and e_1 its generated voltage. If R_2 and R_3 equal the other two noise resistances the effective voltage at the grid is

$$e_{1A-B} = \frac{e_1}{R_1 + \frac{R_2 R_3}{R_2 + R_3}} \times \frac{R_2 R_3}{R_2 + R_3}$$

This calculation must be performed for the three components in turn.

(v) Sample circuit calculations

For a sample problem let us calculate the total noise at the grid of an F-M receiver r-f amplifier stage, assuming the circuit in Fig. 23.26(a) to be under consideration.

As a simplification of procedure the steps in the calculations will be numbered.

- (1) $N^2 R_{ant} = 1200$ ohms (calculated)
- (2) $R_{elect} = 1200$ ohms (Figure 23.22)
- (3) $R_{ckt} = Q\omega L = 8000$ ohms (calculated)
- (4) $R_{eq} = 3100$ ohms (Figure 23.20)

At this point it will be convenient to redraw the circuit as shown in Fig. 23.26(b).

- (5) $N e_{ant} = 2$ microvolts (Fig. 23.18)
- (6) $e_{i.g.} = \sqrt{8 \times 10^{-20} \times 200 \times 10^3 \times 1200}$
 $= 4.4$ microvolts (equation (8))

$$(7) e_{ckt} = 6 \text{ microvolts (Fig. 23.18).}$$

$$(8) e_{shot} = 3.5 \text{ microvolts (Fig. 23.18).}$$

The next step is to find the effective voltage of each source between the grid and ground (or A-B) as shown in Fig. 23.25.

$$(9) e_{ant} \text{ A-B} = \frac{2}{1200 + 1040} \times 1040 = 0.93 \text{ microvolt.}$$

$$(10) e_{i.v.} \text{ A-B} = \frac{4.4}{1200 + 1040} \times 1040 = 2.0 \text{ microvolts.}$$

$$(11) e_{ckt} \text{ A-B} = \frac{6}{8000 + 600} \times 600 = 0.42 \text{ microvolts.}$$

and the total noise is therefore

$$(12) e_{total} = \sqrt{3.5^2 + 0.93^2 + 2.0^2 + 0.42^2} \\ = 4.3 \text{ microvolts [equation (10)].}$$

(vi) Conclusions

Selection of an input tube for a television or F-M receiver is dependent upon many varying circuit conditions and individual requirements. The choice of using balanced or unbalanced input, permeability or capacitor tuning, noisy pentodes or quiet triodes that possibly require neutralization, among others, lies entirely with the design engineer. Considering these reasons and various engineering and economic compromises no particular tube can be chosen and defined as **the input tube**. Complete noise information about the circuits involved is necessary, however, as this is one of the determining factors for good sensitivity and signal-to-noise ratio

Fig. 23.26. Typical F-M receiver input circuit (Ref. B33).

SECTION 7 : INSTABILITY IN R-F AMPLIFIERS

(i) Causes of instability (ii) Inter-electrode capacitance coupling (iii) Summary.

(i) Causes of instability

Instability in r-f amplifiers can be due to many causes and some of these are listed below.

(1) Inter-electrode coupling due to capacitances within the r-f amplifier valve. This coupling may be augmented by additional capacitance external to the valve, due to wiring etc.

(2) Coupling between r-f and aerial coils, and leads, due to lack of adequate shielding or care in placement of the coils and leads relative to one another.

(3) Impedances common to several stages such as the metal shaft of a variable capacitor, power supply impedance (including heater leads), capacitances between switch contacts, a.v.c. line etc.

(4) Feedback at the intermediate frequency or on harmonics of the i-f.

Feedback at i-f can be serious when there is only an aerial stage preceding the converter. In some cases a simple expedient to overcome this difficulty is to connect a series resonant i-f trap between the aerial and earth terminals.

(5) Overall feedback from the a-f section into the aerial stage. This can be checked by bringing the speaker leads into close proximity with the aerial terminal, and the feedback usually manifests itself as a characteristic a-f howl. Practically all of the above factors are under the receiver designer's control even though the elimination of undesired oscillations is often a very difficult practical problem. Further discussion is given in Chapter 35, Sect. 3(v).

(ii) Inter-electrode capacitance coupling

Coupling due to inter-electrode capacitances calls for special consideration since these are an irreducible minimum when due care has been taken with the external circuits. A description of the effects which may be expected has been given in some detail in Chapter 2 Sect. 8 (see also Chapter 26, Sects. 7 and 8), where the nature of the impedance reflected into the grid circuit has been discussed. The connection with circuit instability is largely bound up in the magnitude of the input resistance component of the reflected impedance appearing across the valve grid circuit, and as to whether this input resistance is positive or negative. If the resistance is positive the dynamic impedance of the grid input circuit is lowered and there is a loss in gain and a broadening of the tuning characteristic. For a negative input resistance component the opposite effects hold with the dynamic impedance of the tuned circuit increased and the tuning becoming sharper. When the negative resistance, due to coupling by inter-electrode capacitances from other circuits associated with the valve, equals or is less than the positive resistance of the grid input circuit, oscillation will occur.

In the usual case for a r-f amplifier the primary winding of the r-f coil is resonated outside the tuning range. For a high impedance primary resonated below the lowest tuning frequency the plate circuit of the valve acts as a capacitance and the grid circuit is affected as though a positive resistance and a capacitance were connected in parallel across it. This effect is due to the total grid-to-plate capacitance. When the primary of the r-f coil is resonated above the highest tuning frequency, the valve sees an inductive load and a capacitance and a negative resistance component appear in parallel across the grid input circuit. (This circuit is the aerial coil when only one r-f stage is used).

For the case of the tuned anode load circuit i.e. a single tuned circuit connected directly between plate and B+, the valve sees a resistive load and there is only a capacitance effectively reflected in parallel with the valve grid input circuit. In this latter case, however, because of circuit mistracking, the valve may only see a resistive load at a few points in the tuning range and at other settings of the tuning dial the load may appear as either a capacitance or an inductance depending on whether the resonant frequency is below or above the required signal frequency.

The above effects can be neutralized by suitable circuit arrangements but usually the additional trouble and expense involved are avoided whenever possible.

To obtain a quantitative idea of the permissible values of grid-to-plate capacitance which would just put a circuit on the verge of instability, an investigation was made by Thompson (Ref. B41) who gave the following results.

$$C_{gp} = \frac{A}{\omega g_m R_D^2}$$

where C_{gp} = total capacitance grid to plate (valve internal and external)

$$A = \begin{cases} 2 & \text{for 1 r-f stage} \\ 1 & \text{for 2 r-f stages} \\ 0.764 & \text{for 3 r-f stages} \end{cases}$$

$$\omega = 2\pi \times \text{operating frequency}$$

$$g_m = \text{mutual conductance of r-f amplifier valve (assumed same type and operating conditions in each case),}$$

and R_D = dynamic impedance of the input and output circuits (assumed identical in all cases for simplicity).

Obviously, even for values of C_{gp} less than those obtained from the above expression, there would be a marked effect on the gain and selectivity of the circuits before oscillation actually started.

(iii) Summary

Possible sources of feedback giving rise to instability can often be predicted from the circuit and component layout diagrams of a receiver. An estimate can be made of the possible magnitudes of many of the undesired voltages involved.

It should be evident that it is far better to avoid possible feedback and instability by good electrical and mechanical design rather than spend many fruitless hours tracking down an oscillation which could have been avoided.

A most helpful discussion of instability problems is given in E. E. Zepler's "Technique of Radio Design" (in particular Chapter 9) and the reader is recommended to consult this book as an excellent practical guide.

Some further considerations will be given to circuit instability in Chapter 26, in connection with i-f amplifiers. These circuits, being fixed tuned, are usually more amenable to calculation of possible instability than r-f stages and the results obtained more closely approximate to the practical set-up.

It is necessary to mention that at very high frequencies (say above 50 Mc/s or so) the inductance of the screen-grid lead in screen-grid tetrodes and pentodes can cause an apparent change in plate to control-grid capacitance which is often sufficient to cause instability. If the screen is earthed by means of a capacitor, it is often possible to select a capacitance value which will be series resonant with the screen lead inductance, at the working frequency, and so form a low impedance path to ground. This arrangement is often sufficient to prevent instability from this cause, even over a range of frequencies. For further discussion see Ref. A8.

It is also important to note that at the higher frequencies a capacitor does not behave as a pure capacitance, and its effective inductance and resistance become increasingly important as the frequency increases. With many types of capacitors it is possible that the inductive reactance will exceed the capacitive reactance even at frequencies as low as 30 Mc/s (with electrolytics an additional r-f by-pass should always be used). This effect is sometimes used to make the capacitor series resonant at the working frequency. Even if the capacitor behaves as a small inductance it will be appreciated that in some cases the reactance can be very low and effective by-passing is still possible. In tuned circuits the Q can be materially affected by the increase in r-f resistance of the capacitors and both this and the previous effects should be checked.

The effectiveness of by-pass capacitors and their Q at the working frequency can be readily checked with the aid of a Q meter by placing the capacitor in series with a coil of known inductance and Q . See Ref. B45. Finally, r-f chokes do not always behave as such, and their resonant frequencies should always be checked (see also Chapter 11 Sect. 6).

SECTION 8 : DISTORTION

(i) Modulation envelope distortion (ii) Cross modulation distortion.

Modulation envelope distortion introduced by r-f voltage amplifiers is usually small when compared with that introduced by the later stages in a radio receiver e.g. the i-f amplifier, the detector and, perhaps, the frequency converter. This is particularly true when the magnitude of the signal voltage is small. Amplitude modulation distortion in r-f amplifiers is usually caused by the curvature of the valve characteristic relating control grid voltage to plate current. The usual explanation for the introduction of this distortion is to consider that the portion of the characteristic curve being used can be represented by a power series relating the grid voltage (in this case the modulated carrier wave) and the plate current. It can be shown from this treatment that second order terms (terms containing squares) in the series do not introduce

distortion because of the selectivity of the tuned circuits. Third order terms (those containing cubes) do introduce distortion of the modulation envelope.

R-F amplifier valves are usually designed so that the third order curvature of their characteristics is minimized as far as possible. This is achieved by using a variable pitch for the control grid winding and results in the well known variable- μ (or remote cut-off) characteristic. The variable- μ (or more exactly "variable g_m " characteristic) and the resultant shape of the $e_p - i_p$ curve, have a large bearing on cross modulation distortion as will be discussed presently.

(i) Modulation envelope distortion

Because of the presence of the higher order terms in the power series representation, the magnitude of the r-f signal which can be handled by a particular type of r-f valve is limited if the distortion of the modulation envelope is not to be serious. Methods of measuring and calculating the signal handling capabilities of r-f amplifiers have been discussed in the literature and the reader is referred to K. R. Sturley's "Radio Receiver Design" Part 1 Chapter 4 Sect. 7 for a description of these methods, and to the other references listed at the end of this chapter.

(ii) Cross modulation distortion

Cross modulation distortion is an effect well known to receiver designers. It occurs when two signals are applied to any non-linear element such as a radio valve, under certain operating conditions, having appreciable third order curvature of the grid voltage-plate current characteristic. The effect is most noticeable when a strong local signal is present and the receiver is tuned to a weak signal. Insufficient r-f selectivity is often a major contributing factor in this regard. It is quite useless to have good selectivity in, say, the i-f amplifier once cross modulation has occurred in the r-f or converter stage, as no amount of subsequent selectivity can remove the undesired signal which is now superimposed on the same frequency band as the desired signal, and the modulation on both signals will be heard in the received output.

The r-f amplifier valve must also be designed so that the higher order modulation terms are kept as small as possible. A variable- μ valve will materially assist in handling a wide range of signal voltages without the grid voltage-plate current curvature being such as to allow serious cross modulation to occur.

A careful choice of the bias voltage for the r-f valve, and making the cathode bypass capacitor of sufficiently small value to be effective at radio frequencies only, will often assist in reducing cross modulation.

When the local interfering station is a very powerful one it often becomes necessary to use special rejector circuits as well as high r-f selectivity.

Effects such as external cross modulation are not discussed here but reference can be made to F. E. Terman's "Radio Engineers' Handbook" page 647 for some details.

SECTION 1 : INTRODUCTION

In this chapter it is proposed to consider, briefly, some of the fundamental types of oscillator circuits (used in conjunction with valves) which are commonly employed in radio receivers. Of course there are numerous variations of the fundamental circuits, but generally these changes are only a practical convenience for obtaining some required special condition of operation from the basic circuit.

The types of circuits to be considered are :

- (a) The tuned-plate oscillator
- (b) The tuned-grid oscillator
- (c) The Hartley oscillator
- (d) The Colpitts oscillator
- (e) The electron-coupled oscillator
- (f) The negative transconductance oscillator.

For those interested in the general theory of oscillation, and in the many special circuits available, a list of suitable references is given at the end of the chapter which will serve as a starting point, at least, for a more complete survey of this field of knowledge. Crystal oscillator circuits are not discussed here but a number of useful circuits are given in Refs. 27 (page 164), 26 (page 97) and 31 ; the latter giving a discussion of overtone (harmonic mode) crystal oscillators.

Before proceeding to a discussion of particular types of oscillator circuits, a few of the fundamental principles will be briefly reviewed.

The simplest form of electrical oscillator consists of a combination of inductance (L) and capacitance (C) connected together (as shown in Fig. 24.1), to which has been added, initially, electric or magnetic energy. Suppose that the capacitor C has been charged by some means. The energy stored in the capacitor is then $\frac{1}{2}CE^2$, where E is the maximum potential difference between the plates. At this instant, when E has its maximum value, the current in the circuit is zero. The presence of the inductor will allow the energy stored

FIG. 24.1

in the electric field of the capacitor to be transferred, and to form a magnetic field around the inductor. The capacitor discharges until finally E becomes zero and the current I becomes a maximum. At the instant at which I is a maximum the energy in the magnetic field is $\frac{1}{2}LI^2$, all the available energy is stored in the magnetic field and there is no electric field. The process now reverses, the magnetic field collapses and energy is transferred back to the electric field of the capacitor. This process repeats itself indefinitely if there is no loss of energy in the circuit (radiation is not considered here).

Since the total energy which is stored in each field in turn, is the same, it is permissible to write

$$\frac{1}{2}CE^2 = \frac{1}{2}LI^2 \quad (1)$$

where E and I have their maximum values.

$$\text{Also } E = 1/\omega C \quad (2)$$

$$\text{and so } 1/\omega^2 C = L \quad (3)$$

$$\text{or } f = 1/2\pi\sqrt{LC} \quad (4)$$

where f is natural resonant frequency of the oscillations occurring in the circuit.

Since there is always some resistance (R) present with practical circuit elements, the amplitude of each successive oscillation will decrease until eventually all of the energy is dissipated—mainly in the form of heat in the resistance—and the oscillations will cease. (This is discussed further in Chapter 9, Sect. 1). The addition of extra energy to the circuit from some external source, such that the added energy equals that being lost, would allow the oscillations to continue indefinitely. In the circuits to be considered the power supply is the external source of energy, and the valve is the device controlling the energy which is added to the $L C R$ circuit, in the correct phase and amplitude, to maintain oscillations.

With any valve oscillator an exact analysis of the method of operation is very difficult, if not impossible, and it is usual to treat the circuits as being linear (at least for simple design procedure) although they depend on conditions of non-linearity for their operation. This simplification is valuable because the mathematical analysis which can be carried out yields a great deal of useful information concerning the behaviour of the circuits. That the circuit operation is non-linear can be readily appreciated by considering the fact that the amplitude of the oscillations, once started, does not continue to build up indefinitely. The energy gain of the system reaches a certain amplitude and then progressively falls until equilibrium is established. The limits are usually set by the valve—plate current cut-off occurs beyond some value of the negative grid voltage swing, and plate current saturation or grid current damping will limit the amplitude of the grid swing in the positive direction. For a discussion of the factors governing oscillation amplitude, the reader should consult Refs. 1 and 2.

In the sections to follow, typical circuits applicable to radio receivers will be discussed. It is not proposed to give a mathematical analysis or detailed physical explanations of the operation of the circuits, as this has been more or less adequately done in many text books and periodicals. Suitable references are 1, 3, 5, 7, 10, 11, 24.

At the outset it may be mentioned that, since high oscillator efficiency is not usually as important a factor as some other requirements in radio receivers, the design is generally a combination of empirical and experimental techniques. A large number of the circuit component values are pre-determined by such considerations as tracking the tuned circuit with signal circuits over a band of frequencies and maintaining constant oscillator amplitude over the tuning range. Other factors will be discussed in Sect. 9 of this chapter.

Design procedures such as those used for class "C" power oscillators in transmitters are not carried out in detail for receiver oscillators, although obviously the basic principles are the same in both cases; this will receive further consideration in Sect. 9.

SECTION 2 : TYPES OF OSCILLATOR CIRCUITS

(i) *Tuned-plate* (ii) *Tuned-grid* (iii) *Hartley* (iv) *Colpitts* (v) *Electron-coupled* (vi) *Negative transconductance oscillators*.

(i) Tuned-plate oscillator

Fig. 24.2 shows three arrangements for the tuned plate oscillator. Circuits (A) and (B) use series feed, and circuit (C) uses shunt feed. Circuit (B) is the usual practical arrangement of (A); P is a padding and C a blocking capacitor.

The shunt feed circuit (C) is generally preferred in receivers for the following reasons :

(1) The rotor plates of the tuning capacitor can be directly earthed without using additional series blocking capacitors directly in the tuned circuit.

(2) The resistor R_1 can often be selected to assist in maintaining a constant amplitude of oscillation over the tuning range, since it will give greater damping of the tuned circuit as the frequency increases.

Either arrangement of the grid-leak resistor (R_g) shown in circuits (B) and (C) is satisfactory, but in circuit (C) it gives increased damping on the feedback winding (L_f) which may be advantageous in maintaining constant grid voltage amplitude over a range of frequencies.

Tight coupling and low values of mutual inductance (M) are helpful in maintaining frequency stability with mains voltage variations, as these factors tend to make the circuit relatively independent of valve constants other than interelectrode capacitances (see Ref. 21). L_f is made as small as possible, to reduce M , and also to keep its natural resonant frequency well above the tuning range; this latter factor means that stray capacitance across the feedback winding must be kept as small as possible. The high natural resonant frequency for the feedback circuit is helpful in reducing variations in the tuned circuit (due to reflected impedance), this being particularly important since it reduces tracking error and limitations on the maximum possible tuning range.

The resonant frequency (f) of the tuned-plate oscillator is given approximately by

$$f = \frac{1}{2\pi\sqrt{L_0 G}} \sqrt{1 + \frac{R}{r_p}} = f_0 \sqrt{1 + \frac{R}{r_p}} \quad (5)$$

where L_0 = inductance in tuned circuit

G = capacitance in tuned circuit (this strictly includes any additional stray capacitances shunted across G , e.g. in circuit (C) some capacitive reactance due to C would be present, depending on the value of R and the frequency of operation)

R = total series r-f resistance in tuned circuit [including in circuit (C) the equivalent series resistance due to C and R_1 being shunted across the circuit]

r_p = plate resistance of valve

and f_0 = natural resonant frequency of tuned circuit alone.

For our purposes it is sufficiently close to take

$$f = f_0 = \frac{1}{2\pi\sqrt{L_0 G}} \quad (6)$$

where G is the actual capacitance (including trimmers, padders etc.) tuning L_0 .

The important point to observe is that other components, including the valve, affect the frequency of oscillation. As these components are capable of variation with voltage or temperature fluctuations they will affect oscillator stability, and their effects should be minimized as far as possible. Some improvement in stability is possible by making the grid current small, which agrees with the condition of a low value for L_f , but this is also governed by the permissible value of the grid resistor (R_g).

The condition for the maintenance of oscillation is given by

$$M = - \left[\frac{L_0}{\mu} + \frac{GR}{g_m} \right] \quad (7)$$

where L_0 , G and R have the same meanings as previously,

M = mutual inductance = $k\sqrt{L_f L_0}$ (in the absence of additional capacitance coupling)

k = coefficient of coupling

μ = amplification factor of valve

and g_m = mutual conductance of valve.

The negative sign for M indicates that oscillation will only occur for one connection of the feedback winding.

A suitable factor of merit for an oscillator valve is the product μg_m , which should be as high as possible. This is also a suitable factor for power output valves, and explains why types such as the 6V6 beam power valve work well in feedback oscillator circuits.

The advantages claimed for the tuned-plate oscillator are its relative freedom from frequency changes due to mains voltage variations and, when the circuit is used with converter valves, freedom from signal-grid bias voltage changes.

The tuned plate oscillator in its standard form is not very satisfactory for use at frequencies above about 50 Mc/s.

(ii) The tuned-grid oscillator

The general circuit arrangement for a tuned-grid oscillator is shown in Fig. 24.3. Much of the general discussion given in connection with the tuned-plate oscillator is applicable to this circuit.

FIG. 24.3 TUNED-GRID OSCILLATOR

The tuned-grid oscillator is probably the most widely used in receivers for the standard long-, medium- and short-wave bands. One of its features is the ease with which oscillation can be obtained. The arrangement of the components offers little difficulty, and one particular advantage is that the tuned circuit is completely isolated from the plate supply voltage.

The approximate frequency of oscillation (f) for this circuit is given by

$$f = \frac{f_0}{\sqrt{1 + \frac{L_f R}{L_0 r_p}}} \quad (8)$$

where $f_0 = 1/2\pi\sqrt{L_0 G}$ = natural resonant frequency of tuned circuit

L_0 = tuned circuit inductance

r_p = plate resistance of valve

L_f = feedback winding inductance

R = series r-f resistance (total) in tuned circuit

and G = total tuning capacitance.

The minimum value of M required to maintain oscillation is given approximately by

$$M = - \left[\frac{L_f A}{\mu(1 + A)} + \frac{GR}{g_m} \right] \quad (9)$$

where $A = L_f R / L_0 r_p$

μ = amplification factor of valve

g_m = mutual conductance of valve

r_p = plate resistance of valve

and L_f , R and G are as previously.

If r_p is large and R is small, frequency variation from the natural resonant frequency is reduced, as can be seen from an examination of the equation. Also, as a point of interest, it is seen that f is less than f_0 for the tuned-grid oscillator, and greater than f_0 for the tuned-plate circuit; so that the tuned circuit acts as an inductive reactance (neglecting resistance effects) in the first case, and as a capacitive reactance for the tuned-plate oscillator. These points are further discussed in Ref. 5. The useful upper frequency limit for the tuned-grid circuit is about 50 Mc/s, as the value of the feedback-winding inductance and the resonant frequency of the feedback circuit become troublesome. This applies also to the tuned-plate arrangement.

(iii) Hartley oscillator

Fig. 24.4 shows two possible arrangements for the Hartley oscillator circuit. The circuit (A) is the conventional series-fed circuit, but is not very convenient for use in radio receivers for several reasons.

- (1) The tuning capacitor G cannot be earthed without using blocking capacitors.
- (2) The presence of blocking capacitors presents tracking difficulties.
- (3) The coil L_0 has H.T. applied which may be awkward when making adjustments, particularly during developmental work.
- (4) Untracked stray capacitances are likely to be high.

The alternative arrangement of Fig. 24.4 (B) is the circuit most commonly employed in receivers. The tuned circuit is connected directly to ground. This arrangement avoids the difficulties of circuit (A); furthermore it is particularly convenient for use with converter valves of the 6SA7, 6BE6 pentagrid type.

FIG. 24.4

HARTLEY OSCILLATOR

The angular frequency of oscillation for the Hartley circuit of Fig. 24.4(A) (see Ref. 5) is given approximately by

$$\omega = \omega_0 \sqrt{1 + R_1/r_p} \quad (10)$$

where $\omega_0 = 1/\sqrt{L_0 G}$

$\omega_0 = 2\pi \times f_0$ (f_0 is natural resonant frequency of tuned circuit)

R_1 = r-f resistance of L_1

r_p = plate resistance of valve

L_0 = oscillator coil inductance ($= L_1 + L_2 + 2M$)

and G = tuning capacitance.

For the maintenance of oscillation

$$\mu = \frac{L_1 + M}{L_2 + M} + \frac{Gr_p(R_1 + R_2)L_0}{(L_1 + M)(L_2 + M)} \quad (11)$$

where μ = amplification factor of valve.

L_1 and L_2 are the two sections of L_0 coupled by mutual inductance

M and R_1 and R_2 are the r-f resistances of L_1 and L_2 respectively.

The frequency equation shows that the oscillation frequency f is higher than f_0 , and to reduce this difference r_p should be high and R_1 small. Also, for the circuit to oscillate readily, the mutual conductance of the valve should be high.

A Hartley oscillator offers advantages over the tuned-plate and tuned-grid circuits at frequencies in excess of about 40 Mc/s, the greatest advantage being that the feed-

back winding, being a part of the tuned circuit, does not offer the same difficulties as the other cases, in which the natural resonant frequency approaches the operating frequency.

In the case of the other two types of oscillators mentioned, if the feedback winding has greater inductance than the tuned winding, the oscillator can easily change over from one type to the other (i.e. tuned-plate becomes tuned-grid and vice-versa) and satisfactory tuning is obviously impossible. This trouble is not as unlikely as may be thought since it is often very difficult to obtain sufficient amplitude of oscillation as the frequency increases.

The Hartley circuit can be made to give satisfactory operation to frequencies at least as high as 150 Mc/s, even with multi-grid converter valves (depending, of course, on the valve type used), but its chief disadvantages are

- (1) Its liability to parasitic oscillations as the frequency increases,
 - (2) The possibility of the circuit acting like a modified Colpitts oscillator because of stray and valve interelectrode capacitances,
 - (3) That it is rather awkward to find the optimum tapping point for the best conditions of oscillation, particularly when the frequency becomes fairly high. This is particularly so with valve types such as the 6BE6 on the F-M broadcast band since the tapping point on the oscillator coil has a large effect on conversion gain.
- (1) and (2) generally manifest themselves as sudden changes in oscillation frequency when tuning over the working range, or as "dead" spots, or through the oscillator stopping altogether when the gang capacitance becomes less than a certain value.

It may be mentioned finally that the Hartley circuit has been extensively used on all broadcast bands including the F-M 88-108 Mc/s band; its application in receivers has been largely confined to use with pentagrid converters such as types 6SA7, 6BE6, 6SB7-Y and 6BA7.

(iv) Colpitts oscillator

A circuit for a shunt fed Colpitts oscillator is shown in Fig. 24.5(A). A suitable arrangement (Ref. 9) for use in radio receivers operating at frequencies of the order of 100 Mc/s is that of Fig. 24.5(B). In this latter circuit C_B is the self-capacitance (plus added capacitance if required) of the choke L in the cathode circuit, and C_A is the grid-to-cathode capacitance; L_0 is the oscillator coil inductance and G the variable tuning capacitor. The cathode impedance can readily be controlled by connecting a variable trimmer across L .

FIG. 24.5

COLPITTS OSCILLATOR

The circuit of Fig. 24.5(B) has been successfully used with type 6BE6 converters tuning the 88-108 Mc/s F-M broadcast band and avoids the necessity for tapping the oscillator coil as in the Hartley circuit.

The angular frequency of oscillation of the Colpitts oscillator, from the solution of the circuit of Fig. 24.5(A), is given by

$$\omega = \omega_0 \sqrt{1 + \frac{R}{r_p} \left(\frac{C_2}{C_1 + C_2} \right)} \quad (12)$$

The condition for oscillation maintenance is that

$$\mu = \frac{C_2}{C_1} + \frac{r_p R (C_1 + C_2)}{L_0} \quad (13)$$

where $\omega_0 = 2\pi \times f_0$ (f_0 is the natural resonant frequency of the tuned circuit alone)

$R =$ r-f resistance of L_0

$r_p =$ plate resistance of valve

$\mu =$ amplification factor of valve

$L_0 =$ oscillator coil inductance

and C_1 and C_2 tune L_0 ; they also form a capacitive voltage divider across L_0 ; and the excitation voltage on the grid is proportional to $C_1/(C_1 + C_2)$.

This circuit is most convenient for use at v-h-f, it is very easy to make oscillate, and is not so liable to parasitic oscillations as the Hartley circuit. Its use on the medium and short-wave bands has been rather limited because of difficulties in circuit arrangement when covering frequency bands of about 3 : 1, and also because of the very simple and satisfactory manner in which the tuned-grid and tuned-plate circuits can be made to operate over these ranges. The Colpitts circuit readily lends itself to inductance tuning and with this arrangement has been used satisfactorily on all of the frequency ranges encountered in normal broadcast receiver design.

(v) Electron-coupled oscillator

Electron-coupled oscillators (Refs. 1, 22) can use a large variety of fundamental circuits, such as the Hartley or Colpitts, for generating oscillations. The circuit usually employs a tetrode or pentode valve, or, most often in receivers, is used with a pentagrid converter. Valves having suppressor grids will generally give better frequency stability.

The fundamental principle is that the actual oscillating circuit is connected to the load circuit only by means of the electron stream within the valve. In this way changes in load conditions and high tension voltages have a reduced effect on the actual frequency of oscillation. The improvement in frequency stability with voltage variations appears to be closely bound up with compensating effects due to simultaneous voltage changes on the plate and screen. Variation in load conditions would, ideally, leave the oscillation frequency unchanged since the two circuits are only connected unilaterally through the electron stream. Actually, of course, interelectrode capacitances and stray coupling prevent this condition from being completely fulfilled.

FIG. 24-6 PENTAGRID CONVERTER USING ELECTRON-COUPLED HARTLEY OSCILLATOR

Those pentagrid converters which commonly use the Hartley oscillator circuit arrangement are typical examples of the application of electron-coupling. One such arrangement is shown in Fig. 24.6. It is often advantageous in this type of circuit to connect the screen to the rectifier output through R as this reduces "flutter"; the high tension for the plate is obtained from the power supply in the usual manner.

With this latter arrangement C_2 generally consists of an electrolytic capacitor and a mica capacitor (to act as a r-f by-pass) connected in parallel.

(vi) Negative transconductance oscillators

Several types of negative transconductance oscillators have been suggested using r-f pentode valves. These circuits have a negative bias on the suppressor grid and rely for their operation on the fact that, over a particular range of negative voltage on this grid, the suppressor-screen transconductance is negative. With suitable operating conditions a positive increment in the negative suppressor grid voltage will allow the plate current to increase and the screen current to decrease even when the screen voltage is increased; the changes in screen and suppressor voltage being approximately equal. The screen and suppressor are coupled together by means of a capacitor, and the tuned circuit is connected in a suitable manner between plate and screen. Detailed descriptions of this type of oscillator can be found in Refs. 7 and 23. Circuits using this arrangement with pentode valves are not very convenient since the negative transconductance is only of the order of -250 micromhos.

Since this oscillator is a two terminal type it is often a very convenient arrangement ; one particular example is its use as a beat-frequency oscillator in a radio receiver. A particular form of the negative transconductance oscillator (Ref. 13)—which employs, also, the principle of electron coupling—using a pentagrid converter valve (e.g. type 6A8, but **not** 6SA7, 6BE6 etc.) is shown in Fig. 24.7. The negative transconductance is brought about as follows. Electrons moving towards the plate are turned back to the inner screen (G_3) and the oscillator anode (G_2) when the control grid (G_4) has a more negative voltage applied to it. The net effect of an increase of negative voltage on the signal grid is to increase the current to the oscillator-anode and to grid G_3 .

FIG. 24.7 NEGATIVE TRANSCONDUCTANCE OSCILLATOR

Any increase in the current to G_3 is practically offset by a decrease in the current to G_5 , the outer part of the screen grid, and the result is that the screen current remains fairly constant for wide variations in signal-grid voltage. The variation in oscillator-anode current, however, is equivalent to a negative transconductance between the control grid (G_4) and the oscillator-anode (G_2). In type 6A8 this amounts to about -400 micromhos. Because of this negative transconductance it is possible to create an oscillatory condition by coupling G_4 to G_2 , provided that the rest of the circuit is suitably arranged.

The circuit of Fig. 24.7 has been used at frequencies up to 18 Mc/s. It has also been employed in several types of communications receivers (having intermediate frequencies of from 255 Kc/s to 3 Mc/s) as a beat-frequency oscillator and has given very good results as regards stability of operation, particularly when temperature compensation has been applied to the tuned circuit.

It is near enough, for practical purposes, to take the frequency of oscillation as being

$$f_0 = 1/(2\pi\sqrt{L_0 C}) \quad (14)$$

SECTION 3 : CLASS A, B AND C OSCILLATORS

An oscillator can be made to work under a variety of conditions. The impulses applied to the tuned circuit, to maintain oscillation, can be such that the valve plate current may be flowing from something less than 180° of the electrical cycle to almost the full 360° . Depending on the period for which the impulses are applied, the oscillator may be classified as Class A, B or C.

High quality laboratory oscillators often use the Class A condition, while high power oscillators, such as those sometimes used in transmitters (where efficiency might occasionally be more important than obtaining an output voltage relatively free from harmonics) might possibly use Class C operation ; of course even in high power transmitters a master oscillator is the usual arrangement and efficiency is not an important factor in its operation. Oscillators in superheterodyne receivers do not need to have very high efficiency, but the output must be relatively free from harmonics if whistle interference is not to be a serious problem ; this generally leads to something approaching Class B operation (Ref. 5).

It should be noted that, for all usual operating conditions, grid current flows for at least part of the input voltage cycle.

SECTION 4 : CAUSES OF OSCILLATOR FREQUENCY VARIATION

(i) *General* (ii) *Changes in supply voltage* (iii) *Temperature and humidity changes*
(iv) *Oscillator harmonics.*

(i) General

Frequency drift in the oscillator section of superheterodyne receivers (F-M or A-M) is important for a number of reasons. The most obvious is that as a result of such drift the actual intermediate frequency output from the frequency changer will not be that to which the i-f amplifier is tuned, giving a loss in amplification and the added possibility of considerable frequency distortion in A-M receivers, and non-linear distortion in F-M receivers. Other special effects will be discussed separately.

Oscillator frequency variations which can be offset in the original design may be due to changes in

- (a) Supply voltage
- (b) Temperature
- (c) Humidity
- (d) A.V.C. bias on the signal grid of multielectrode converter valves. This will be discussed in Chapter 25 Sect. 2.

Also, it should be noted that a high percentage of oscillator harmonics can lead to oscillator instability. Mechanical stability of the circuit is a prime requirement.

Detailed discussion regarding oscillator frequency stability can be found in Refs. 1, 4, 5, 10, 11, 15, 19, 20, 21 and 28.

(ii) Changes due to supply voltage

Some change in oscillator frequency always occurs when there is a change in the voltages on the valve electrodes, because of changes in valve "constants."

For the simple triode oscillator, plate voltage changes may be minimized by using a supply voltage having good regulation; the regulation requirement is often determined by the variations in the total current drawn by the complete receiver when the signal voltages are changing. This may necessitate a separate voltage supply for the oscillator valve, and where extremely high oscillator stability is required a separate voltage regulator valve (e.g. OD3/VR150) may be incorporated. A common manifestation of poor regulation of the H.T. is the "flutter" experienced on the short-wave bands.

For screen grid valves the same precautions are taken as for a triode, but often very appreciable improvement is possible, with some valve types, by offsetting screen and plate current changes one against the other. Although the principle of offsetting changes due to various electrodes against each other is of assistance, it should be noted that with some converter valves in which voltage changes are additive (e.g. 6J8-G), better stability is possible than with other valve types (e.g. 6A8, 6K8) in which the plate and screen voltage variations are subtractive. Pentagrid converter valves of the 6SA7 class are particularly critical as to screen voltage changes and a separate screen supply is often essential.

(iii) Temperature and humidity changes

After a receiver has been switched on, it is found that the oscillator frequency tends to alter for some considerable time, up to say an hour or more. Usually it is found that the internal effects of the valve heating up become negligible after a period of about ten minutes. The base of the valve is responsible for a certain amount of drift, but this can be minimized by the use of high-quality porcelain or micanol bases. With the miniature valve types the electrode connections come straight through the button stem instead of through a glass pinch, and the temperature variations due to the complete valve assembly are kept to an absolute minimum.

The most serious frequency drift through temperature changes is generally caused by capacitance variations due to the heating of the various dielectrics in the circuit.

This is minimized by the use of high quality dielectrics such as special grades of porcelain.

Inductance changes due to temperature rise also cause frequency variation, and low-loss dielectric formers are essential. If sufficient mechanical stability is possible air cored coils are often preferable, but not always.

Good circuit layout is an essential requirement and all sources of heat should be kept away from tuning capacitors and coils.

When all the requirements as to dielectrics, circuit layout etc. have been met as far as is possible, final temperature compensation is made by using capacitors having negative temperature coefficients. These capacitors are available commercially in a wide range of capacitance values, and with various negative temperature co-efficients. The manufacture of this type of capacitor is possible because of the availability of ceramic materials having dielectric constants which decrease with an increase in temperature*. It should be realized that exact compensation by simple capacitance adjustment is only feasible, in general, at one point in a given tuning range, but a very appreciable improvement over a band of frequencies is possible without exact compensation at any one point. A method for obtaining exact compensation at two points (although here again a compromise adjustment may be preferable) in a given tuning range, using the principles of superheterodyne tracking, has been given by Bushby (Ref. 19) ; it is also shown that a compromise adjustment is possible, although exact compensation is not practicable, at three points in the tuning range. Methods for carrying out long period frequency-drift compensation, due to temperature changes, are outlined in Ref. 19.

Changes in oscillator frequency with humidity can be minimized by using coils, capacitors and insulating materials which are properly baked to remove moisture and then impregnated (with suitable waxes or varnishes) to prevent the absorption of moisture.†

It may be worth noting here that carbon resistors have negative temperature co-efficients. Wire-wound resistors have positive or negative temperature co-efficients depending on the type of resistance wire used.‡

(iv) Oscillator harmonics

There is an effect, supposed to be due to cross modulation between the fundamental frequency and its harmonics and between the harmonics themselves, which results in the production of currents at the fundamental frequency. These new currents may be out of phase with the original current at the fundamental frequency and so tend to shift the frequency of oscillation. Most of the evidence regarding this effect is experimental and a complete explanation has not been given (see Ref. 1, p. 82). However, it does provide an additional reason for having a minimum of oscillator excitation.

*See also Chapter 4 Sect. 9(ii)f and Chapter 38 Sect. 3(vi).

†See Chapter 11 Sect. 7.

‡See Chapter 4 Sect. 9(i).

SECTION 5 : METHODS OF FREQUENCY STABILIZATION

Some of the causes of oscillator frequency variations have already been discussed, and some general methods of reducing the frequency changes have been outlined. A large number of methods have been detailed in the literature for obtaining frequency stability, such as the use of negative feedback, resistance stabilization and the various methods using reactances as given by Llewellyn (Ref. 21). Since this subject is extensive, we shall content ourselves here with stating a few of the main factors which should be observed when designing an oscillator for a superheterodyne receiver. Suitable references are listed at the end of this chapter.

(A) **Mechanical stability** of all components and wiring should be as good as possible. Care is necessary to avoid mechanical vibration (such as that due to sound waves from the loudspeaker).

(B) **Circuit layout** should be such that sources of heat (e.g. valves) are kept as far away as possible from frequency determining elements. In some cases it may be feasible to place the oscillator coil and tuning capacitor under the chassis, with the oscillator valve mounted on the top of the chassis.

(C) For feedback type oscillators, such as tuned-plate and tuned grid circuits, **the windings should be closely coupled**. The feedback winding should be as small as possible and stray capacitances across it should be low.

(D) **Grid current** should be kept as low as possible consistent with stable operation.

(E) All **supply voltages** should be as constant as possible. With pentodes it may be possible to offset plate and screen current changes.

(F) All **dielectrics** in the circuit should have low temperature coefficients and be non-hygroscopic. This applies particularly to the valve socket which becomes hotter during operation than most other sections of the oscillator circuit.

(G) Efforts should be made to stabilize the electrical constants of all components by suitable **heat treatment and impregnation**.

(H) When designing the oscillator and signal circuits it will be found from the data on superheterodyne tracking given in Chapter 25 Sect. 3, that there is some choice of inductance and capacitance values (due to the distribution of trimming capacitances) even though the frequency coverage and type of tuning capacitor are pre-determined by other conditions. Where it is permissible, **the L/C ratio of the oscillator tuned circuit** should be arranged so that it is as small as possible.

(I) The **Q of the oscillator tuned circuit** should be as large as possible consistent with other circuit requirements.

(J) Better stability is possible if the valve can be connected across only part of the tuned circuit. Often this is not convenient in radio receivers because of the reduction in available oscillator voltage, but considerable improvement in stability is possible in those cases where **tapping down** can be applied.

(K) When all other precautions have been taken, **temperature compensation** should be carried out, using capacitors having negative temperature co-efficients [see Chapter 4 Sect. 9(ii)f also Chapter 38 Sect. 3(vi)].

(L) When possible causes of frequency drift are being considered it should not be overlooked that **valve interelectrode capacitances** will change during the initial warm-up period. A typical example occurs in the Hartley circuit of Fig. 24.4(B) in which the heater-cathode capacitance is directly across part of L_0 ; in this case connecting one side of the heater directly to cathode and adding a suitable r-f choke in series with the other heater lead will minimize the trouble. This arrangement is also helpful in reducing microphonics caused by heater-cathode capacitance variations.

(M) **Judicious location of negative temperature co-efficient capacitors** is helpful. For example if part of the compensating capacitance is located at the valve socket terminals, short-time drift due to the valve and socket warm-up period can often be very appreciably reduced.

(N) The values of R_G and C_G should be selected carefully to **avoid "squegging"** (see Sect. 6). This should be checked with a large number of representative valves of the same type.

(O) Selection of the most suitable **valve type** has received some discussion in previous sections. Usually the choice is rather limited in receiver applications.

(P) **Electron coupling** to the load circuit is often helpful, and is used in many applications. Most frequency changers employ this principle.

(Q) **Harmonic operation of the oscillator** may be advantageous in some cases, since better frequency stability is sometimes possible when the fundamental frequency of operation is reduced. The disadvantage of this arrangement is the greatly increased possibility of spurious frequency combination.

The majority of receivers use the oscillator fundamental frequency, and this frequency is generally (but not always) higher than the received signal frequency. This includes all broadcast bands up to 108 Mc/s.

(R) **Increased spacing between the plates of variable capacitors** is helpful in obtaining good oscillator stability, as the effects of small variations in the position of plates, during operation, is reduced. The opportunity to make use of this occurs, for example, with the variable capacitors used in F-M receivers, where the capacitance range may be approximately 5-20 μF . In this case it is often possible to use double spacing between the plates of the oscillator tuning capacitor.

SECTION 6 : UNSTABLE OSCILLATION

Unstable oscillation can be due to a number of causes, some of which have been mentioned in Sections 4 and 5.

Flutter has received some consideration and the cure is generally to use a separate series resistor from the power supply to provide the B+ for the oscillator plate (or screen in some converters), by-passed by a large capacitor (say an 8 μF electrolytic).

Squegging (see Refs. 5 and 8) is caused by excessive oscillator-grid voltage amplitude and incorrect proportioning of the values for the grid resistance and capacitance. The effect manifests itself as a variation in oscillator output which changes at an audio or ultrasonic rate. The only precautions usually required are to select suitable values for R_g and C_g and to adjust the oscillator grid current to the lowest suitable value. Most valve manuals suggest that values for C_g should lie between 20 to 100 μF depending on the operating frequency. Small values of the product $R_g C_g$ are called for at the higher frequencies. The effect should be carefully checked with several valves of the same type. In some cases "squegging" occurs at the high frequency end of the tuning range only, and this often calls for the use of a series grid "stopping" resistor, or a parallel resistor shunted across the oscillator tuned circuit; these resistors provide greater damping at the higher frequencies and so serve to equalize the oscillator grid voltage across the tuning range.

Other miscellaneous effects which are of interest are :

(A) Hum causing amplitude or frequency modulation of the local oscillator in a receiver.

In A-M receivers the selectivity of the i-f amplifier can cause the frequency modulation to give rise to amplitude modulation (superimposed on the desired carrier) and the hum, after detection, appears in the receiver output, in addition to the hum due to amplitude modulation of the oscillator. With F-M receivers the hum provides additional frequency modulation of the carrier. The cure is generally to improve the power supply filtering.

(B) Frequency modulation, at an audio frequency rate, caused by vibration of the oscillator tuning capacitor plates, or some other part of the oscillator circuit, by sound waves from the loud speaker (often called "microphonics"). This effect is particularly troublesome at the higher carrier frequencies. The natural period of the tuning capacitor is important and any method of altering this often provides a cure ;

this frequency should not coincide with the bass resonant frequency of the loud speaker. Often it is necessary to mount the capacitor on rubber and provide flexible leads to the dial, etc.

(C) Microphonics caused by heater-cathode capacitance variations. This effect is minimized by connecting one side of the heater directly to cathode, where this is possible, and using a r-f choke in the other heater lead to avoid shunting the tuned circuit with the heater circuit, e.g. see Fig. 24.6 where the result of omitting a r-f choke would be to short out part of the tuning inductance.

Microphony in superhet. oscillators is covered in Ref. 32.

SECTION 7 : PARASITIC OSCILLATIONS

"Parasitic oscillation" is the name given to any undesired oscillation in a circuit. Tuned circuits will always have at least one additional resonance point determined by the leads and stray capacitances. Usually in radio-frequency circuits these parasitic oscillations have very high frequencies, but they become troublesome and lead to "dead" spots and large fluctuations in oscillator amplitude if sufficient care is not taken with the arrangement of leads and components. Audio frequency circuits are also liable to this form of oscillation which in this case is generally apparent as distortion.

The usual cure for these troubles is the use of "stopping" resistors (or neutralization in some converter circuits) in series with one or more of the valve electrodes concerned. Care is necessary, however, as the presence of the resistors may adversely affect the performance of the stage concerned.

Carelessness in shunting large capacitors with small ones may result in an undesired resonance. The leads provide the inductance and the circuit may be series resonant in the working range of frequencies. Band-switching in all-wave receivers needs to be carried out carefully if an undesired resonance is not to appear in a tuning range.

For a further discussion of parasitic oscillations the reader is referred to Ref. 8 (Chapter 12, p. 264) and Ref. 5 (Chapter 6, p. 269). Some useful data are also given in Ref. 9, p. 9.

SECTION 8 : METHODS USED IN PRACTICAL DESIGN

In the design of oscillator circuits for radio receivers many of the component values required are specified by other circuit considerations. This is readily seen from the procedure given in Chapter 25 Sect. 3 (in connection with tracking) for determining the value of inductance, and the tuning, trimming and padding capacitance values for the oscillator circuit.

In most cases, once a suitable valve has been selected (the choice here is usually restricted), details of the required grid-leak resistance, oscillator grid current (which in conjunction with R_g determines the grid voltage) electrode voltages etc. are directly available from the valve data sheets. The type of circuit is usually restricted to the tuned-plate, tuned-grid, or the Hartley for frequencies up to about 50 Mc/s and to the Hartley and Colpitts for frequencies above this. It is required of the receiver designer to reproduce, if possible, the specified operating conditions (although this is often a rather tricky job) together with such modifications as he deems necessary.

For the feedback type of oscillator a useful "rule of thumb" is to make the number of feedback turns about half to one third of the total on the main winding; correct amplitude is obtained by selecting the number of turns to give the required oscillator-grid current. The tapping point on Hartley and Colpitts circuits also approximates, very roughly, to this rule, which provides a convenient starting point for the necessary experimental work.

With the feedback type of circuit, provided that the coupling between the windings is sufficiently high, the number of turns on the feedback winding suggested by the

above procedure will usually be somewhat greater than is necessary, and it is only necessary to strip off the excess turns until the required conditions are approached. Of course, this does not immediately ensure that the circuit will be satisfactory in all respects, since the oscillator normally tunes over a band of frequencies. Owing to the tolerances permitted in the manufacture of all valve types, it is necessary to check the circuit with a number of valves. These, preferably, should include samples which fall on the upper and lower limits of the permissible range of g_m allowed by the particular manufacturer, otherwise satisfactory results may not be obtained in the mass production of receivers.

Where the available operating data are given for voltages somewhat different from those required, valve conversion factors (see Chapter 2, Sect. 6, can be applied to obtain the new conditions.

Occasionally a receiver designer is faced with the problem of using a valve for which some data are available, but for which conditions for oscillator operation are not given. Several procedures are available. Exact or approximate methods of analysis can be used, just as for power oscillators (see Refs. 10, 11 and 24), but often it is possible to arrive at a suitable set of operating conditions on the basis of past experience (or by comparison with similar valve types for which the required data are given). The only important factor, as far as the use of the valve is concerned, is that the maximum ratings—including the peak plate current—should not be exceeded. Other factors previously discussed, such as keeping the oscillator grid current as low as possible and operating the valve so that harmonic generation is not excessive, suggest that conditions more nearly approaching Class B operation are called for, particularly as high efficiency with receiving type valves is not often (if ever) a design requirement in a radio receiver.

Once a suitable set of operating conditions has been obtained, experimental techniques are resorted to, exactly as before. Preliminary calculations other than the empirical methods suggested, as to tapping points, number of feedback turns etc., can be made if so desired, but the extra trouble involved is hardly worth the effort.

Methods for calculating the inductance required for feedback windings have been suggested (see Ref. 8, page 117) but generally the results give values which are too low. For this reason the experimental approach is generally the best procedure since it must be resorted to finally, in any case, before a design is completed.

SECTION 9: BEAT FREQUENCY OSCILLATORS

The use of a beat-frequency (or heterodyne) oscillator is called for in the communications type of receiver; for example when receiving Morse signals from a c.w. transmitter. The principles involved are fully explained in the usual text books (see Ref. 10, page 446 and Ref. 25, pages 63, 67-70). The output from the local beat oscillator is injected at a suitable point in the i-f amplifier, and when the resultant voltage is applied to the detector circuit together with the received carrier voltage, one of the currents at the detector output has a frequency which is equal to the difference between the frequency of the two applied voltages; this difference frequency is the one heard in the receiver output.

The amplitude of the local oscillator voltage introduced into the i-f amplifier should be sufficiently large so that it is always considerably greater than the voltage, at the same point, due to the strongest signal likely to be received. If this condition is not observed there will be appreciable loss in signal-to-noise ratio, and so one of the main advantages of this method of reception will be lost. Because the amplitude of the oscillator voltage should be large, very careful screening is necessary if spurious frequency responses are to be avoided, or at least be reduced to negligible proportions.

If locking between the local beat-oscillator and a very strong signal is to be avoided, very loose coupling into the i-f amplifier is called for. This often suggests an oscillator which can be electron-coupled to the load. The circuit of Fig. 24.7 is a particularly useful one for this application, and only requires a single winding for the tuning coil.

However, almost any oscillator circuit is suitable. Variation of the beat-frequency is best accomplished by variation of the beat-oscillator tuning (say a range of ± 3 Kc/s) since it should be clear that the best conditions for reception normally occur when the receiver is tuned exactly to the required carrier frequency.

The a.v.c. should not be operated by the beat oscillator as this would cause a serious loss in receiver sensitivity. For this reason a.v.c. is often disconnected when heterodyne reception of this type is being carried out.

Some receivers have the beat-oscillator voltage injected directly into the diode circuit, but it does not necessarily follow that this is the most suitable point. At the detector the incoming carrier voltage has its largest amplitude, and so the beat oscillator voltage also has to be correspondingly high. A simple solution which is helpful in some cases is to inject the oscillator output voltage into the grid circuit of the last i-f amplifier valve, which can be operated with fixed bias to provide constant gain.

Harmonic operation of the beat oscillator is sometimes helpful in obtaining improved stability and in reducing undesired interference effects.

Considerations as to stability of operation are of prime importance, and the factors previously discussed should be kept in mind when designing this circuit.

Useful data on beat oscillator circuits are given in Ref. 8 (page 128), and also in Refs. 26 and 27.

SECTION 1 : THE OPERATION OF FREQUENCY CONVERTERS AND MIXERS

(i) *Introduction* (ii) *General analysis of operation common to all types* (iii) *The oscillator section of converter tubes* (iv) *The detailed operation of the modulator or mixer section of the converter stage* (v) *Conclusion* (vi) *Appendix.*

Reprinted by special permission from the article by E. W. Herold entitled "The operation of frequency converters and mixers for superheterodyne reception" in the Proceedings of the I.R.E. Vol. 30 No. 2 (February 1942) page 84.

(i) Introduction

The better modern radio receivers are almost universally designed to use the superheterodyne circuit. In such a circuit, the received signal frequency is heterodyned with the frequency of a local oscillator to produce a difference frequency known as the intermediate frequency. The resultant signal is amplified by a selective, fixed-tuned amplifier before detection. Since the heterodyne action is usually accomplished by means of a suitable vacuum tube, it is the purpose of this paper to discuss the chief similarities and differences among the tubes which might be used, as well as to explain their behaviour.

The combination of signal and local-oscillator frequencies to produce an intermediate frequency is a process of modulation in which one of the applied frequencies causes the amplitude of the other to vary. Although this process was originally called heterodyne detection and, later, first detection, it is now called frequency conversion. The portion of the radio receiver which produces conversion may, therefore, be identified as the converter. If conversion is accomplished in a single vacuum tube which combines the functions of oscillator and modulator, this tube may logically be termed a converter tube. When separate tubes are used for the oscillator and the modulator portions of the converter, respectively, the tube for the latter purpose is conveniently called a modulator or mixer tube. This terminology will be used in this paper.

Although in some of the earliest superheterodynes, frequency conversion was accomplished by a triode oscillator and triode modulator (Ref. 1) other circuits used a single triode which served as both modulator and oscillator (Ref. 2). A triode used in the latter way could, therefore, be called a converter tube. The introduction of two-grid tubes (i.e. tetrodes) permitted a wide variety of modulator and converter arrangements which frequently gave superior performance to that possible with triodes (Ref. 3-7).

When indirectly heated cathodes became more common, conversion circuits in which the oscillator voltage was injected in the cathode circuit were used. These

circuits reduced considerably the interaction between oscillator and signal circuits which would otherwise be present. (Ref. 8). When tetrodes and pentodes became available, the use of the triode was dropped except as the local oscillator. It was not long, however, before the desirability of more complete separation of oscillator and signal circuits became evident. Multigrid converter tubes were, therefore, devised to permit this separation in a satisfactory manner, at least for the frequencies then in common use. (Refs. 9-14). In some of these it was also possible to control the conversion gain by an automatic-volume-control voltage, a decided advantage. The most satisfactory of the earlier multigrid tubes was known as the pentagrid converter, a type still widely used. A similar tube having an additional suppressor grid is used in Europe and is known as the octode.

When it became desirable to add high-frequency bands to superheterodyne receivers which also had to cover the low broadcast frequencies, the converter problem became more difficult. The highest practicable intermediate frequency appeared to be about 450 to 460 kilocycles, a value which was only about 2 per cent of the highest frequency to be received. Its use meant that the oscillator frequency was separated from the signal frequency by only 2 per cent and the signal circuit, therefore, offered appreciable impedance at the oscillator frequency. A phenomenon known as "space-charge coupling," found in the pentagrid converter, indicated that signal and oscillator circuits were not separated as completely as would be desirable. (Ref. 15). In addition, the permissible frequency variations of the oscillator had to be held to less than the intermediate-frequency bandwidth, namely, 5 to 10 kilocycles; at the highest frequency to be received, the oscillator frequency was required therefore to remain stable within 0.05 per cent. In the pentagrid converter, the most serious change in oscillator frequency occurred when the automatic-volume-control voltage was changed, and was sometimes as much as 50 kilocycles. Economic considerations have led to the use of at least a three-to-one frequency coverage for each band in the receiver. With capacitance tuning, the circuit impedance is very low at the low-frequency end of the high-frequency band so that failure to oscillate was occasionally observed in the pentagrid converter.

In Europe, where converter problems were similar, a tube known as the triode-hexode (Ref. 16) was developed to overcome some of the disadvantages of the pentagrid converter. In the pentagrid tube, the oscillator voltage is generated by, and therefore applied to, the electrodes of the assembly closest to the cathode (i.e., the *inner* electrodes). In the European form of triode-hexode, the oscillator voltage is generated by a separate small triode section mounted on a cathode common to a hexode-modulator section. The triode grid is connected internally to the third grid of the hexode section. In this way, by the application of the oscillator voltage to an *outer* grid and the signal to the inner grid of the modulator, space-charge coupling was greatly reduced and automatic-volume-control voltage could be applied to the modulator section of the tube without seriously changing the oscillator frequency. In some European types, a suppressor grid has been added so that such tubes should be called triode-heptodes.

The first American commercial development to provide improved performance over that of the pentagrid converter also utilized oscillator voltage injection on an outer grid but required a separate tube for oscillator (Ref. 17). This development, therefore, resulted in a modulator or mixer tube rather than a converter. There were many advantages accompanying the use of separate oscillator tube so that such a solution of the problem appeared to be reasonably satisfactory.

The demand arose shortly, however, for a one-tube converter system with better performance than the original pentagrid type for use in the standard all-wave receiver. A tube, the 6K8, in which one side of a rectangular cathode was used for the oscillator and the other side was used for the mixer section, was developed and made available. (Ref. 18). This tube used inner-grid oscillator injection, as with the pentagrid converter, but had greatly improved oscillator stability. Another solution, also introduced in the United States, was a triode-heptode which is an adaptation of the European triode-hexode. This type used outer-grid injection of the oscillator voltage

generated by a small auxiliary triode oscillator section. A recent converter (the SA7 type) for broadcast use is designed to operate with oscillator voltage on both cathode and first-grid electrodes. (Ref. 19). This tube, in addition to having excellent performance, requires one less connecting terminal than previous converter tubes.

This paper will present an integrated picture of the operation of converter and modulator tubes. It will be shown that the general principles of modulating or mixing by placing the signal on one grid and the oscillator voltage on another, or by placing both voltages on the same grid, are the same for all types of tubes. The differences in performance among the various types particularly at high frequencies are due to a number of important secondary effects. In this paper, some of the effects such as signal-grid current at high frequencies, input impedance, space-charge coupling, feedback through interelectrode capacitances, and oscillator-frequency shift will be discussed.

(ii) General analysis of operation common to all types

A. Conversion transconductance of modulator or mixer tubes

The basic characteristic of the converter stage is its conversion transconductance, i.e., the quotient of the intermediate-frequency output current to the signal input voltage. The conversion transconductance is easily obtained by considering the modulation of the local-oscillator frequency by the signal in the tube and, as shown in another paper (Ref. 17) is determined by the transconductance of the signal electrode to the output electrode. The general analysis of a modulator, or mixer tube, is applicable to all mixers no matter how or on what electrodes the oscillator and signal voltages are introduced.

Under the assumption that the signal voltage is very small and the local oscillator voltage large, the signal-electrode transconductance may be considered as a function of the oscillator voltage only. The signal-electrode-to-plate transconductance g_m may, therefore, be considered as periodically varying at the oscillator frequency. Such a periodic variation may be written as a Fourier series

$$g_m = a_0 + a_1 \cos \omega_0 t + a_2 \cos 2\omega_0 t + \dots$$

where ω_0 is the angular frequency of the local oscillator. Use of the cosine series implies that the transconductance is a single-valued function of the oscillator electrode voltage which varies as $\cos \omega_0 t$. When a small signal, $e_s \sin \omega_s t$, is applied to the tube, the resulting alternating plate current to the first order in e_s may be written

$$\begin{aligned} i_p &= g_m e_s \sin \omega_s t \\ &= a_0 e_s \sin \omega_s t + e_s \sum_{n=1}^{\infty} a_n \sin \omega_s t \cos n\omega_0 t \\ &= a_0 e_s \sin \omega_s t + \frac{1}{2} e_s \sum_{n=1}^{\infty} a_n \sin (\omega_s + n\omega_0)t \\ &\quad + \frac{1}{2} e_s \sum_{n=1}^{\infty} a_n \sin (\omega_s - n\omega_0)t. \end{aligned}$$

If a circuit tuned to the frequency $(\omega_s - n\omega_0)$ is inserted in the plate, the modulator tube converts the incoming signal frequency ω_s to a useful output at an angular frequency $(\omega_s - n\omega_0)$ which is called the intermediate frequency. Since n is an integer, it is evident that the intermediate frequency, in general, may be chosen to be the difference between the signal frequency and any integral multiple of the local-oscillator frequency; this is true even though a pure sine-wave local oscillation is applied to the tube. The harmonics of the local-oscillator frequency need only be present in the time variation of the signal-electrode transconductance. The ordinary conversion transconductance is simply a special case when $n = 1$. The conversion transconductance at the n th harmonic of the local oscillator is given by

$$g_{cn} = \frac{i(\omega_s - n\omega_0)}{e_s} = \frac{a_n}{2}.$$

Substituting the value of the Fourier coefficient a_n it is found that

$$g_{cn} = \frac{1}{2\pi} \int_0^{2\pi} g_m \cos n\omega_0 t d(\omega_0 t).$$

When n is set equal to unity, this expression becomes identical with the one previously derived. (Ref. 17).

Thus, the conversion transconductance is obtained by a simple Fourier analysis of the signal-electrode-to-output-electrode transconductance as a function of time.

Fig. 25.1. Signal - electrode transconductance versus oscillator-electrode voltage for a typical mixer tube. The applied oscillator voltage is shown at A and B is the resulting time variation of transconductance.

FIG. 25.1

Such an analysis is readily made from the tube characteristics directly by examination of the curve of signal-electrode transconductance versus oscillator-electrode voltage. The calculation of the conversion transconductance at the n th harmonic of the oscillator is made from this curve by assuming an applied oscillator voltage and making a Fourier analysis of the resulting curve of transconductance versus time for its n th harmonic component. The analysis is exactly similar to the one made of power output tubes, except that, in the latter case, the plate-current-versus-control-electrode-voltage curve is used. Fig. 25.1 shows a curve of signal-grid transconductance versus oscillator-electrode voltage for a typical modulator or mixer tube. In the usual case, the oscillator voltage is applied from a tuned circuit and so is closely sinusoidal in shape as at A in the figure. The resulting curve of transconductance versus time is shown at B. Any of the usual Fourier analysis methods may be used to determine the desired component of curve B. Half of this value is the conversion transconductance at the harmonic considered. Convenient formulas of sufficient accuracy for many purposes follow. Referring to Fig. 25.2a, a sine-wave oscillator voltage is assumed and a seven-point analysis is made (i.e., 30-degree intervals). The conversion transconductances g_{cn} are

$$g_{c1} = \frac{1}{12}[(g_7 - g_1) + (g_5 - g_3) + 1.73(g_6 - g_2)]$$

$$g_{c2} = \frac{1}{12}[2g_4 + \frac{1}{2}(g_3 + g_5 - g_6 - g_2) - (g_7 + g_1)]$$

$$g_{c3} = \frac{1}{12}[(g_7 - g_1) - 2(g_5 - g_3)].$$

The values g_1, g_2 , etc., are chosen from the transconductance characteristic as indicated in Fig. 25.2a. The values computed from the above formulas are, of course, most accurate for g_{c1} and of less accuracy for g_{c2} while a value computed from the formula for g_{c3} is a very rough approximation.

Simple inspection of the formula for g_{c1} , the conversion transconductance used for conversion at the fundamental, is somewhat instructive. It is evident that highest conversion transconductance, barring negative values, as given by this formula, occurs when g_1 , g_2 and g_3 are all equal to zero, and g_5 , g_6 , and g_7 are high. These requirements mean that sufficient oscillator voltage should be applied at the proper point to cut off the transconductance over slightly less than the cycle as pictured in Fig. 25.2b. For small oscillator voltages optimum operation requires the differences $(g_7 - g_1)$, $(g_5 - g_3)$ and $(g_6 - g_2)$ to be as large as possible; this is equivalent to operation at the point of maximum slope. It should be noted that the minimum peak oscillator voltage required for good operation is approximately equal to one half the difference between the oscillator-electrode voltage needed for maximum signal-grid transconductance and that needed to cut off this transconductance. Thus, inspection of the curve of transconductance versus oscillator-electrode voltage gives both a measure of the fundamental conversion transconductance which will be obtained and the amount of oscillator excitation required. Conversion at a harmonic, in general, requires considerably greater oscillator excitation for maximum conversion transconductance.

In practical cases using grid-controlled tubes of the usual kind, the maximum fundamental conversion transconductance which a given tube will give can quickly be determined within 10 per cent or so by simply taking 28 per cent of the maximum signal-grid-to-plate transconductance which can be attained. For conversion at second harmonic, optimum oscillator excitation gives a conversion transconductance of half this value, while for third-harmonic conversion the value is divided by three.

Although the same characteristic of all modulator or mixer tubes is used to determine the conversion transconductance, the shape of this characteristic varies between different types of mixers. This variation will be more clearly brought out in the later sections of the paper.

B. Conversion transconductance of converter tubes

In converter tubes with oscillator sections of the usual kind, the oscillator voltage is usually present on more than one electrode. Furthermore, the phase of the oscillator-control-grid voltage is opposite to that of the oscillator-anode alternating voltage, so that the two would be expected partially to demodulate each other. The transconductance curve which should be used in this case is the one in which the oscillator electrode voltages are simultaneously varied in opposite directions.

Fortunately, with most of the commonly used converter tubes such as the pentagrid, octode, triode-hexode, etc., the effect of small variations of oscillator-anode voltage

FIG. 25.2

Fig. 25.2a. Points used for 30-degree analysis of conversion transconductance. Fig. 25.2b. Oscillator amplitude and bias adjusted for high conversion transconductance at oscillator fundamental, i.e., $g_1 = g_2 = g_3 = 0$.

on the electrode currents is so small that usually it may be neglected. Thus, the conversion transconductance of these converter tubes may be found exactly as if the tube were a modulator or mixer, only.

With the circuit of Fig. 25.3 (Refs. 19-21) a Hartley oscillator arrangement is used and oscillator-frequency voltage is present on the cathode. The effect of such a voltage is also to demodulate the electron stream through the action of the alternating cathode potential on the screen-to-cathode and signal-grid-to-cathode voltages. When a relatively high-transconductance signal grid is present, as in the figure, this demodulation is considerably greater than in the normal cathode-at-ground circuit.

Fig. 25.3. Converter circuit with oscillator voltage on both grid No. 1 and cathode.

of signal-grid transconductance, it is often sufficiently accurate to disregard the alternating-current variation of cathode potential and simply shift the signal-grid in the negative direction by the peak value of the alternating cathode voltage. If the resulting signal-grid-transconductance-versus-oscillator-grid-voltage curve is used for an analysis of conversion transconductance, the data obtained will not be far different from the actual values obtained in the circuit of Fig. 25.3 where normal (unshifted) signal-grid bias values are used.

In order to determine the conversion transconductance of a tube to be used in this circuit, a signal-grid transconductance curve is needed. Such a curve, however, must be taken with cathode and oscillator-grid potential varied simultaneously and in their correct ratio as determined by the ratio of cathode turns to total turns of the coil which is to be used. However, because the conversion transconductance is approximately proportional to the peak value

C. Fluctuation noise

The fluctuation noise of a converter stage is frequently of considerable importance in determining the over-all noise. The magnitude of the fluctuation noise in the output of a converter or mixer tube may be found either by direct measurement using a known substitution noise source such as a saturated diode or by making use of the noise of the same tube used as an amplifier and finding the average mean-squared noise over an oscillator cycle. (Refs. 22, 23). Since these methods give values which are substantially in accord, and since the noise of many of the usual tube types under amplifier conditions is readily derived from theory (Ref. 24), the latter procedure is convenient. Thus, if $\overline{i_{pn}^2}$ is the mean-squared noise current in the output of the converter or mixer tube considered as an amplifier (i.e. steady direct voltages applied) the mean-squared intermediate-frequency noise is

$$\overline{i_{i-f}^2} = \frac{1}{2\pi} \int_0^{2\pi} \overline{i_{pn}^2} d(\omega t)$$

or the average of $\overline{i_{pn}^2}$ over an oscillator cycle. The values of $\overline{i_{pn}^2}$ obtained from theory require a knowledge of the currents and transconductance of the tube and are usually proportional to these quantities. Thus, the converter-stage output noise, which is the average of $\overline{i_{pn}^2}$ over the oscillator cycle, is usually proportional to the average electrode currents and average transconductance when the oscillator is applied. Specific examples will be given in following sections of this paper treating typical modes of converter operation.

Tube noise is conveniently treated by use of an equivalent grid-noise-resistance concept whereby the tube noise is referred to the signal grid. The equivalent noise resistance of a converter or mixer tube is

$$R_{eq} = \frac{\overline{i_{i-f}^2}}{(4kT_R \Delta f) g_{cn}^2}$$

where $k = 1.37 \times 10^{-23}$, T_R is room temperature in degrees Kelvin, and Δf is the effective over-all bandwidth for noise purposes. Since Δf is invariably associated with $\overline{i_{i-n}^2}$, the bandwidth cancels in the determination of R_{eq} which is one of the advantages of the equivalent-resistance concept. For $T_R = 20$ degrees centigrade,

$$R_{eq} = 0.625 \times 10^{20} \frac{1}{g_{cn}^2} \frac{\overline{i_{i-n}^2}}{\Delta f}.$$

A summary of values of R_{eq} for common types of converter will be found in a preceding paper. (Ref 23).

The equivalent noise resistance R_{eq} alone does not tell the entire story as regards signal-to-noise ratio, particularly at high frequencies. For example, if the converter stage is the first stage of a receiver, and bandwidth is not a consideration, the signal energy which must be supplied by the antenna to drive it will be inversely proportional to the converter-stage input resistance. On the other hand, the noise energy of the converter or mixer tube is proportional to its equivalent noise resistance. The signal-to-noise ratio therefore, will vary with the ratio of input resistance to equivalent noise resistance, and this quantity should be as high as possible. When bandwidth is important, the input resistance should be replaced by the reciprocal of the input capacitance if it is desired to compare various converter systems for signal-to-noise ratio.

(iii) The oscillator section of converter tubes

The oscillator section of converters is often required to maintain oscillation over frequency ranges greater than three to one for circuits using capacitance tuning. Although this requirement is easily met at the lower broadcast frequencies, the effect of lower circuit impedances, transit-time phenomena in the tube, and high lead reactances combine to make the short-wave band a difficult oscillator problem. Ability to oscillate has, in the past, been measured by the oscillator transconductance at normal oscillator-anode voltage and zero bias on the oscillator grid. Recent data have shown that, in the case of pentagrid and some octode converters, an additional factor which must be considered is the phase shift of oscillator transconductance (i.e. transadmittance) due to transit-time effects*. (Ref. 26).

The ability of a converter to operate satisfactorily at high frequencies depends largely on the undesirable oscillator frequency variations produced when electrode voltages are altered. The frequency changes are mainly caused by the dependence on electrode voltages of oscillator-electrode capacitances, oscillator transconductance, and transit-time effects. There are many other causes of somewhat lesser importance. Because of the complex nature of the problem no satisfactory quantitative analysis is possible. In the case of the pentagrid and the earlier forms of octode converters there are indications that the larger part of the observed frequency shift is due to a transit-time effect. It is found that the phase of the oscillator trans-admittance and, therefore, the magnitude of the susceptive part of this transadmittance varies markedly with screen and signal-grid-bias voltages. Since the susceptive part of the transadmittance contributes to the total susceptance, the oscillation frequency is directly affected by any changes.

(iv) The detailed operation of the modulator or mixer section of the converter stage

This section will be devoted to a consideration of the modulator or mixer portion of the converter stage. This portion may be either a separate mixer tube or the modulator portion of a converter tube. Since with most of the widely used converter tubes in the more conventional circuits the alternating oscillator-anode voltage has a negligible effect on the operation of the modulator portion, only the effect of oscillator control grid need be considered. Thus the analysis of the operation of most converter tubes is substantially the same as the analysis of the same tubes used as a mixer or modulator only, just as in the treatment of conversion transconductance.

*M. J. O. Strutt (see Ref. 26) has published data on this phase shift in octodes. It was measured to be as high as 60 degrees at 33 megacycles.

There are three methods of operation of mixer or modulator tubes. The oscillator voltage may be put on the same grid as the signal voltage, it may be put on the inner grid (the signal applied to an outer grid), or it may be impressed on an outer grid (with the signal on the inner grid). Each of these modes of operation has characteristics which depend on the mode rather than on the tube used in it. Tubes which may be used in any one mode differ from one another mainly in the degree in which they affect these characteristics. The treatment to follow, therefore, will not necessarily deal with specific tube types: instead, the phenomenon encountered will be illustrated by the use of data taken on one or more typical tubes for each of the modes of operation.

A. Tubes with oscillator and signal voltages applied to same grid

Typical tubes used for this type of operation are triodes and pentodes. The oscillator voltage may be introduced in series with the signal voltage, coupled to the signal input circuit inductively, capacitively, and/or conductively, or it may be coupled into the cathode circuit. In all but the last case, by operating below the grid-current point, the oscillator circuit is not loaded directly by the mixer tube. When cathode injection is used, however, an effective load equal to the mean cathode conductance (slightly greater than the mean transconductance) is imposed on the oscillator circuit. The cathode injection circuit has the advantage that oscillator-frequency voltage between the signal input circuit and ground is minimized, thus reducing radiation when the converter stage is also the first stage of the receiver.

A typical transconductance-versus-bias curve for a variable- μ radio-frequency pentode is shown in Fig. 25.4. The use of the Fourier analysis for conversion transconductance at oscillator fundamental indicates that a value of approximately a quarter of the peak transconductance can be attained. Because of the tailing off of the lower end of the curve, highest conversion transconductance requires a large oscillator swing. Very nearly the maximum value is obtained, however, at an operating bias shown by the dotted line, with an oscillator peak amplitude approximately equal to the bias. With lower oscillator amplitudes, and the same fixed bias, the fundamental conversion transconductance drops in approximate proportion to the oscillator amplitude.

FIG. 25.4
Fig. 25.4. Transconductance characteristic of a typical variable- μ , radio-frequency pentode.

Strictly speaking, when the cathode injection type of operation is used the effect of the oscillator voltage which is impressed between screen and cathode, and plate and cathode should be considered. Practically, however, there is little difference over the simpler circuit in which the oscillator voltage is impressed on the signal grid only. It is for this reason that the cathode-injection circuit is placed in the same category as those in which the oscillator voltage is actually impressed on the same electrode as the signal.

In a practical circuit the effective oscillator voltage is, of course, the oscillator voltage actually existent between grid and cathode of the tube. When the oscillator voltage is impressed in series with the signal circuit or on the cathode, this effective voltage is different from the applied oscillator voltage by the drop across the signal circuit. In the usual case, with the oscillator frequency higher than the signal frequency, the signal circuit appears capacitive at oscillator frequency. This capacitance and the grid-to-cathode capacitance, being in series, form a capacitance divider and reduce the effective oscillator voltage. The reduction would not be a serious matter if it remained a constant quantity; but in receivers which must be tuned over an appreciable frequency range this is not the case. The result is a variation in conversion gain over the band. A number of neutralizing circuits have been described in the

patent literature which are designed to reduce the oscillator-frequency voltage across the signal circuit and thus minimize the variations. (Refs. 27, 28).

Coupling of the oscillator voltage into, or across, the signal circuit is also accompanied by changes in effective oscillator voltage when the tuning is varied. These changes are not so great with pure inductive coupling as with pure capacitance coupling. In many practical cases, both couplings are present.

A method of reducing the variation of conversion gain with effective oscillator voltage in tubes in which oscillator voltage and signal are placed on the same grid, employs automatic bias. Automatic bias may be obtained either by a cathode self-bias resistor (by-passed to radio frequency) or by a high-resistance grid leak, or both. An illustration of the improvement which may be obtained in this way is shown in Fig. 25.5. Three curves of conversion transconductance, at oscillator fundamental, against effective peak oscillator volts are shown for the typical variable- μ pentode of Fig. 25.4 used as a mixer. For the curve *a*, a fixed bias was used at approximately an optimum point. The curve is stopped at the grid-current point because operation beyond this point is not practicable in a receiver. Curve *b* shows the same tube operated with a cathode self-bias resistor. This curve is also stopped at the grid-current point. Curve *c* shows operation with a high-resistance grid leak. It is evident that, above an oscillator voltage of about 3, curve *b* is somewhat flatter, and *c* is considerably flatter than the fixed-bias curve *a*. The high-resistance grid leak used for *c* may be made a part of the automatic-volume-control filter but care must be taken that its value is considerably higher than the resistance in the automatic-volume-control circuit which is common to other tubes in the receiver. If this is not done, all the tubes will be biased down with large oscillator swings. When a high-resistance leak is used, the automatic-volume-control action does not begin in the mixer tube until the automatic-volume-control bias has exceeded the peak oscillator voltage. Because of the high resistance of the leak, the signal circuit is not loaded appreciably by the mixer tube. In a practical case, precautions must be taken that a pentode in the converter stage is not operated at excessive currents when accidental failure of the oscillator reduces the bias. A series dropping resistor in the screen-grid supply will prevent such overload. When a series screen resistor is used, the curve of conversion transconductance versus oscillator voltage is even flatter than the best of the curves shown in Fig. 25.5. Series screen operation, therefore, is highly desirable (Ref. 23).

One of the effects of feedback through interelectrode capacitance in vacuum tubes is a severe loading of the input circuit when an inductance is present in the cathode circuit. Thus, in mixers using cathode injection, the signal circuit is frequently heavily damped since the oscillator circuit is inductive at signal frequency in the usual case. The feedback occurs through the grid-to-cathode capacitance and can be neutralized to some extent by a split cathode coil with a neutralizing capacitance. (Ref. 28). Such neutralization also minimizes the voltage drop of oscillator frequency across the signal circuit.

Loading of the signal circuit by feedback from the plate circuit of modulators or mixers may also be serious when the signal-grid-to-plate capacitance is appreciable. This is especially true when a low capacitance intermediate-frequency circuit, which presents a comparatively high capacitive reactance at signal frequency, is used, as in wide-band intermediate-frequency circuits. The grid-plate capacitance of radio-frequency pentodes is usually small enough so that the effect is negligible in these tubes. In triodes, however, feedback from the intermediate-frequency circuit may be serious and the grid-plate capacitance should be minimized in tube and circuit design. Although neutralization is a possible solution to the plate feedback, a more promising solution is the use of a specially designed intermediate-frequency circuit which offers a low impedance at signal frequency by the equivalent of series tuning and yet causes little or no sacrifice in intermediate-frequency performance.

At high frequencies, the converter stage exhibits phenomena not usually observable at low frequencies. One group of phenomena is caused not by the high operating frequency, per se, but rather by a high ratio of operating frequency to intermediate

Fig. 25.5. Conversion transconductance of a typical variable- μ , radio-frequency pentode. Oscillator and signal voltages both applied to grid No. 1. *a*, fixed-bias operation; *b*, cathode resistor used to obtain bias; *c*, bias obtained by means of a high-resistance grid leak. Fig. 25.6. Input conductance of a typical variable- μ , radio-frequency pentode, at 60 megacycles.

frequency (i.e., a small separation between signal and oscillator frequencies). Among these phenomena may be listed pull-in and inter-locking between oscillator and signal circuits and poor image response. In mixers in which oscillator and signal are impressed on the same grid, the first of these effects is usually pronounced because of the close coupling between the oscillator and signal circuits. It can be reduced by special coupling from the local oscillator at an increase in the complexity of the circuit.

Other phenomena, which are due to the high operating frequency, occur in mixers irrespective of the intermediate-frequency. The most important of these are those caused by transit-time effects in the tube and by finite inductances and mutual inductances in the leads to the tube. When the oscillator and signal are impressed on the grid of a mixer, the effects are not dissimilar to those in the same tube used as an amplifier. So far as the signal is concerned, the operation is similar to that of an amplifier whose plate current and transconductance are periodically varied at another frequency (that of the oscillator). The effects at signal frequency must, therefore, be integrated or averaged over the oscillator cycle. The input conductance at 60 megacycles of the typical radio-frequency pentode used for Figs. 25.4 and Fig. 25.5 as a function of control-grid bias is shown in Fig. 25.6. The integrated or net loading as a function of oscillator amplitude, when the tube is used as a mixer at this frequency, is given in Fig. 25.7, both with fixed-bias operation and with the bias

Fig. 25.7. Input conductance of a typical pentode when used as a mixer at 60 megacycles, *a*, fixed-bias operation; *c*, bias obtained by means of a high-resistance grid leak.

obtained by a grid leak and condenser. The conductance for all other frequencies may be calculated by remembering that the input conductance increases with the square of the frequency. The data given do not hold for cathode injection because of the loading added by feedback, as previously discussed.

When automatic volume control is used on the modulator tube, an important effect in some circuits is the change in input capacitance and input loading with bias. This is especially true when low-capacitance circuits are in use, as with a wide-band amplifier. With tubes having oscillator and signal voltages on the same grid, because of the integrating action of the oscillator voltage, the changes are not so pronounced as with the same tube used as amplifier. A small, unbypassed cathode resistor may be used with an amplifier tube (Refs. 29, 30) to reduce the variations; it should give a similar improvement with the modulator.

The question of tube noise (i.e., shot-effect fluctuations) is important in a mixer, or modulator, especially when this tube is the first tube in a receiver. There is little doubt that triode or pentode mixers, in which signal and oscillator voltages are impressed on the control grid, give the highest signal-to-noise ratio of any of the commonly used types of mixers. The reason for this has been made clear by recent studies of tube noise. (Ref. 24). It is now well established that tube noise is the combined result of shot noise in the cathode current which is damped by space charge to a low value and additional fluctuations in the plate current caused by random variations in primary current distribution between the various positive electrodes. Thus, in general, tubes with the smallest current to positive electrodes other than the plate have the lowest noise. It is seen that the tetrode or pentode modulator, with a primary screen current of 25 per cent or less of the total current, is inherently lower in noise than the more complex modulators in which the current to positive electrodes other than the plate usually exceeds 60 per cent of the total current. The triode, of course, has the lowest noise assuming an equivalent tube structure. The conversion transconductance of triode, tetrode, or pentode mixers is usually higher than that of multielectrode tubes using a similar cathode and first-grid structure. That this is so is again largely due to the lower value of wasted current to other electrodes.

The noise of triodes and pentodes used as mixers in the converter stage is conveniently expressed in terms of an equivalent noise resistance R_{eq} as mentioned in Sect. 1(ii)C. The noise as a mixer, of both the triode and the pentode, may be expressed in one formula based on the now well-understood amplifier noise relations. (Ref. 24). The equivalent noise resistance of the triode is obtained simply by equating the screen current to zero. An approximate formula for equivalent noise resistance of oxide-coated-cathode tubes is

$$R_{eq} \text{ (of triode and pentode mixers)} = \frac{2.2 \bar{g}_m + 20 \bar{I}_{c2}}{g_c^2} \cdot \frac{1}{1 + \alpha}$$

where \bar{g}_m is the average control-grid-to-plate transconductance (averaged over an oscillator cycle), \bar{I}_{c2} is the average screen current, g_c is the conversion transconductance, and α is the ratio of the screen current to plate current. Valuable additions to the above relation are given by formulas which enable a simple calculation of noise resistance from amplifier data found in any tube handbook. These additional relations are approximations derived from typical curve shapes and are based on the maximum peak cathode current I_0 and the maximum peak cathode transconductance g_0 . The data are given in Table 1. It has been assumed that oscillator excitation is approximately optimum. In this table, E_{c0} is the control-grid voltage needed to cut off the plate current of the tube with the plate and screen voltages applied, and α is the ratio of screen to plate current.

TABLE 1
Mixer Noise of Triodes and Pentodes
(Oscillator and Signal both Applied to Control Grid)

Operation	Approximate Oscillator Peak Volts	Average Transcon- ductance \bar{g}_m	Average Cathode Current \bar{I}_k	Conversion Transcon- ductance g_c	Equivalent Noise Resistance R_{eq}
At Oscillator Fund- amental	$0.7 E_{c0}$	$\frac{0.47}{1 + \alpha} g_0$	$0.35 I_0$	$\frac{0.28}{1 + \alpha} g_0$	$\frac{13}{g_0} + 90 \frac{I_0}{g_0^2} \alpha$
At Oscillator 2nd Harmonic	$1.5 E_{c0}$	$\frac{0.25}{1 + \alpha} g_0$	$0.20 I_0$	$\frac{0.13}{1 + \alpha} g_0$	$\frac{31}{g_0} + 220 \frac{I_0}{g_0^2} \alpha$
At Oscillator 3rd Harmonic	$4.3 E_{c0}$	$\frac{0.15}{1 + \alpha} g_0$	$0.11 I_0$	$\frac{0.09}{1 + \alpha} g_0$	$\frac{38}{g_0} + 260 \frac{I_0}{g_0^2} \alpha$

As an example of the use of the table, suppose it is desired to find the equivalent noise resistance of a particular triode operated as a converter at the oscillator second harmonic. The local oscillator can be permitted to swing the triode mixer grid to zero bias. With a plate voltage of 180 volts and zero bias, the tube data sheet shows a transconductance, $g_o = 2.6 \times 10^{-3}$ mho. Thus the equivalent noise resistance is $31/g_o$ or 12 000 ohms and the conversion transconductance at second harmonic is $0.13 g_o$, or 340 micromhos. Since, with this plate voltage the tube cuts off at about 8 volts, a peak oscillator voltage of around 12 volts will be required.

The above table may also be used to obtain a rough estimate of the input loading of pentode or triode mixers, since the high-frequency input conductance is roughly proportional to the average transconductance g_m and to the square of the frequency. Thus, if the loading at any transconductance and frequency is known, the loading as a mixer under the conditions of the table may quickly be computed.

Fig. 25.8. Signal-grid-(grid No. 4) to-plate transconductance versus oscillator-grid (grid No. 1) voltage curve of a typical mixer designed for inner-grid injection. Signal-grid bias = -3 volts.

B. Tubes with oscillator voltage on an inner grid, signal voltage on an outer grid

When the oscillator voltage is impressed on the grid nearest the cathode of a mixer or converter, the cathode current is varied at oscillator frequency. The signal grid, on the other hand, may be placed later in the electron stream to serve only to change the distribution of the current between the output anode and the other positive electrodes. When the two control grids are separated by a screen grid, the undesirable coupling between oscillator and signal circuits is reduced much below the value which otherwise would be found.

The signal-grid-to-plate transconductance of the inner-grid injection mixer is a function of the total current reaching the signal grid; this current, and hence the signal-grid transconductance, will vary at oscillator frequency so that mixing becomes possible. The signal-grid transconductance as a function of oscillator-grid potential of a typical modulator of this kind is shown in Fig. 25.8. It will be observed that this characteristic is different in shape from the corresponding curve of Fig. 25.4 for the tube with oscillator and signal voltages on the same grid. The chief point of difference is that a definite peak in transconductance is found. The plate current of the tube shows a saturation at approximately the same bias as that at which the peak in transconductance occurs, indicating the formation of a partial virtual cathode. The signal grid, over the whole of these curves, is biased negatively and so draws no current. The oscillator inner grid (No. 1 grid) however, draws current at positive values of bias. This separation of signal and oscillator grids is advantageous, inasmuch as the signal circuit is not loaded even though the oscillator amplitude is sufficient to draw grid current. In fact, in the usual circuit, the oscillator grid is self-biased with a low-resistance leak and condenser and swings sufficiently far positive to attain the peak signal-grid transconductance.

The conversion transconductance of such a tube has a maximum with an oscillator swing which exceeds the point of maximum signal-grid transconductance in the one

direction and which cuts off this transconductance over slightly less than half the cycle, in the other. Curves of conversion transconductance against peak oscillator voltage are shown in Fig. 25.9. Curve *a* is for fixed-bias operation of the oscillator grid, curve *b* is with a high-resistance (i.e. several megohms) grid leak and condenser for bias, and curve *c* is with the recommended value of grid leak (50 000 ohms) for this type of tube. It is seen that best operation is obtained with the lower resistance value of grid leak. With this value, the negative bias produced by rectification in the grid circuit is reduced enough to allow the oscillator grid to swing appreciably positive over part of the cycle. An incidental advantage to the use of the low-resistance leak when the tube is self-oscillating (i.e., a converter) is that undesirable relaxation oscillations are minimized.

Fig. 25.9. Conversion transconductance of a typical mixer designed for inner-grid injection of oscillator. Signal-grid bias = -3 volts. *a*, fixed-bias operation of oscillator grid; *b*, oscillator-grid bias obtained through high-resistance grid leak; *c*, oscillator-grid bias obtained through a 50,000-ohm grid leak.

In mixers or converters in which the oscillator voltage is present on both the cathode and the oscillator grid in the same phase (e.g. Fig. 25.3) it is usually necessary to utilize a relatively sharp cut off in the design of the oscillator grid so as to cut off the cathode current when the signal grid is positive (Ref. 19). By this means, the signal grid is prevented from drawing current. At the same time, however, the high currents needed for a high peak value of signal-grid transconductance cannot be obtained without a greater positive swing of the oscillator grid than with a more open oscillator grid structure. Thus, it is clear that it is desirable to have a negative bias on the oscillator electrode which is considerably smaller than the peak oscillator voltage. For this reason, optimum results are obtained on these tubes with very low values of oscillator grid leak (e.g. 10 000 to 20 000 ohms).

The effects of feedback through the interelectrode capacitance are small in well-designed multigrid mixers and converters of the kind covered in this section. The signal-grid-to-plate capacitance is usually small enough to play no part in the operation; even with a high L -to- C ratio in the intermediate-frequency transformer, the capacitive reactance of the intermediate-frequency circuit at signal frequency is only a very small fraction of the feedback reactance. The other interelectrode capacitance which plays some part in determining circuit performance (excluding, of course, the input and output capacitances) is the capacitance from the oscillator electrode or electrodes to the signal grid. This capacitance is a source of coupling between these two circuits. In well-designed converter or modulator tubes of the type discussed in this section, however, the coupling through the capacitance may be made small compared with another form of internal coupling known as "space-charge coupling" which will be treated later in this discussion.

Coupling between oscillator and signal circuits is of no great consequence except when an appreciable voltage of oscillator frequency is built up across the signal-grid circuit. This is not usually possible unless the signal circuit is nearly in tune with the oscillator as it is when a low ratio of intermediate frequency to signal frequency is used. The effect of oscillator-frequency voltage induced across the signal circuit depends on its phase; the effect is usually either to increase or to decrease the relative modulation of the plate current at oscillator frequency and so to change the conversion transconductance. This action is a disadvantage, particularly when the amount of induced voltage changes when the tuning is varied, as usually occurs.

In some cases, another effect is a flow of grid current to the signal grid; this may happen when the oscillator-frequency voltage across the signal-grid circuit exceeds the bias. Grid current caused by this effect can usually be distinguished from grid current due to other causes. By-passing or short-circuiting the signal-grid circuit reduces the oscillator-frequency voltage across the signal-grid circuit to zero. Any remaining grid current must, therefore, be due to other causes.

Current to a negative signal grid of a tube operated with inner-grid oscillator injection is sometimes observed at high frequencies (e.g. over 20 megacycles) even when no impedance is present in the signal-grid circuit. This current is caused by electrons whose effective initial velocity has been increased by their finite transit time in the high-frequency alternating field around the oscillator grid. These electrons are then able to strike a signal grid which is several volts negative. The magnitude of the signal-grid current is not usually as great as with tubes applying the oscillator voltage to an outer grid* although it may prevent the use of an automatic-volume-control voltage on the tube.

An investigation of coupling effects in the pentagrid converter showed that the coupling was much larger than could be explained by interelectrode capacitance. It was furthermore discovered that the apparent coupling induced a voltage on the signal circuit in opposite phase to that induced by a capacitance from oscillator to signal grid. (Ref. 15). The coupling which occurred was due to variations in space charge in front of the signal grid at oscillator frequency. A qualitative explanation for the observed behaviour is that, when the oscillator-grid voltage is increased, the electron charge density adjacent to the signal grid is increased and electrons are repelled from the signal grid. A capacitance between the oscillator grid and the signal grid would have the opposite effect. The coupling, therefore, may be said to be approximately equivalent to a negative capacitance from the oscillator grid to the signal grid. The effect is not reversible because an increase of potential on the signal grid does not increase the electron charge density around the oscillator grid. If anything, it decreases the charge density. The equivalence to a negative capacitance must be restricted to a one-way negative capacitance and, as will be shown later, is restricted also to low-frequency operation.

In general, the use of an equivalent impedance from oscillator grid to signal grid to explain the behaviour of "space-charge coupling" is somewhat artificial. A better point of view is simply that a current is induced in the signal grid which depends on the oscillator-grid voltage. Thus, a transadmittance exists between the two electrodes analogous to the transconductance of an ordinary amplifier tube. Indeed, the effect has been used for amplification in a very similar manner to the use of the transconductance of the conventional tube. (Ref. 32, 33).

It is found that the transadmittance from the oscillator to the signal electrode Y_{mo-s} is of the form

$$Y_{mo-s} = k_1 \omega^2 + j k_2 \omega.$$

At low frequencies (i.e., $k_1 \omega^2 \ll k_2 \omega$) the transadmittance is mainly a transsusceptance but, as the frequency rises, the transconductance component $k_2 \omega$ becomes of more and more importance, eventually exceeding the transsusceptance in magnitude. The early work on "space-charge coupling" indicated that the effect was opposite to that of a capacitance connected from oscillator to signal grid and could be cancelled by the connection of such a capacitance of the correct value (Refs. 15, 34). The effect of such cancellation could be only partial, however, since only the transsusceptance was balanced out by this arrangement. For complete cancellation it is also necessary to connect a conductance, the required value of which increases as the square of the frequency, between the oscillator grid and the signal grid so that the transconductance term is also balanced out. (Ref. 35, 36).

The cancellation of "space-charge coupling" may be viewed in another way. A well-known method of measuring the transadmittance of a vacuum tube is to connect an admittance from control grid to output electrode and to vary this admittance until no alternating-current output is found with a signal applied to the control grid.

*The next part of this section contains a more detailed discussion of signal-grid current in outer-grid oscillator injection tubes.

(Ref. 37). The external admittance is then equal to the transadmittance. In exactly the same way, the transadmittance which results from the space-charge coupling may be measured. As a step further, if an admittance can be found which substantially equals the transadmittance at all frequencies or over the band of frequencies to be used, this admittance may be permanently connected so as to cancel the effects of space-charge coupling. As has been previously stated, the admittance which is required is a capacitance and a conductance whose value varies as the square of the frequency. Such an admittance is given to a first approximation by the series connection of a capacitance C and a resistance R . Up to an angular frequency $\omega = 0.3/CR$ the admittance of this combination is substantially as desired. At higher values of frequency, the conductance and susceptance fail to rise rapidly enough and the cancellation is less complete. Other circuits are a better approximation to the desired admittance. For example, the connection of a small inductance, having the value $L = 1/2CR^2$, gives a good approximation up to an angular frequency $\omega = 0.6/CR$. The latter circuit is, therefore, effective to a frequency twice as high as the simple series arrangement of capacitance and resistance. Inasmuch as in some cases the value of inductance needed is only a fraction of a microhenry, the inductance may conveniently be derived from proper proportioning and configuration of the circuit leads.

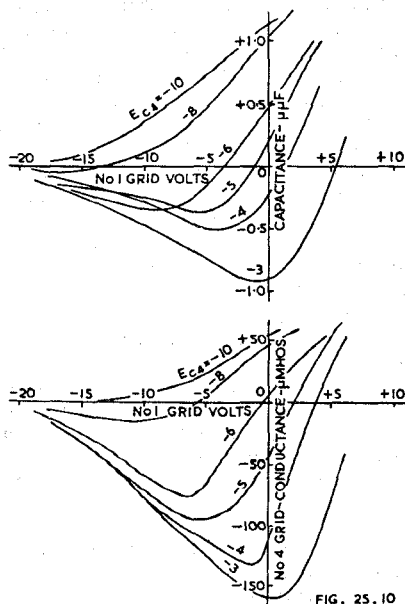

FIG. 25.10

Fig. 25.10. Signal grid (grid No. 4) admittance of a typical mixer designed for inner-grid injection of oscillator at 31.5 megacycles. Curves taken with no oscillator voltage applied. Data represents electronic admittance only (i.e. "cold" values were subtracted from measured values before plotting.)

It is of interest to note the order of magnitude of the transadmittance which is measured in the usual converter and mixer tubes. (Refs. 26, 35, 36, 38). In the formula for Y_{mo-} , given above, k_1 is in the neighborhood of 10^{-21} and k_2 is around 10^{-12} . Cancellation is effected by a capacitance of the order of one or two micro-microfarads and a series resistance of 500 to 1000 ohms.

The correct value of the cancelling admittance may be found experimentally by adjustment so that no oscillator voltage is present across the signal-grid circuit when the latter is tuned to the oscillator frequency. Another method which may be used is to observe either the mixer or converter plate current or the oscillator grid current

as the tuning of the signal is varied through the oscillator frequency. With proper adjustment of the cancelling admittance there will be no reaction of the signal-circuit tuning on either of these currents.

There are two disadvantages which accompany the cancellation of space-charge coupling as outlined. In the first place, the signal-grid input admittance is increased by the cancelling admittance. This point will be brought up again after discussing the input admittance. The second disadvantage is that the oscillator frequency shift with voltage changes in converter tubes may be somewhat increased by the use of this cancelling admittance. When separate oscillator and mixer tubes are used, the latter effect may be made less serious.

The next point to be considered is the input admittance of the signal grid. Signal-grid admittance curves of a typical modulator designed for use with the oscillator voltage impressed on the first grid are shown under direct-current conditions (i.e., as a function of oscillator-grid bias for several values of signal-grid bias) in Fig. 25.10. The admittance is separated into conductive and susceptive components, the latter being plotted in terms of equivalent capacitance. The admittance components of the "cold" tube (no electrons present) have been subtracted from the measured value so that the plotted results represent the admittance due to the presence of electrons only. The data shown were taken at 31.5 megacycles with a measuring signal which did not exceed 1.0 volt peak at any time. A modified Boonton Q meter was used to take the data. It should be noted that the presence of a marked conductive component of admittance is to be expected at frequencies as high as those used.

Fig. 25.11. Signal-grid (grid No. 4) conductance of a typical mixer designed for inner-grid injection of oscillator. Lines are drawn with slope of 2. Curve *a* taken with $E_{c1} = 0$, $E_{c4} = -3$ volts. Curve *b* taken with $E_{c1} = -6$, $E_{c4} = -6$ volts.

The most striking feature of the data of Fig. 25.10 is that both susceptive and conductive components are negative over a large portion of the characteristic. The Appendix discusses this feature in somewhat more detail. The measurements show that the susceptive component is analogous to a capacitance. The capacitance curves given are independent of frequency up to the highest frequency used (approximately 50 megacycles). The conductive component, on the other hand, increases as the square of the frequency also up to this frequency. The conductance is, therefore, negative even at very low frequencies although its magnitude is then very small. Thus, the conductance curves of Fig. 25.11 are valid for any frequency by multiplication of the conductance axis by the square of the ratio of the frequency considered, to the frequency used for the data (i.e., 31.5 megacycles). Data taken at various frequencies for two particular values of grid bias voltage E_{c1} are plotted in Fig. 25.11. The square-law relation is shown to check very closely.

Fig. 25.10 should be considered remembering that the oscillator voltage is applied along the axis of abscissas. Considering an applied oscillator voltage, the admittance

curves must be integrated over the oscillator cycle to find the admittance to the signal frequency. The operation is just as if the tube were an amplifier whose input admittance is periodically varied over the curve of Fig. 25.10 which corresponds to the signal-grid bias which is used. Curves of the modulator input conductance at 31.5 megacycles for various applied oscillator voltages are shown in Fig. 25.12. The oscillator-grid bias is obtained by means of the recommended value of grid leak for the tube (50 000 ohms). Curves are shown for two values of signal-grid bias voltage E_{s4} . As before, data for other frequencies are obtained by multiplying the conductance by the square of the frequency ratio.

The practical effect of the negative input admittance in a circuit is due to the conductive portion only, inasmuch as the total input capacitance remains positive in general*. An improved image ratio, and somewhat greater gain to the converter signal grid over other types of modulator is to be expected when this type of oscillator injection is used. At high frequencies, when a comparatively low intermediate frequency is used, it is usually desirable to cancel the space-charge coupling of the tube in the manner previously discussed. When this cancellation is made reasonably complete by the use of a condenser and resistor combination connected from the oscillator grid to the signal grid, the losses in this admittance at signal frequency are usually sufficient to wipe out the negative input admittance. The net positive input conductance however is often less than that found with other types of mixer.

The change in signal-grid input capacitance with automatic-volume-control is small in this type of modulator, particularly with the larger values of oscillator swing because of the integrating action of the oscillator voltage.

The fluctuation noise which is found in the output of inner-grid oscillator-injection mixers and converters is not readily evaluated quantitatively. The fluctuation noise is primarily due to current-distribution fluctuations but is complicated by the possibility of a virtual cathode ahead of the signal grid. Data have been taken, however, which indicate some degree of proportionality between the mean-square noise current and the plate current. The signal-to-noise ratio for this type of modulator is, therefore, approximately proportional to the ratio of conversion transconductance to the square root of the plate current. It is considerably less than for the pentode modulator with both signal and oscillator voltages on the control grid.

The noise of the converter or mixer with oscillator on an inner grid may be expressed in terms of an equivalent grid resistance as

$$R_{eq} = \frac{20\bar{I}_b}{g_c^2} F^2$$

where \bar{I}_b is the operating plate current, g_c is the conversion transconductance, and F^2 is a factor which is about 0.5 for tubes with suppressor grids and at full gain. For tubes without suppressor or for tubes whose gain is reduced by signal-grid bias, F^2 is somewhat larger and approaches unity as a maximum. With this mode of operation there is not so much value in expressions for R_{eq} based on maximum transconductance and maximum plate current because these quantities are neither available nor are they easily measured. For operation at second or third harmonics of the oscillator (assuming optimum oscillator excitation) the plate current \bar{I}_b and the conversion transconductance g_c are roughly $\frac{1}{2}$ or $\frac{1}{3}$, respectively, of their values with fundamental operation so that the equivalent noise resistance for second-harmonic and third-harmonic operation is around two and three times, respectively, of its value for fundamental operation.

C. Mixers with oscillator voltage on an outer grid, signal voltage on inner grid

With this type of mixer, the cathode current is modulated by the relatively small signal voltage which is impressed on the control grid adjacent to the cathode. The oscillator voltage, on the other hand, is impressed on a later control grid so that it

*It should not be forgotten that the data given do not include the "cold" susceptance and conductance of the tube. The latter is a relatively small quantity, however.

Fig. 25.18. Cross-sectional views of mixer designed for outer-grid-injection of oscillator. The views show only the portions of the tube inside of and including the oscillator injection grid.

they travelled in the forward direction* (Ref. 45). The progressive steps towards an improvement of this kind are illustrated in Fig. 25.18 where cross-sectional views of the portion inside the oscillator grid of various developmental modulators are shown. The drawing (a) shows the original design, data on which have been given in Figs. 25.15, 25.16 and 25.17. Drawing (b) of Fig. 25.18 shows a tube in which two side electrodes operated at a high positive potential were added. In a tube of this kind many of the electrons returned by the No. 3 grid (oscillator grid) travel paths similar to the dotted one shown; they are then collected by the auxiliary electrodes and thus do not re-enter the signal grid space. Tubes constructed similarly to (b) showed a considerable improvement in the signal-grid admittance increment due to returned electrons. Construction (c) shows the next step in which the side electrodes are increased in size and operated at somewhat lower potential. Because of the undesirability of an additional electrode and lead in the tube, the construction shown at (d) was tried. In this case the auxiliary electrodes are bent over and connected electrically and mechanically to the screen grid. Curves showing the progressive reduction in the signal-grid conductance increment due to returned electrons are shown in Fig. 25.19. The curves are labelled to correspond with the drawings of Fig. 25.18.

Fig. 25.19. Signal-grid (grid No. 1) conductance of the outer-grid-injection mixers shown in Fig. 25.18. Data taken at 31.5 megacycles with no oscillator voltage applied.

It should be noted that the use of the oscillator-grid support rods in the centre of the electron streams as shown in Fig. 25.18 (d) was found to improve the performance. No change in signal-grid conductance with oscillator-grid potential could be observed with this construction.† The conductance of the tube as a modulator, therefore, was reduced to less than half of that of construction (a). At the same time, a check of signal-grid current with a high-frequency oscillator applied to the No. 3 grid showed that this current was reduced to 1/20 of that of the original construction (a). The change in construction may be looked upon as dividing the constant A in the grid-current formula previously given, by a factor of more than 20.

*The same principles have now been applied to inner-grid-injection mixers and converters. See references 19 and 45.

†It should be mentioned that it is also possible to construct tubes in which the signal-grid conductance decreases somewhat with increasingly negative No. 3 grid bias. This effect is caused by the inductance of the inner screen-grid lead which causes a negative conductance in the input circuit when the inner screen current is high, as at negative No. 3 grid bias values. This negative conductance cancels part of the positive conductance of the signal grid.

periodically alters the current distribution between anode and screen grid. The connections of signal and oscillator voltages to this type of modulator are just the reverse, therefore, of the mixer treated in the preceding section. The behaviours of the two types are also quite different although they both include internal separation of signal and oscillator electrodes through a shielding screen grid.

FIG. 25.12

FIG. 25.13

Fig. 25.12. Signal-grid (grid No. 4) conductance of a typical mixer designed for inner-grid injection of oscillator, at 31.5 megacycles. Oscillator voltage applied. Oscillator-grid bias obtained through 50,000-ohm grid leak. Electronic portion of conductance, only, plotted.

Fig. 25.13. Signal-grid (grid No. 1) transconductance versus oscillator-grid (grid No. 3) voltage of a typical mixer designed for use with outer-grid injection of oscillator. Signal-grid bias = -3 volts.

The signal-grid transconductance curve as a function of oscillator-grid voltage of a typical mixer designed for use with the oscillator on an outer grid is shown in Fig. 25.13. It differs in shape from similar curves for the other two classes of modulator in that an approximate saturation is reached around zero bias on the oscillator grid. The conversion transconductance for such a tube is, therefore, more accurately predicted from normal amplifier transconductance. In fact, in the manufacture of this type of mixer, a test of signal-grid transconductance at somewhere near the saturation point (e.g., zero bias) on the oscillator grid has been found to correlate almost exactly with the conversion transconductance. The cut off point of the curve must remain approximately fixed, of course, since this point affects the oscillator amplitude which is necessary.

FIG. 25.14

Fig. 25.14. Conversion transconductance of a typical mixer designed for outer-grid injection of oscillator. Signal-grid bias, $E_{c1} = -3$ volts. Curve *a* corresponds to fixed No. 3 grid bias, $E_{c3} = -8$ volts. Curve *b* corresponds to bias obtained through a 50 000-ohm grid leak.

The conversion transconductance of the typical outer-grid injection mixer tube which was used for Fig. 25.13 is shown in Fig. 25.14. Curve *a* which is for fixed bias on the oscillator grid is seen to be higher than curve *b* for which bias is obtained by a 50 000-ohm grid leak and condenser. The latter connection is most widely used, however, because of its convenience. A compromise using fixed bias together with a grid leak is most satisfactory of all. (Ref. 40). When this combination is used, the curve of conversion transconductance follows curve *a* of Fig. 25.14 to the intersection with curve *b* and then follows along the flat top of curve *b*.

In a well-designed mixer with the signal voltage on the grid adjacent to the cathode and the oscillator voltage on an outer grid, effects due to feedback through the inter-electrode capacitance may usually be neglected. The only effect which might be of

importance in some cases is coupling of the oscillator to the signal circuit through the signal-grid-to-oscillator-grid capacitance. In many tubes a small amount of space-charge coupling between these grids is also present and adds to the capacitance coupling (contrary to the space-charge coupling discussed in Section B which opposes the capacitance coupling in that case). Measurements of the magnitude of the space-charge coupling for this type of modulator show that it is of the order of 1/5 to 1/10 of that present in inner-grid-injection modulators. Coupling between oscillator and signal circuits causes a voltage of oscillator frequency to be built up across the signal input circuit. This oscillator-frequency voltage, depending on its phase, aids or opposes the effect of the normal oscillator-grid alternating voltage. The action is additive when the signal circuit has capacitive reactance to the oscillator frequency, as in the usual case. When the oscillator-frequency voltage across the signal input circuit exceeds the bias, grid current is drawn to the signal grid, an undesirable occurrence. This grid current may be distinguished from signal-grid current due to other causes by short-circuiting the signal-input circuit and noting the change in grid current. With the majority of tubes, another cause of signal-grid current far exceeds this one in importance. This other cause will now be discussed.

The most prominent high-frequency effect which was observed in mixers of the kind under discussion, was a direct current to the negative signal grid even when no impedance was present in this grid circuit. This effect was investigated and found to be due to the finite time of transit of the electrons which pass through the signal grid and are repelled at the oscillator grid, returning to pass near the signal grid again. (Refs. 17, 41, 42). When the oscillator frequency is high, the oscillator-grid potential varies an appreciable amount during the time that such electrons are in the space between screen grid and oscillator grid. These electrons may, therefore, be accelerated in their return path more than they were decelerated in their forward path. Thus, they may arrive at the signal grid with an additional velocity sufficient to allow them to strike a slightly negative electrode. Some electrons may make many such trips before being collected; moreover, in each trip their velocity is increased so that they may receive a total increase in velocity equivalent to several volts. A rough estimate of the grid current to be expected from a given tube is given by the semi-empirical equation

$$I_{e1} = AI_k E_{osc} \omega \tau_{2-3} e^{BE_{c1}}.$$

Where A and B depend on electrode voltages and configuration, I_{e1} is the signal-grid current, E_{c1} is the signal-grid bias, I_k is the cathode current, E_{osc} is the impressed oscillator voltage on the oscillator grid, ω is the angular frequency of the oscillator, and τ_{2-3} is the electron transit time in the space between screen grid and oscillator grid.

Data on the signal-grid current of a typical mixer at 20 megacycles are shown in Fig. 25.15 where a semi-logarithmic plot is used to indicate the origin of the above equation.

The reduction of signal-grid current by operation at more negative signal-grid bias values is an obvious remedy. When this is done, in order to prevent a reduction in conversion transconductance, the screen voltage must be raised. A better method of reducing the undesired grid current lies in a change of tube design. It will be shown in a later part of this discussion that the constant A and/or the transit time τ_{2-3} of the above formula may be reduced considerably by proper electrode configuration.

Another high-frequency phenomenon which is particularly noticed in outer-grid-injection mixers is the high input conductance due to transit-time effects. The cause for this was first made evident when the change of signal-grid admittance with oscillator-grid potential was observed. Fig. 25.16 gives data on the susceptive and conductive components of the signal-grid admittance of this type of modulator as a function of oscillator-grid bias (no oscillator voltage applied). The data were taken at 31.5 megacycles and, as in the other input admittance curves, show the admittance components due to the presence of electrons only. It is seen that when the No. 3 grid is made sufficiently negative the input admittance is greatly increased. This

Fig. 25.20. Cross-sectional views of improved mixers designed for outer-grid injection of oscillator. The views show only the portions of the tube inside of and including the oscillator injection grid.

Another method of reducing the effect of electrons returned by the oscillator grid is to reduce the effect of electron transit time in the tube. This may be done by reducing the spacings, particularly the screen-grid-to-oscillator-grid spacing. This method of improving modulator performance has two disadvantages compared with the one discussed in connection with Fig. 25.18. The reduction in spacing is accompanied by a more sloping (i.e. less steep) signal-grid transconductance versus oscillator-grid voltage curve. This change in construction requires an increase in applied oscillator voltage to attain the same conversion transconductance. The second disadvantage is that such a method reduces the transit time and hence, the undesirable high-frequency effects only by an amount bearing some relation to the reduction in spacing. Since this reduction is limited in a given size of tube, the method whereby electron paths are changed is much more effective. The method of reducing spacing, on the other hand, is extremely simple to adopt. A combination of both methods may be most desirable from the point of view of best performance with least complexity in the tube structure.

Fig. 25.21. Signal-grid (grid No. 1) current of the outer-grid injection mixers shown in Fig. 25.20. Curve *a* corresponds to the original design (*a*) of Fig. 25.18 and is shown for comparison. Data taken with a 20-megacycle oscillator voltage of 12 volts peak amplitude applied to the oscillator-grid. $E_{c_3} = -10$ volts, $E_{c_2 \text{ and } 4} = 100$ volts, $E_b = 250$ volts.

In a mixer which must operate at high frequencies, it is not usually sufficient to eliminate the effects of returned electrons in order to assure adequate performance. For this reason the development of the principles shown in Fig. 25.18 was carried on simultaneously with a general programme of improving the tube. To this end, tubes were made with somewhat reduced spacing and with a rectangular cathode and a beam-forming signal grid (i.e., one with comparatively large supports). A number of developmental constructions are shown in Fig. 25.20. Construction (g), it will be noted, has finlike projections on the screen-grid channel members*. In construction (h) a reduction of spacing between screen and oscillator grids was combined with the channel construction. The relative performance of these constructions, so far as signal-grid current is concerned is shown in Fig. 25.21. The frequency used was 20 megacycles. The curve for the original design (taken from Fig. 25.15)

*This construction was devised by Miss Ruth J. Erichsen who was associated with the writer during part of the development work herein described.

is included and is drawn as *a*. All four of the constructions of Fig. 25.20 were satisfactory as regards signal-grid conductance; in every case the change in conductance as the oscillator grid was made negative was a negligible factor. Construction (h) required approximately 20 per cent more oscillator voltage than (e), (f), or (g) because of the reduction in slope of the transconductance versus No. 3 grid voltage curve which accompanied the reduced spacing between the screen and the No. 3 grid.

Outer-grid-injection mixers have the same or slightly greater signal-grid capacitance changes with automatic volume control as are found in amplifier tubes. In this respect they are inferior to inner-grid-injection converters or mixers. The use of a small unbypassed cathode resistance (Ref. 29, 30) is a help, however.

In closing this section, the subject of fluctuation noise will be considered. Experimental evidence indicates that the major portion of the noise in mixers with oscillator voltage on an outer grid is due to current-distribution fluctuations. (Ref. 24). The oscillator voltage changes the current distribution from plate to screen so that the mixer noise is given by the average of the distribution fluctuations over the oscillator cycle. In terms of the equivalent noise resistance the average has been found to be (Ref. 23),

$$R_{eq} = \frac{20 \left[\overline{I_b} - \frac{\overline{I_b^2}}{\overline{I_a}} \right]}{g_c^2}$$

where $\overline{I_b}$ is the average (i.e. the operating) plate current and $\overline{I_b^2}$ is the average of the square of the plate current over an oscillator cycle. $\overline{I_a}$ is the cathode current of the mixer section and is substantially constant over the oscillator cycle. This relation is not very useful in the form given. It is usually sufficiently accurate for most purposes to use an expression identical with that which applies to tubes with inner-grid oscillator injection, namely,

$$R_{eq} = \frac{20 \overline{I_b}}{g_c^2} F^2,$$

where F^2 is about 0.5 for tubes with suppressor grids and somewhat higher for others. By assuming a typical tube characteristic, the noise resistance may be expressed in terms of the cathode current $\overline{I_a}$ of the mixer section and the maximum signal-grid-to-plate transconductance g_{max} as

$$R_{eq} = 120 \frac{\overline{I_a}}{(g_{max})^2}$$

for operation at oscillator fundamental. For operation at second or third harmonic of the oscillator, the noise resistance will be approximately doubled, or tripled, respectively.

(v) Conclusion

It has been shown that the principle of frequency conversion in all types of tubes and with all methods of operation may be considered as the same (i.e. as a small-percentage amplitude modulation). The differences in other characteristics between various tubes and methods of operation are so marked, however, that each application must be considered as a separate problem. The type of tube and method of operation must be intelligently chosen to meet the most important needs of the application. In making such a choice, it is frequently of assistance to prepare a table comparing types of tubes and methods of operation on the basis of performance data. An attempt has been made to draw such a comparison in a qualitative way for general cases and for a few of the important characteristics. Table 2 is the result. It must be understood, of course, that the appraisals are largely a matter of opinion based on experience and the present state of knowledge. Furthermore, in particular circuits and with particular tubes, the relative standings may sometimes be quite different. A study of the fundamentals brought out in the previous sections of this paper should help in evaluating such exceptions.

TABLE 2
Approximate Comparative Appraisals of Methods of Frequency Conversion

Desirable Characteristic	Oscillator and Signal Voltages on No. 1 Grid		Oscillator Voltage on No. 3 Grid, Signal on No. 1 Grid		Oscillator Voltage on No. 1 Grid Signal on No. 3 Grid
	Triode	Pentode	Pentode	Hexode or Heptode	Hexode or Heptode
High conversion trans-conductance	Good	Good	Fair	Fair	Fair
High plate resistance	Poor	Good	Poor	Good	Good
High signal-to-noise ratio	Good	Good	Poor	Poor	Poor
Low oscillator-signal circuit interaction and radiation	Poor	Poor	Good	Good	Fair
Low input conductance at high frequencies	Poor ¹	Fair	Poor	Poor ²	Good
Low signal-grid current at high frequencies	Good	Good	Poor	Poor ²	Fair
Low cost of complete converter system	Good	Fair	Fair	Poor	Good

1. Due to feedback ; may be increased to Fair by proper circuit design.

2. May be increased to Fair by special constructions as described in text.

(vi) Appendix

Discussion of negative admittance of current-limited grids

In Figs. 25.10, 11 and 12 it was seen that the electronic signal-grid (i.e. input) admittance components (i.e. the admittance due to the presence of electrons) of a mixer designed for No. 1 grid injection of the oscillator are negative over a considerable portion of the normal operating range. Figs. 25.10 and 11, however, were taken with static voltages applied and so indicate that the phenomenon is not caused by an alternating oscillator voltage but is associated with the characteristics of the tube itself.

The input admittance of negative grids in vacuum tubes is the sum of three factors : (1) the "cold" admittance, or the admittance of the tube with the electron current cut off ; (2) the admittance due to feedback from other electrodes through tube and external capacitance, etc. ; and (3) the admittance due to the presence of the electrons in the tube. The first two factors have been well known for many years although certain aspects of the second have only recently received attention. (Refs. 29, 30 and 48). The third factor, however is not so well understood although the excellent work done during the last ten years has paved the way for a complete understanding of the subject. (Ref. 49). The present discussion is concerned only with this last point, namely the admittance of negative grids due to the presence of electrons in the tube.

Early work on transit-time effects in diodes and negative-grid triodes had indicated that, at very high frequencies, the conductance became negative in certain discrete bands (i.e., at large transit angles). It was not, at first, appreciated that conditions were possible with negative-grid triodes in which the input conductance could become negative even at low frequencies (i.e., at small transit angles). Data taken on the input (No. 4 grid) conductance of pentagrid converters by W. R. Ferris of this

laboratory during 1934 showed that these tubes had a negative input conductance which varied as the square of the frequency and which remained negative at low frequencies. The conductance appeared, therefore, to behave in the same way as the positive input conductance of ordinary negative-grid tubes, except for a reversal in sign. The data on the pentagrid were taken with an external oscillator voltage applied to the No. 1 grid. The work of Bakker and de Vries (Ref. 50) disclosed the possibility of a negative input conductance at small transit angles in a triode operated under current-limited conditions. They gave an experimental confirmation for a triode operated at reduced filament temperature. Data taken by the writer during 1936 on a pentagrid converter showed that the negative conductance was present in this tube even when direct voltages, only, were applied and that it was accompanied by a reduction in capacitance. A fairly complete theory of the effect was developed in unpublished work by Bernard Salzberg, formerly of this laboratory, who extended the theory of Bakker and de Vries to the more general case of multigrid tubes with negative control grids in a current-limited region. Other experimental work was done on the effect during 1936 by J. M. Miller and during the first half of 1937 by the writer. In the meantime, the papers of H. Rothe (Ref. 51), I. Runge (Refs. 52, 53), and L. C. Peterson (Ref. 54) showed that independent experimental and theoretical work had been done on the negative-admittance effect in other laboratories.

In a rough way, the negative admittance found under current-limited conditions may be explained as follows: The electron current in a tube is equal to the product of the charge density and the electron velocity. If this current is held constant, a rise in effective potential of the control electrode raises the velocity and so lowers the charge density. A reduction in charge density with increase in potential, however, results in a reduction in capacitance, provided no electrons are caught by the grid. Thus, the susceptive component of the part of the admittance due to the current through the grid, is negative. Because of the time lag due to the finite time of transit of the electrons, there is an additional component of admittance lagging the negative susceptance by 90 degrees, i.e., a negative conductance. The value of the negative conductance will be proportional to both the transit angle and to the value of the susceptance. Since both of these quantities are proportional to frequency, the negative conductance is proportional to the square of the frequency.

The general shape of the curves of Fig. 25.10 may be explained as follows: At a No. 1 grid bias of about -20 volts, the cathode current is cut off and the electronic admittance is zero. At slightly less negative values of No. 1 grid bias, the electron current is too small to build up an appreciable space charge ahead of the signal grid (No. 4 grid). The latter grid, although it exhibits some control of the plate current does not control the major portion of the current reaching it and is thus in a substantially current-limited region. Its susceptance and conductance are, therefore, negative. Higher currents increase the negative admittance until, at some value of No. 1 grid bias, the electron current is increased to the point at which a virtual cathode is formed in front of some parts of the signal grid. At these parts, the current which reaches the grid is no longer independent of this grid potential, and as a result, a positive susceptance and conductance begin to counteract the negative admittance of other portions of the grid. The admittance curves reach a minimum and for still higher currents approach and attain a positive value. The current necessary to attain the minimum admittance point is less when the signal-grid bias is made more negative so that the minima for increasingly negative No. 4 grid-bias values occur at increasingly negative No. 1 grid-bias values.

It may be noted that the signal-grid-to-plate transconductance is at a maximum in the region just to the right of the admittance minima of Fig. 25.10 (compare Fig. 25.8). The admittance of such a tube used as an amplifier remains negative, therefore, at the maximum amplification point.

SECTION 2 : CONVERTER APPLICATIONS

By E. WATKINSON, A.S.T.C., A.M.I.E. (AUST.), S.M.I.R.E. (AUST.).

(i) *Broadcast frequencies* (ii) *Short waves* (iii) *Types of converters.*

(i) Broadcast frequencies

A. Spurious responses

If a sinusoidal signal is applied to the signal grid of a converter and a sinusoidal oscillator voltage to the oscillator grid, harmonics of each signal appear in the mixer plate circuit, together with sum and difference frequencies between each of the applied voltages and their harmonics. There is a component of plate current at each of these spurious response frequencies and each could be selected by a suitably tuned circuit.

Alternatively when the plate circuit is fixed tuned to the intermediate frequency, undesired combinations of signal and oscillator harmonics can produce components of plate current at or near the intermediate frequency. These components heterodyne the desired difference frequency between signal and oscillator voltages.

The most important spurious response is at the image frequency of the desired signal, i.e. removed from the oscillator frequency by an amount equal to the intermediate frequency but on the side of the oscillator frequency remote from the desired signal. Such a signal mixes with the oscillator to produce the intermediate frequency in the same way as the desired signal, and interference from it is not dependent on the characteristics of the converter. With other responses, produced by a combination of signal and oscillator harmonics, the amount of interference is dependent on the operating conditions of the converter. Thus it is desirable to reduce the oscillator amplitude as far as possible without affecting sensitivity or low-voltage operation, with the object of decreasing the magnitude of the higher order components in the transconductance-time curve (B in Fig. 25.1) of the mixer.

Spurious responses are also possible at the harmonics of the intermediate frequency but these are due to feedback from the output of the i-f amplifier rather than to the converter.

For a discussion and chart of the various possible combinations of the signal, harmonics of the signal, the oscillator voltage and harmonics of the oscillator voltage see Ref. 78.

B. The signal-frequency circuit

1. Signal-grid loading

The reason for positive and negative loading effects produced respectively by outer-grid and inner-grid oscillator injection converters is explained in Sect. 1 of this chapter.

Converters with high capacitance between signal-grid and plate may also load the input circuit by feedback from the plate circuit, particularly at the low-frequency end of the broadcast band where the signal frequency approaches the intermediate frequency.

The input loading has resistive and reactive components, and the value of the resistive component (Ref. 78) is

$$R_p = \frac{(G_p + G_0)^2 + B_0^2}{g_m B_{gp} B_0}$$

where $G_p = 1/\tau_p$ = anode slope conductance,

G_0 = conductance of the external anode-load admittance at the signal frequency,

B_0 = susceptance of the external anode-load admittance at the signal frequency,

g_m = mutual conductance of the signal grid with oscillator operating,

and B_{gp} = susceptance of the grid-plate capacitance at the signal frequency.

Since the resonant frequency of the plate circuit is so far from the resonant frequency of the grid circuit when tuned to any point in the broadcast band, the expression can be simplified to

$$R_p = \frac{B_0}{g_m B_{gp}}$$

The grid-circuit loading is thus directly proportional to the grid-plate capacitance of the converter, and it is only in types in which this is high that input loading becomes appreciable. For example the 6A8-G has a plate to signal grid capacitance of $0.26 \mu\mu\text{F}$ and with an i-f transformer tuned by $85 \mu\mu\text{F}$ to 455 Kc/s the resistive component of the loading due to feedback across the valve is about 0.25 megohm at 600 Kc/s rising to 0.45 megohm at 1000 Kc/s and 0.55 megohm at 1400 Kc/s.

The resistive component of the loading is also proportional to the reactance of the capacitor tuning the plate circuit of the converter. This capacitor should be given as large a value as possible if grid loading is the main consideration.

The reactive component of the input loading, which is always capacitive, appears in parallel with the tuning capacitor and can usually be ignored.

Some converters have much lower plate-grid capacitance, e.g. the 6J8-G has a maximum of $0.01 \mu\mu\text{F}$, and in such cases the signal-grid circuit loading due to feedback from the plate circuit is negligible.

External coupling between oscillator and signal frequency circuits can cause another effect which may be mistaken for input circuit loading. This effect occurs in triode-hexode and similar types of converters when a tuned-plate oscillator circuit is used, the loss of gain being most noticeably at the high-frequency end of the broadcast band. In such a case, conversion sensitivity over the broadcast band is reasonably flat, but aerial (or r-f grid) sensitivity shows poor gain at the high-frequency end even although the coil, checked separately, gives constant gain over the band.

The coupling (capacitive or inductive) between the oscillator plate and the signal-grid causes an oscillator voltage to be applied to the signal grid which opposes the effects of the correctly injected oscillator voltage—see Sect. 1(iv)A of this chapter. In severe cases the coupling may even be sufficient to give an oscillator voltage on the signal grid in excess of the bias, leading to severe damping of the input circuit. Tuned-plate oscillator circuits are most likely to produce this effect because the required oscillator grid voltage is a constant whether plate tuning or grid tuning is used and with a tuned plate circuit this voltage must be developed across the smaller untuned grid winding of the oscillator coil. At the same time the oscillator plate voltage, instead of being appreciably smaller than the oscillator grid voltage as in a tuned-grid circuit, is appreciably greater.

A mechanical re-arrangement of the layout to isolate the oscillator-plate circuit from the signal-grid circuit will usually cure the trouble. In a difficult case it may be possible to arrange the wiring so that an opposite coupling between oscillator-grid and signal-grid will produce the required result.

2. Signal-circuit regeneration

It is possible to use controlled regeneration in a converter stage to give improved gain, image ratio and signal-to-noise ratio. Various possibilities are given in Ref. 65.

Fig. 25.22. Screen regeneration in converter stage.

One practical and economical circuit is shown in Fig. 25.22. V_1 is a triode-hexode and its $0.01 \mu\text{F}$ screen by-pass capacitor C_1 is returned to ground through the $0.05 \mu\text{F}$ a.v.c. by-pass capacitor C_2 . The signal-frequency voltage from the screen circuit developed across C_2 is injected into the grid circuit in the correct phase to give positive feedback at signal frequencies.

The regeneration obtained with this circuit is proportional to the reactance of C_2 and is therefore inversely proportional to frequency. An improvement of about 4 db in sensitivity and image ratio and 2 db in signal-to-noise ratio can be obtained at the low-frequency end of the broadcast band with sufficient stability margin for production purposes. The regeneration is negligible at 1400 Kc/s.

In a small $3/4$ valve receiver in which the aerial coil trimmer is connected from aerial to grid for maximum gain, sensitivity is greater at 1400 Kc/s than at 600 Kc/s, thus the circuit of Fig. 25.22 is useful in minimizing the sensitivity difference between the ends of the band.

Regeneration always has the disadvantage that variations in gain e.g. with different valves, are emphasized, but this need not be serious so long as moderate amounts of regeneration are used—sufficient for instance to give an improvement of the order outlined above. The circuit is applicable to other outer-grid injection converters, although component values may need modification.

C. Operating conditions

Recommended conditions for all types of converters are published by valve manufacturers and these are satisfactory for normal applications. However variations are often required, perhaps to use common voltage supplies for electrodes in the converter and other valves, or perhaps to obtain say maximum signal-to-noise ratio even at the expense of sensitivity.

The usual design procedure in such cases is to supply screen, oscillator plate and bias voltages by means of variable resistor boxes and to control the oscillator amplitude by means of resistors shunted across the untuned primary. In some cases, to be mentioned later, the effect of varying the primary impedance may need investigation.

The valve operating conditions are set approximately to those recommended and then each voltage in turn is adjusted for maximum performance. This may need to be done more than once as variations in, say, bias voltage will affect the required screen voltage.

In a typical case, the requirement from a converter might be maximum sensitivity and as the bias voltage is reduced the gain might rise to a maximum and then fall. This is due to an increase in conversion transconductance as the bias is reduced, followed by a decrease in plate resistance which more than offsets the increasing transconductance. However, with the bias voltage set for maximum sensitivity the screen dissipation may be excessive. A decrease in screen voltage followed by a further decrease in bias may give a similar sensitivity with satisfactory screen dissipation. It is important that the bias should not be reduced to a point at which some valves may draw grid current. The contact potential of indirectly-heated types normally does not exceed -1.0 volt and the applied bias in such cases can be safely reduced to between -1.5 to -2.0 volts provided that electrode ratings are not exceeded. In the case of battery types, the contact potential is normally zero or positive, so that it is not necessary to apply a negative bias voltage to avoid grid damping.

Increased oscillator amplitude is likely to improve sensitivity to a broad maximum followed by a slight fall. However, as spurious responses increase rapidly with oscillator drive, the amplitude should not be any greater than necessary. It is advisable to carry out checks at least at the limits of the tuning range to be covered.

To obtain maximum signal-to-noise ratio a similar procedure would be adopted but the final operating conditions would probably differ, e.g. in the case of a triode-hexode the screen voltage might be reduced. On the other hand, if the converter noise is of the same order as the signal-grid circuit noise, as is possible on the broadcast band, the effect of variations in converter conditions on the signal-to-noise ratio of the receiver would not be great.

When operating voltages have been determined, resistor boxes may still be useful for obtaining a suitable screen voltage-divider circuit if a.v.c. design is at all critical. If a minimum amount of control is required on the converter, for example to avoid a rapid increase of noise as a.v.c. is applied, a single series resistor from $B+$ will allow the screen voltage to rise in a triode-hexode type of converter and so decrease the

amount of control for a given a.v.c. voltage. Such a circuit will also minimize cross-modulation. However in converters without a suppressor grid the screen voltage must not approach the plate voltage because secondary emission from the plate will cause a large reduction in plate resistance and lead to damping of the first i-f transformer, so that some bleed from screen to ground may be needed. The best compromise can readily be determined with resistor boxes.

If maximum a.v.c. control is required from a triode-hexode converter, for example when it is followed by a reflexed amplifier, and play-through must be reduced to a minimum, a large screen bleed may be needed.

Maximum a.v.c. control can be obtained in pentagrid converters by reducing the oscillator plate voltage to a minimum consistent with satisfactory oscillator performance. For example with 20 volts bias on the signal grid, the conversion transconductance of a 6A8-G is reduced to less than one half of the original figure when the oscillator plate voltage is changed from 200 to 100 volts, although at minimum signal-grid bias the oscillator plate voltage has little effect on the conversion transconductance.

Final operating conditions should not be decided upon until the tests outlined above have been repeated with a number of valves, some of which should preferably have characteristics near the upper and lower acceptance limits for the type.

(ii) Short waves

A. Alignment

Short wave alignment of the converter stage is complicated by two factors, firstly by "pulling" of the oscillator frequency due to adjustments to the signal-grid circuit, and secondly by the fact that in many cases the range of the oscillator circuit trimmer is sufficient for it to be adjusted either to the correct response or to the image response.

1. **Pulling** : Pulling is due to coupling, either in the converter valve or externally, between the signal and oscillator circuits, and unless suitable precautions are taken it can result in faulty alignment at the high-frequency trimming point on the short-wave band. The effect is that as the signal-frequency trimmer is adjusted towards its correct setting, thus increasing the output, the oscillator is simultaneously detuned, which decreases the output when the signal is detuned from the peak of the i-f response. Thus the output rises to a maximum and then falls again, as is normal, but the maximum, instead of being the correct setting, is the point at which the detuning of the oscillator causes the gain to fall more rapidly than the increase due to the approach towards resonance of the signal-grid trimmer.

The true maximum can be found by alternately peaking the signal circuit and retuning the oscillator circuit to resonance (by means of the main tuning control on the receiver) or by carrying out the two operations simultaneously—i.e. by slowly moving the signal-grid trimmer and continually tuning through the signal, noting the amount of output on each occasion and continuing until a maximum is reached. This procedure is known as "rocking" the tuning control.

If there is a noise source available with constant output over a band of frequencies at the alignment point (e.g. valve noise in a sensitive receiver, or a noise diode) it is possible to trim the signal-frequency circuit without rocking as the wide-band signal source avoids the effects of detuning. The signal input should not be large enough to operate the a.v.c.

2. **Images** : Some of the difficulty experienced in short wave alignment at the end of the band is due to confusion between the correct response and the image. This results from the fact that the correct signal appears to differ depending on whether the signal generator is tuned or the receiver is tuned. For example, if a receiver with a 450 Kc/s intermediate frequency and with its oscillator on the high-frequency side of the signal frequency is correctly tuned to an 18 Mc/s signal the receiver oscillator is set to 18.45 Mc/s. The generator can then be tuned to a frequency 450 Kc/s **higher** than the oscillator i.e. 18.9 Mc/s and the image response will be found, or alternatively with the generator still set to 18 Mc/s the receiver can be tuned to the **lower** frequency of 17.1 Mc/s when the local oscillator will be at 17.55 Mc/s, 450 Kc/s from the signal, and an image will be heard again.

Whenever there is any doubt as to which is the correct response, the frequencies should be worked out—conditions will be reversed from the example above if the oscillator is at a lower frequency than the signal—but a simple rule is that if the receiver is being tuned and the oscillator is on the **high** frequency side of the signal, then the **higher** frequency signal is the correct one.

A similar effect to an image response can also occur during signal-frequency trimmer adjustment. With the oscillator on the high-frequency side of the signal it may be found that as the signal-frequency trimming capacitance is increased, the output, with rocking, rises to a maximum, falls and rises to a second maximum, which is the correct one. On the other hand if the receiver is left aligned at the first maximum it is found that the adjustment is approximately correct for the image frequency.

This effect has no direct connection with the image response, but is due to the decrease in sensitivity which can occur when the signal-grid circuit is tuned to the oscillator frequency—owing to grid damping in a severe case, or out-of-phase oscillator injection in other cases. Thus as the signal-circuit tuning initially approaches the correct setting the gain rises, decreases again when the separation from the oscillator frequency is small, and then rises to the correct peak. In a sensitive receiver the illusion of correct alignment on the wrong peak is heightened by an increase in the level of the background noise due to the increased receiver sensitivity near the image frequency.

B. Operating conditions

Converters can be set up for operation on the short-wave band in a manner similar to that described for the broadcast band. However additional steps are also worthwhile. Particularly when harmonic mixing—see C(4) below—is being used, it is advisable to investigate the effects of different values of oscillator-grid resistor. To avoid varying two quantities at the same time the oscillator voltage should be kept as constant as possible while the value of the grid leak is altered, and readings should be taken at least at each end of the short-wave band. After the optimum grid leak value has been chosen, previously selected operating potentials should be rechecked.

When the converter is a type with inner-grid oscillator voltage injection, improved sensitivity may be obtained with the oscillator operating at a lower frequency than the signal instead of under the more usual higher frequency condition.

In Sect. 1 of this chapter it was explained that the space charge in front of the signal grid develops a voltage at oscillator frequency on the signal grid and that this voltage, depending upon its phase, increases or decreases the oscillator-frequency modulation of the electron stream. In a particular case with the oscillator at a higher frequency than the signal, the tuned circuit connected to the signal grid would present capacitive reactance to the oscillator voltage. A positive increment of oscillator-grid voltage increases the current flow and thus increases the space charge in front of the signal grid, i.e. the space charge becomes more negative. Since there is capacitive reactance between the space charge and signal grid and between signal grid and ground, a negative increment of space charge potential results in a (smaller) negative increment of signal-grid potential. Thus a positive change in potential on the oscillator grid results in a negative change in potential on the signal grid, so that the effective oscillator modulation is reduced with a consequent reduction in sensitivity.

However when the oscillator is operated at a lower frequency than that of the signal, the signal-grid circuit presents an inductive reactance to the oscillator voltage and the phase of the oscillator voltage on the signal grid is reversed. Thus the effective modulation of the electron stream is increased and sensitivity is improved.

In practice, if neutralizing is not used, an improvement in sensitivity of two or three times is sometimes obtainable by changing from high-frequency to low-frequency oscillator operation, with an increase of the image ratio in the same proportion. The improvement in sensitivity and image ratio decreases towards the low-frequency end of the short-wave band as the separation between signal and oscillator circuits (i.e. the intermediate frequency) becomes a larger fraction of the oscillator frequency.

For correct tracking with the oscillator on the low-frequency side of the signal, the padder is moved from the oscillator to the signal-frequency circuit(s) but this

does not introduce serious complications. However, a large band coverage is more difficult with the oscillator on the low side because the oscillator circuit covers a greater frequency ratio than the signal circuit, whereas on the high side it covers a smaller ratio.

It is possible for external coupling between oscillator and signal circuits to exceed that which occurs due to internal coupling in the converter itself and it is advisable to check that the external coupling is negligible before investigating the effects of low-side and high-side oscillator operation. A valve voltmeter can be used across the circuit and the variation of the indication as the signal circuit is tuned through the oscillator frequency, with the circuit connected to and disconnected from the signal grid, shows the relative amount of coupling due to internal and external sources.

A further desirable step in the investigation of short-wave performance is the determination of the best sensitivity that can be obtained by adjustment of the magnitude and phase of the oscillator voltage on the signal grid. This can be done by using a very small capacitor, variable in order to adjust the amplitude of the oscillator voltage, and connected between either signal-grid and oscillator grid or signal-grid and oscillator plate to vary the phase of the oscillator voltage. In the absence of appreciable coupling within the receiver, some increase in sensitivity is usually obtained with a particular value of neutralizing capacitor, because maximum sensitivity is obtained not when the oscillator voltage on the signal grid is a minimum but when it is the correctly-phased maximum that can be present without signal-grid current flowing.

Thus, when using a plate tuned triode-hexode converter, it may be found experimentally that sensitivity is improved at 18 Mc/s with a $0.5 \mu\text{F}$ capacitor connected between oscillator grid and signal grid. In such a case it is usually possible to obtain a capacitance of approximately the correct value without using a separate component by a suitable arrangement of the wave-change switch wiring.

However, when neutralizing is used, a measurement should be made of the effect of the neutralizing capacitance on the frequency stability of the receiver at 18 Mc/s. In general, sensitivity improvements due to oscillator voltage on the signal-grid must be offset against decreased frequency stability. The frequency shift in pentagrid converters of the 6SA7 type increases so rapidly with increased capacitance between signal-grid and oscillator grids that a neutralizing capacitance cannot be used in a normal short-wave receiver if a.v.c. is applied to the control grid.

Unless special precautions are taken, grid current variations over the short-wave band are greater than desired. The increase at the high-frequency end of the band occurs because, although the coupling between primary and secondary of the oscillator coil which is required to maintain oscillation is reduced, the actual coupling remains unchanged. A small resistor (say 25 ohm $\frac{1}{4}$ watt) wired between the tuned circuit and the oscillator grid is the usual method of obtaining reasonably uniform grid current over the band. The effective parallel circuit damping of the resistor in series with the capacitance of the oscillator grid is inversely proportional to the square of the frequency so that a large reduction in grid current can be obtained at the high-frequency end of the band without noticeably affecting the grid current at the low-frequency end.

Such a resistor is sometimes also required to prevent squegging of the local oscillator when the amplitude of oscillation is high and the time constant of the oscillator grid circuit is much greater than the time required for one cycle of the oscillator frequency. For further information on squegging see Chapter 35 Sect. 3(vi)C and Ref. 73.

C. Frequency stability

All the problems of frequency stability experienced with a separate oscillator (see Chapter 24) occur when the oscillator section of a converter is used as the local oscillator in a superheterodyne receiver and in addition there are further causes of instability due to interaction between the oscillator and mixer sections of the valve.

1. Frequency variations due to the local oscillator

Local oscillators are always self-biased triodes so that the only potential applied to the circuit from external sources is the plate-supply voltage. Two common types

of frequency instability are due to this link with the rest of the receiver. The first is "flutter" due to fluctuations in the B supply voltage as a result of the output-valve current varying at audio frequencies. These fluctuations vary the oscillator frequency so that the signal is continually detuned, giving a-f signals which make the "flutter" self-sustaining. The mechanism of "flutter" is more fully described in Chapter 35 Sect. 3(vi)B and methods of overcoming it are given.

The second detuning effect for which the B supply is responsible is due to the application of a.v.c. to the controlled stages of a receiver. This reduces the B current, causes the B voltage to rise, and thus produces detuning which will vary, for instance, with the instantaneous level of a fading station.

Although in a particular case the detuning may not be sufficient to produce the symptoms described, it may still give unpleasant tuning at the high-frequency end of the short-wave band, a typical effect being that the receiver does not tune smoothly but jumps from one side of a signal to the other.

When testing for these effects, modulated and unmodulated signals of magnitudes varying from maximum to minimum should be used at the highest tuning frequency of the receiver and the volume control setting should also be varied. If equipment for measuring frequency shift is not available a useful test is to tune the receiver as accurately as possible to a large signal (perhaps 0.1 volt) with the volume control suitably retarded and then reduce the input to the smallest usable signal and turn up the volume control. If the signal is still tuned, frequency shift may be considered satisfactory. The test should be repeated with different signal inputs in case positive and negative frequency shifts should cancel over the range of inputs first selected.

If flutter occurs on a large unmodulated signal there are circumstances under which it can be ignored. When the modulation is switched on it may be found that the output valve is severely overloaded, and that when the volume control is turned down to give no more than full a-f output the flutter may not occur. In such a case the flutter would not be noticed in normal use of the receiver and if a cure cannot be effected cheaply it may not be warranted.

In practice it is found that frequency stability can often be improved by the simple expedient of increasing the oscillator grid current. In one particular triode-hexode the 18 Mc/s frequency shift for a given change in control grid bias was reduced to one tenth by increasing the oscillator grid current from 200 to 600 μ A. Frequency shift due to other causes, and with other types of converters can be improved in the same way, although in varying degrees. The improvement may of course have to be offset against a decrease in sensitivity and an increase in noise.

A third type of oscillator frequency instability due to the B supply is experienced in F-M receivers. If there is a hum voltage superimposed on the B supply to the oscillator plate this will produce frequency modulation of the local oscillator, and the F-M detector will convert the resultant hum modulation of the signal carrier into a-f hum.

2. Frequency variations due to the mixer

The space charge adjacent to oscillator electrodes in a converter valve can be varied by altering the potentials on mixer electrodes. This, of course, gives rise to oscillator-frequency variations. The mixer screen voltage is particularly important because one of the two grids comprising the screen is adjacent to an oscillator electrode, so that it is desirable to keep this voltage as constant as possible. This frequently necessitates a separate decoupling resistor and capacitor for the converter screen because with a common supply to converter and i-f amplifier screens the application of a.v.c. to the i-f amplifier (even if the converter stage is not controlled) alters the mixer screen voltage and thus causes frequency shift. On rare occasions this shift may be used to offset another in the opposite direction due to a different effect.

When frequency shift is troublesome it is desirable to isolate each of the causes and determine its direction, as cancellation is sometimes possible even if a complete cure is not.

The effects upon oscillator frequency of varying a.v.c. voltages applied to a signal-grid electrode are more complex. With either outer-grid or inner-grid oscillator

injection a space charge adjacent to the oscillator grid can be varied by altering the direct potential applied to the signal grid. That this is not always the main source of frequency drift can be seen in some receivers with this type of instability by measuring the frequency shift for a given change in converter a.v.c. voltage with the signal generator connected firstly to the aerial terminal and then to the converter grid. It may be found that the frequency shift in the former case is many times that with the signal generator connected to the converter-grid, and it may even be in the opposite direction.

This type of instability is due to coupling between oscillator and control-grid circuits. In Sect. 1(iv)B of this chapter it is explained that at high frequencies it is usual for oscillator voltage to appear at the signal-grid of the converter. Coupling between signal- and oscillator-grid circuits results in some of this voltage being returned to the oscillator circuit and, in a manner similar to the operation of a reactance-tube modulator, this results in a modification of the effective capacitance at the oscillator grid. A constant variation of this capacitance would be of no significance, but any alteration of converter operating conditions which resulted in a variation of oscillator voltage on the signal grid, e.g. the application of a.v.c. voltages, would alter the effective reflected capacitance at the oscillator grid and thus cause oscillator frequency shift. (Ref. 87).

With a given set of conditions the simplest method of curing this type of frequency shift is usually to minimize the coupling between oscillator and signal grid circuits. In general, coupling is capacitive, partly within the valve and partly external to it. In most modern valves the internal capacitance is not troublesome and to effect a cure it may be necessary to separate short-wave aerial and oscillator coils from each other, to separate the wiring from the two grids or from the two sections of the gang condenser, and to use wave-change switch contacts on the opposite side of the wafer. In the particular case of the 6BE6, it is desirable to reduce the external capacitance between the two grids of the valve to $1\ \mu\mu\text{F}$ or less.

Another possible cure for this type of frequency shift is the use of harmonic mixing, in which the frequency difference between signal and oscillator circuits is so great that no significant amount of oscillator frequency voltage appears on the signal grid.

3. Tuned-plate operation

An analysis of tuned-grid and tuned-plate oscillators (Chapter 24 Sect. 2) shows the differences between the two types of operation. However, it is mainly because of the structure of some types of converters that tuned-plate operation is preferable. When the oscillator section of a converter has a common electron stream with the mixer section, the oscillator-plate electrode is designed to modulate the electron stream as little as possible since modulation by the oscillator plate cancels that from the oscillator grid. It is also desirable in equipment design to keep the oscillator plate alternating voltage as small as possible. With a tuned-grid oscillator, the plate voltage is smaller than the grid voltage and the reverse is the case with a tuned-plate oscillator. Accordingly, tuned-grid oscillators are always used for converters having a common electron stream for the oscillator and mixer sections.

Triode-hexode and triode-heptode converters have a separate triode for use as a local oscillator, and oscillator injection into the mixer section is carried out by a special injector grid which is in most cases internally connected to the oscillator grid. The capacitance and coupling effects of the injector grid are thus introduced into the oscillator circuit, and if a tuned-grid oscillator is used they appear directly across the tuned circuit.

However with a tuned plate oscillator these effects are coupled to the tuned circuit from the oscillator primary winding and their effect is thus minimized. An improvement in oscillator frequency stability, with respect to the effect of a.v.c. application to the signal grid, of five times has been measured with a typical triode-hexode on converting from a tuned-grid to a tuned-plate oscillator, while frequency shift for a given change in B supply voltage was halved under the same conditions.

4. Harmonic mixing

Many of the difficulties experienced in high-frequency applications of converters are due to the small percentage of frequency difference between the oscillator and

signal-frequency circuits. It was shown in Sect. 1 of this chapter that a sinusoidal oscillator voltage applied to the injector grid of the mixer section can also give mixing at harmonics of the oscillator frequency. By taking advantage of this inherent converter characteristic it is possible to separate widely the resonant frequencies of the oscillator and signal frequency tuned circuits and thus eliminate many difficulties in high-frequency converter applications.

There are disadvantages to harmonic mixing but in some cases they are outweighed by the advantages to be obtained. Firstly there is some loss in sensitivity over a part, at least, of the tuning range and secondly there are spurious responses due to incoming signals mixing with the oscillator fundamental.

With careful design the loss in sensitivity is small. In the normal 6 to 18 Mc/s short-wave range it will probably not be greater and may be less than 2 db from 10 to 18 Mc/s. The maximum loss is usually at 6 Mc/s, and should not exceed 3 db, about 2 db or less being normal. Even when the converter is the first valve in the receiver no serious decrease in signal-to-noise ratio of the complete receiver should be experienced.

Because of a number of secondary effects which occur with harmonic mixing, this performance is better than would be expected from an investigation of maximum second harmonic conversion transconductance alone, although it presupposes that the best conditions for harmonic mixing are used. It will be found that higher grid current is necessary, particularly at the low-frequency end of the band, and a lower value of grid leak than normal is often useful in obtaining maximum sensitivity. In general, it is desirable to investigate the converter conditions carefully, as described previously, and for satisfactory performance inner-grid mixers should operate with the second harmonic of the oscillator on the low-frequency side of the signal.

The reason for this is as follows. The modulation of the electron stream by grid 1 gives a transconductance-time curve similar to Fig. 25.1B, and the space charge in front of the signal grid fluctuates at the same rate. This fluctuation, although of the same frequency as the local oscillator, has large harmonic components and since the space charge is coupled capacitively to the signal-grid circuit and this is tuned approximately to the second harmonic frequency, most of the voltage induced into the signal-grid circuit is at the frequency of the second harmonic of the oscillator. This second harmonic voltage remodulates the electron stream with a phase which depends on whether the signal frequency circuit has capacitive or inductive reactance at the second harmonic frequency so that the re-modulation aids or opposes, depending on its phase, the original second-harmonic modulation by grid 1. For inner-grid injection converters, the oscillator second-harmonic frequency should be lower than the signal frequency for aiding re-modulation.

It will be found that with harmonic mixing the same padding can be used as that required for the same frequency coverage with fundamental mixing.

Although the spurious responses which arise due to fundamental mixing are a disadvantage of harmonic operation, a tuned r-f stage ahead of the converter will reduce them to negligible proportions, not greater than -60 db in a typical case. Moreover, even when fundamental mixing is used there are responses, although smaller ones, due to signals mixing with the oscillator harmonics. Fundamental spurious responses 30 db below the signal could be taken as representative of receivers, without a r-f stage, using second-harmonic mixing so that these responses cause appreciably less interference than the normal image.

The benefits to be obtained from harmonic mixing are evident when operating, for example, the 1R5 converter on the 6 to 18 Mc/s short-wave band. Because the 1R5 has no separate oscillator-plate electrode, an oscillator circuit is often used in which the screen is connected to the oscillator primary winding to operate as the oscillator plate. A neutralizing capacitor is then needed between signal grid and oscillator grid and the determining of a suitable capacitance and its tolerances, the minimizing of coupling between signal and oscillator circuits and the stabilizing of the oscillator with reference to supply-voltage variations involve a considerable amount of work, as does the duplicating of the results in production receivers.

However, with harmonic mixing neutralizing is not required. This is because a neutralizing capacitor is used with a 1R5 to balance-out the grid 3 oscillator voltage due to internal capacitive coupling from grids 2 and 4 and not due to space charge coupling. Since the oscillator frequency voltage on grids 2 and 4 is developed across a tuned circuit the harmonic content is low, and thus with harmonic mixing the second harmonic voltage developed on grid 3 is low. Moreover, no other voltages of any magnitude appear on grid 3 because, at frequencies other than those in the vicinity of the oscillator second harmonic, the impedance between grid 3 and ground is small.

Thus a major difficulty experienced with fundamental oscillator frequency voltage on the control grid, is eliminated by harmonic operation. On the other hand the small amount of second-harmonic voltage that does appear on the grid 3 cannot be neutralized because no source consisting only of second harmonic voltages is available.

Another feature of harmonic operation of the 1R5, and similar types of converters, is that sensitivity is increased by negative input impedance at high frequencies due to a negative transconductance between the signal grid and screen and to large capacitance between these electrodes. The oscillator primary winding acts as a capacitive load at signal frequencies and feedback through the inter-electrode capacitance produces negative resistance across the signal-grid circuit.

In a normal case, the amount of regeneration is small, but if there is an unusually large impedance in the screen circuit, e.g. if a very large oscillator primary winding is used, the regeneration may become excessive.

The regeneration is not usually noticed when the oscillator fundamental is used for mixing because, as the screen circuit impedance is increased, the feedback of oscillator frequency voltage from screen to signal grid becomes excessive before noticeable signal-frequency regeneration occurs.

Another aspect of harmonic mixing, common to all types of converters, is that because the signal and oscillator circuits are tuned to widely differing frequencies, coupling between the two circuits can be ignored and variations of coupling within the valve due to changing electrode potentials have little effect on the frequency of the local oscillator. The improvement in stability during alignment is very noticeable and in most cases the need for rocking the tuning control while aligning the short-wave aerial trimmer disappears.

Frequency stability due to effects such as varying oscillator-input capacitance is not improved by harmonic oscillator operation because in general the oscillator tuning capacitance is unchanged at a given signal-frequency setting so that for a given capacitance change the frequency change is proportional to frequency. Although the oscillator operating on half the normal frequency has half the normal shift, the second harmonic will be no more stable than an oscillator fundamental on the same frequency.

(iii) Types of converters

A. Outer-grid oscillator injection

Converters using outer-grid oscillator injection always have a separate oscillator section and are characterized by relatively good oscillator-frequency stability, relative freedom from interaction between oscillator and signal circuits on high frequencies and positive input loading of the signal-grid circuit, which increases in proportion to the square of the frequency.

In the absence of undesired coupling between signal and oscillator-grid circuits, improved sensitivity will be obtained on short waves with these types by operating the oscillator at a higher frequency than the incoming signal.

(1) **Type 6J8-G**: The electrode arrangement of the triode-heptode type 6J8-G is shown in Fig. 25.23. This converter is very stable in operation which makes it useful in dual-wave receivers in spite of its low conversion transconductance. It has a high plate resistance (4 megohms) under recommended operation conditions so that the use of a high impedance first i-f transformer is more effective in increasing conversion gain than in the case of other converter types, for example the 6A8-G.

It is desirable not to apply a.v.c. to the 6J8-G on short waves if this is possible, but if a.v.c. is used a tuned-plate oscillator circuit will greatly improve the frequency stability.

(2) **Types 6AE8, X79 and X61M** : The electrode arrangements of these triode-hexodes is similar to that of Fig. 25.23 but there is no suppressor grid adjacent to the plate. Because of this it is necessary in circuit design to avoid conditions which may lead to secondary emission from the hexode plate to the screen.

Frequency stability with respect to B voltage variations is good, although it is desirable to use plate tuning of the oscillator if a.v.c. is applied to the hexode section on short waves. The conversion transconductances are high (approximately 750 micromhos with 2 volts bias and a screen voltage of 85) and few special precautions are required to obtain non-critical operation and good performance on the broadcast and short-wave bands.

FIG. 25.23

Fig. 25.23. *Electrode arrangement of the triode-heptode type 6J8-G.*

FIG. 25.25

Fig. 25.25. *Electrode arrangement of the pentagrid type 6A8-G.*

The operating characteristics of most outer-grid injection triode-hexodes are similar to those of the above types.

B. Inner-grid oscillator injection

Converters using inner-grid oscillator injection, with the exception of the 6K8(G), have combined oscillator and mixer sections using a common cathode stream. In general the oscillator frequency stability is poorer than that of outer-grid injection types and coupling between control and signal grids is greater, although modern valves are much improved in these respects. Under maximum gain conditions the input loading of the signal grid is negative but becomes less negative and ultimately positive as the signal grid bias is increased.

To obtain maximum short-wave sensitivity without neutralizing, the oscillator should operate on the low-frequency side of the signal.

(1) **Type 6A8-G** : The structure of the pentagrid (or heptode) type 6A8-G is shown in Fig. 25.25. It will be noticed that the oscillator plate consists only of two side rods without a normal grid winding, and that there is no suppressor grid, which leads to a low plate resistance (0.36 megohm under typical operating conditions). Nevertheless the conversion transconductance of 550 micromhos is sufficient to give reasonable conversion gain.

When used with high impedance i-f transformers the 6A8-G may introduce some grid loading at the low-frequency end of the broadcast band due to feedback (Miller

Effect) from the plate circuit to the control grid through the relatively high ($0.26 \mu\text{F}$) plate-to-grid capacitance. This effect is normally only just noticeable but may be aggravated by locating the 6A8-G against the back of the signal-frequency section of the tuning condenser so that appreciable capacitance is present between the plate of the valve and the stator assembly of the gang. The effect shows up as apparently poor aerial coil gain so that the cause may not be suspected. It is not of course peculiar to the 6A8-G but the already high plate-to-grid capacitance, the size of the valve and the lack of internal or external shielding make the effect more likely to occur with this type. The effect may be minimized by external shielding of the valve.

Part of the oscillator plate (grid 2) current is due to electrons which have passed from the cathode through grids 1 and 3 and then been repelled by grid 4 back through grid 3 to grid 2 again. The oscillator characteristics and thus the oscillator frequency stability are therefore very dependent on the potentials applied to grids 2, 3 and 4 and, for short wave operation, a.v.c. should not be applied to the valve. In addition it may be necessary to decouple the oscillator-plate voltage supply with an electrolytic capacitor and even to obtain it directly from the rectifier output—suitably decoupled to eliminate hum—in order to avoid feeding a-f variations from the output valve back to the oscillator plate and thus causing flutter.

To obtain consistent performance it is desirable to keep the oscillator-plate voltage higher than the screen voltage.

FIG. 25.26

Fig. 25.26. Electrode arrangement of the triode-hexode type 6K8(G).

FIG. 25.27

Fig. 25.27. Electrode arrangement of the pentagrid type 6SA7(GT).

(2) **Type 6K8-G**: The structure of the inner-grid injection triode-hexode type 6K8-G is shown in Fig 25.26. It was designed to provide more stable short-wave performance than the 6A8-G and has a higher oscillator transconductance and operates with lower oscillator excitation. Its lower conversion transconductance (350 micromhos) gives a lower conversion gain than that obtainable from the 6A8-G although the plate resistance (0.6 megohm) is higher.

A.V.C. can be applied to the 6K8-G on short-waves but the frequency stability with respect to changes in other electrode voltages is only fair.

(3) **Types 6BE6 and 6SA7(GT)**: The main point of interest in the structure of the pentagrid types 6BE6 and 6SA7(GT), Figs. 25.27, and 25.29 is that there is no electrode which functions only as an oscillator plate.

By the omission of this electrode, it is possible to obtain a relatively high oscillator transconductance, without greatly increasing the total cathode current.

The oscillator circuits employed with these types have certain unconventional features and Fig. 25.28 may be taken as typical. The lack of a separate oscillator

plate results in certain disadvantages in short-wave performance but because a voltage supply is required for one less electrode than usual the cost of components required is a minimum. The main difference between the 6BE6 and the 6SA7(GT) is the considerably higher oscillator transconductance of the 6BE6, due to the use of a formed No. 1 grid in this type.

When the circuit of Fig. 25.28 is used, the oscillator provides peak plate current at the instant when the oscillating voltage (E_k) on the cathode (with respect to ground)

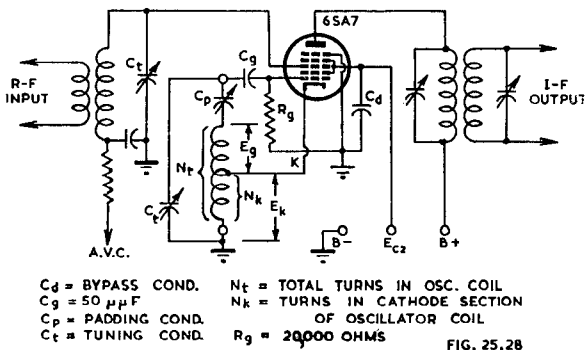

Fig. 25.28. Typical self-excited converter circuit for type 6SA7(GT).

and the oscillating voltage (E_g) on the No. 1 grid are at their peak positive values. For maximum conversion transconductance this peak value of plate current should be as large as possible. The effect on plate current of the positive voltage on the cathode is approximately the same as would be produced by an equal voltage of negative sign applied to the signal grid. Hence the amplitude of oscillator voltage on the cathode limits the peak plate current. This amplitude should therefore be small.

Fig. 25.29. Electrode arrangement of pentagrid type 6BE6.

During the negative portion of an oscillation cycle the cathode may swing more negative than the signal grid. If this occurs, positive signal-grid current will flow unless the oscillator grid is sufficiently negative to cut-off the cathode current. This signal-grid current flowing through the signal-grid circuit resistance will develop a negative bias on the signal grid and may also cause a negative bias to be applied to the i-f and r-f stages through the a.v.c. system. As a result, sensitivity will be decreased. In order to prevent signal-grid current, the d.c. bias developed by the oscillator grid should be not less than its cut-off value.

Because the peak plate current depends on how far positive the oscillator grid swings with respect to the cathode, it is desirable that this positive swing be as large as possible. It follows that the oscillator grid-leak resistance should be low, but not so low as to cause excessive damping of the tank circuit. It has been found, for operation in frequency bands lower than approximately 6 Mc/s, that all these requirements are generally best satisfied when the oscillator circuit is adjusted to provide, with recommended values of plate and screen voltage, a value of E_k of approximately 2 volts peak, and a d.c. oscillator-grid current of 0.5 mA through a grid-leak resistance of 20 000 ohms. This will give a peak positive voltage of the oscillator grid with respect to cathode of about 4 volts.

On the normal short-wave band of 6 to 18 Mc/s, minimum grid current occurs at the low-frequency end of the band and the design procedure consists in adjusting the oscillator circuit so that sufficient grid current (200 μ A minimum) is obtained at 6 Mc/s without developing excessive cathode voltage (approximately 2.5 volts r.m.s. maximum) at 18 Mc/s. The oscillator-grid bias is then somewhat less than cut-off at 6 Mc/s, but the signal-grid current should not be so high as to cause trouble. Oscillation at the high-frequency end of the band however, may be greater than optimum unless a grid stopper is used, but over-excitation will improve frequency stability.

If, for manufacturing reasons, the use of a tapped coil is not desirable, a normal primary winding can be used for the cathode connection, although it will be necessary to reverse the connections from those for a plate-tickler oscillator. This coil arrangement allows one side of the paddler to be grounded.

Another method of connection which is satisfactory for the broadcast band is to use a plate-tickler oscillator circuit with the screen electrode as the oscillator plate and the cathode grounded. This connection can also be used on the short-wave band but the interaction between signal and oscillator circuits causes severe pulling and other associated troubles. A neutralizing capacitor between signal and oscillator grids will minimize these effects—neutralizing is not recommended with a cathode-coupled oscillator—and an alternative system is the use of harmonic mixing.

Whenever the screen is connected to an oscillator primary winding the oscillator voltage on this electrode must be kept to a minimum, i.e. primaries must have as few turns as possible with maximum coupling to secondaries. In addition, it is often desirable to use a small carbon resistor in series with the oscillator grid electrode to prevent the oscillator voltage on the screen from rising excessively at the high-frequency end of the band. The reasons are, firstly, that modulation by the oscillator voltage on the screen is out of phase with the modulation due to the oscillator grid, which decreases conversion sensitivity and, secondly, that as the signal grid is between the two electrodes forming the screen a large oscillator voltage on the screen results, through capacitive coupling, in a comparatively large oscillator voltage on the signal grid, particularly on short waves. This voltage can be neutralized, but normal neutralization is effective for only one frequency and set of operating conditions and when a large amount of neutralization is used and a balance between two large equal and opposite voltages is obtained, any small change in conditions results in a large oscillator voltage reappearing on the signal grid.

The arrangement of shields on grid 2 and of the siderods of grid 3 make the oscillator section of these types much more stable with respect to electrode voltage variations than the 6A8-G, and it can be used satisfactorily with a.v.c. applied on short waves.

Nevertheless in any short-wave application care must be taken to reduce to a minimum any coupling between signal and oscillator grids if frequency stability is to be satisfactory. In the case of the 6BE6, the external capacitive coupling between oscillator and signal grids should be limited to 1 μ F for satisfactory short wave performance.

FIG. 25.31

Fig. 25.31. Self-excited 1R5 converter circuit.

FIG. 25.32

Fig. 25.32. Circuit for short-wave operation of 1R5 converter.

(4) **Type 1R5** : The electrode structure of the 1R5 is similar to that of the 6BE6 and 6SA7(GT) without the shields on grid 2, and with a filament instead of the heater and cathode. Circuits for use with the 1R5 are complicated by the lack of a separate cathode electrode but this may be overcome by using a choke as shown in Fig. 25.31. Alternatively the choke may be omitted and a filament lead returned to A+ through a separate winding of the same number of turns as, and wound over the tapped section of, the oscillator coil.

However, neither of these circuits is satisfactory on short waves if the full range—6 to 18 Mc/s—is to be covered, and even on the broadcast band there may be difficulty in obtaining sufficient grid current. The circuit of Fig. 25.32, with or without the padder feedback shown, is more suitable.

Neutralizing is desirable on short waves if conversion is carried out with the oscillator fundamental. The neutralizing capacitor should be connected across the short-wave coils only, because a different value is normally required on the broadcast band, and oscillator voltage on grid 3 is usually less with no neutralizing than with the capacitance (from $2\frac{1}{2}$ to $5\ \mu\text{F}$) required on short waves.

The purpose of the neutralizing capacitor in a circuit such as Fig. 25.32 is not so much the balancing out of oscillator voltage due to the space charge in front of grid 3, but the neutralizing of a voltage due to capacitive coupling between grid 3 and grids 2 and 4. Therefore, as previously mentioned, it is essential to reduce the oscillator voltage on the screen to the lowest practicable value.

If there is a tendency for the 1R5 to squeak at the high-frequency end of the short-wave band it is often possible to save the small carbon resistor in the oscillator grid lead, which is the usual cure, by reducing the value of oscillator grid leak to say 30 000 ohms or slightly lower. This frequently increases sensitivity, other conditions being unchanged, and it is worth trying even if there are no signs of squegging. In most receivers the oscillator grid circuit damping caused by the low value of oscillator grid leak or by the grid stopper is desirable to reduce the oscillator voltage on the screen of the converter at the high-frequency end of the band with a consequent improvement in sensitivity.

A very satisfactory way to operate the 1R5 is to use harmonic mixing as described previously. The increased freedom in layout, the increased stability in all respects—which simplifies production alignment—and the removal of the need for neutralizing more than compensate for the slight disadvantages which in any case are of little importance if the receiver has a r-f stage.

SECTION 3 : SUPERHETERODYNE TRACKING

BY B. SANDEL, A.S.T.C.

(i) General (ii) (A) Formulae and charts for superheterodyne oscillator design (B) Worked examples (iii) (A) Padded signal circuits (B) Worked example.

(i) General

The problem of tracking (whether it be in a straight or a superheterodyne receiver) is to set, simultaneously, to some desired resonant frequency, each of a series of tuned circuits which are mechanically coupled together and operated from a single control.

In a superheterodyne receiver the problem is one of maintaining a constant frequency difference (equal to the intermediate frequency) between the signal circuits (such as the aerial and r-f stages) and the oscillator circuit. It is a relatively simple matter to make the difference between the signal and oscillator frequency equal to the i-f at two points in the tuning range. This condition is called two point tracking, and is applied whenever the error in frequency difference between the circuits does not become a large percentage of the total pass band. Where the tuning error is likely to become excessive, it can be reduced by the addition of another component, in the form of a capacitor or inductor, into the oscillator or signal circuits. In this case it is possible to proportion the circuit components so that zero frequency error exists between the intermediate frequency and the difference between the signal and oscillator circuits at three frequencies in the tuning range, instead of two; furthermore the error at frequencies between the tracking points is appreciably reduced.

The most usual application of three point tracking has been in receivers covering the standard long, medium and short wave bands, and where the tuning element is a variable capacitor. For this reason attention will be confined to this system of tuning and a suitable design method will be detailed. Those interested in tracking permeability tuned circuits are referred to the articles of Refs. 107 and 111. These give a method of three point tracking using identical variable inductors in the signal and oscillator circuits.

FIG. 25.33

Fig. 25.33. Circuits used for tracking analysis.

pears to be to select a method of determining values for circuit components which

(a) Does not involve an excessive number of arithmetical operations and will allow the use of a slide rule (or four figure logs) for all calculations, except in special cases.

(b) Gives values for the components that fall within a few per cent of those actually required in the circuits.

(c) Allows the change required in other circuit components to be rapidly estimated, when the value of one component in the circuit is changed by an amount which falls within a previously determined range of values.

(d) Lends itself to graphical methods of estimating the component values.

After the component values have been calculated it is usually advisable to build a pilot model receiver in which the values of all the elements (padder, coils and trimmers) can be varied over a small range (say $\pm 10\%$). In this way it is a fairly simple matter to secure tracking at the three points required, and at the same time to determine what tolerances are permissible in the component values before mistracking becomes excessive. Fixed padders and coils can then be used for further models of the same receiver; although production difficulties can be reduced by using "slug" inductance variation in the oscillator coils as well as the usual variable parallel

It is necessary to point out that the theoretical solutions, so far published, of the three point tracking problem are all idealized in so far that they ignore in part, or completely, the effects of primary windings on the signal and oscillator coils. The best approach under these conditions appears

capacitance trimmers in the oscillator and signal circuits (many receiver manufacturers also use "slug" tuning of the signal circuits).

A few points which may be of interest are :

(1) The tracking error on the broadcast bands need not exceed a few Kc/s e.g. the error between tracking points need not exceed about 3 Kc/s on the 540-1600 Kc/s medium wave band using tracking frequencies of 600, 1000 and 1400 Kc/s. This error is negligible, in most cases, since the oscillator tuning takes charge and the lack of alignment affects the aerial and r-f circuits which are relatively unselective.

A typical curve of tracking errors is shown in Fig. 25.34.

(2) High impedance primaries, on the aerial and r-f coils, are practically always used in modern receivers covering the medium waveband. The coefficient of coupling in aerial and r-f coils, and the location of the primary resonant frequencies have very important effects on tracking. Suitable values for these factors are discussed in Chapter 23, Sects. 2 and 3.

(3) When a series capacitance (padder) is used in the oscillator circuit only, the operating frequency of the oscillator must be higher than the signal frequency if three point tracking is to be secured.

Three point tracking is obtainable if both the signal and oscillator circuits use series padders, whether the oscillator frequency is higher or lower than the signal frequency provided, of course, that the component values are correctly proportioned. If only the signal circuits are padded the oscillator frequency must be lower than the signal frequency to obtain three point tracking.

A typical example of padding of the signal and oscillator circuits occurs in band-spread receivers, where the short wave band is covered in a number of steps (e.g. 6 bands may be used to tune from 6-18 Mc/s), and it is required to have approximately straight line frequency tuning with a standard variable capacitor (i.e. one whose capacitance versus rotation approximates to a straight-line frequency law). The tuning law need not be linear, however, and the shape of the calibration curve is largely under the control of the receiver designer.

(4) Care is necessary in the placement of components so as to minimize untracked stray capacitances. For example, the padder may be placed at the earthy end of the oscillator coil to assist in this regard.

(5) The selection of the best tracking points to give minimum error over a band of frequencies has received considerable attention from a number of designers. It has been generally accepted that the tracking error is reduced by setting the two outer tracking points somewhat in from the band limits, and locating the third tracking point at the geometrical-mean frequency (or some frequency near this value) of the outer tracking frequencies. However, it has been shown by Green (Ref. 105) that the **maximum** tracking error is reduced by bringing the high frequency point in from the band limit, setting the low frequency tracking point at or very close to the band limit, and making the third frequency the geometrical-mean of the two outer tracking frequencies. It has also been shown that the tracking errors are independent of the manner in which the total trimming capacitance is distributed across the oscillator coil and the variable capacitor ; although it should be noted that the manner in which these capacitances are distributed can have an adverse effect on the L/C ratio, particularly at low frequencies.

(6) Although the details set out in (5) are of interest they result in additional complication in the initial receiver design. A more suitable arrangement, for preliminary calculations, is to take the band limits as coinciding with the two outer tracking fre-

FIG. 25.34

(b)

Fig. 25.34. Typical tracking curves.

quencies, and make the third point either the arithmetical-mean or geometrical-mean of the outer frequencies. This leads to fairly simple design calculations, and gives values for the components which are reasonably close to the optimum. The small differences in component values required to set to the optimum tracking frequencies (or whatever the designer chooses) can then be made experimentally. It should be observed that it has been usual to align receivers to tracking points on various bands which have been established by long practice as giving sufficiently satisfactory results e.g. on the medium wave band 600, 1000 and 1400 Kc/s are in common use, but these are a compromise, due partly to a lack of more exact knowledge, and also because of the frequency allocations of the main broadcasting stations. If a station were to be located at, say, 540 Kc/s then the loss in receiver sensitivity, due to mistracking, would be serious if 600 Kc/s were to be taken as the low frequency tracking point.

(7) The feedback winding on the oscillator coil should be as small as possible, consistent with correct oscillator operation, if good tracking is desired. For minimum error the oscillator feedback winding should have its natural resonant frequency well above the highest oscillator tuning frequency; this means that stray capacitances across the winding should be kept as low as possible. The natural resonant frequency is important because the coefficient of coupling between the two oscillator coil windings is usually large, and the amount of reactance reflected into the tuned circuit not only varies with frequency, but also sets a limit to the maximum possible tuning range. The limitation in tuning range is a particularly serious factor in receivers covering the short wave range in one band.

An additional and important reason for making the feedback winding as small as possible, is that for good oscillator stability the highest possible coefficient of coupling should be used, consistent with the smallest possible value of mutual inductance ($M = k\sqrt{L_p L_s}$).

(8) When tracking a superheterodyne receiver at three points in the tuning range (we will assume that the oscillator frequency is higher than the signal frequency) it often happens that the centre tracking (crossover) frequency does not fall at the frequency required. The question then arises as to how the oscillator series padder value should be altered.

First the signal circuit trimmer capacitance (or inductance) is altered so as to give maximum output. If the capacitance was increased then the oscillator series padder should be increased. For a decrease in signal trimmer capacitance (or inductance) the oscillator series padder should be decreased.

Complete re-alignment and re-checking is necessary after the padder value has been altered and it is important to remember that the oscillator inductance and trimmer capacitance values will also require alteration. This is a simple process when the oscillator coil is "slug" tuned, and the trimmer capacitance is adjustable.

Fig. 25.34 is also helpful in this regard, and the tracking error can be considered in terms of L_0 if so desired. It should be clear that if the value of L_0 is increased the padder value should be decreased (and vice versa) to retain the desired oscillator frequency coverage.

A good alignment procedure is to set first the signal and oscillator circuits at the band limits. Tracking is then obtained at the required points by setting the signal generator to the required tracking frequency and rocking the receiver dial while altering the oscillator trimmer capacitance (at the high frequency tracking point) and the oscillator inductance (at the low frequency tracking point) until maximum signal output is obtained. Tracking at the centre frequency can be checked either by alteration of the signal circuit trimmers, which have not been altered after the initial adjustment at the band limits, or, alternatively, by leaving the signal circuit trimmers untouched and rocking the receiver dial while adjusting the oscillator inductance (or capacitance) for maximum output. It is preferable to track the oscillator to the signal circuits since these give the required tuning law. A complete re-check is always necessary after the initial alignment procedure is completed. Of course correct tracking can be obtained by a number of methods, but the procedure suggested above has proved very satisfactory for receiver development.

(ii) (A) Formulae and charts for superheterodyne oscillator design

The equations quoted below are due to Payne-Scott and Green (Ref. 102) and Green (Refs. 103, 105). Design charts are available in the references for the cases of arithmetical-mean and geometrical-mean tracking. The charts shown in Figs. 25.35 to 25.39 are for geometrical-mean tracking only.

For the circuit arrangements used in the derivation of these equations see Fig. 25.33.

FIG. 25.35

Fig. 25.35. Charts giving $T_{c_{\max}}$ for geometrical-mean tracking.

Fig. 25.36. Charts giving high values of P_{min} for geometrical-mean tracking.

FIG. 25.36

Fig. 25.37. Chart giving low values of P_{min} for geometrical-mean tracking.

FIG. 25.37

FIG. 25.38

Fig. 25.38. Chart giving high values of $T_{L,max}$ for geometrical-mean tracking.

FIG. 25.39

Fig. 25.39. Chart giving low values of $T_{L_{max}}$ for geometrical-mean tracking.

Notation for the equations $\omega_1 = 2\pi \times$ low-frequency tracking point of the signal circuit (f_1) $\omega_2 = 2\pi \times$ high-frequency tracking point of the signal circuit (f_2) $\omega_3 = 2\pi \times$ third tracking frequency for the signal circuit (f_3) $\omega_i = 2\pi \times$ intermediate frequency (f_i)

$$\alpha = \frac{\omega_2}{\omega_1} = \frac{f_2}{f_1}$$

$$\beta = \frac{\omega_2 + \omega_i}{\omega_1 + \omega_i} = \frac{f_2 + f_i}{f_1 + f_i}$$

$$\gamma = \frac{\omega_3}{\omega_1} = \frac{f_3}{f_1}$$

 $L, L_0 =$ signal and oscillator inductances $G_{max} =$ incremental capacitance of each section of the ganged capacitors (i.e. difference between the maximum and minimum values of the capacitor) $T =$ capacitance in signal circuit at signal frequency f_s (includes gang min. cap.) $T_L =$ fixed capacitance in parallel with L_0 $T_c =$ fixed capacitance in parallel with G in the oscillator circuit $P =$ oscillator padding capacitance.

When the extreme tracking points do not coincide with the band limits, the following additional notation is required.

 $\omega_1' = 2\pi \times$ low-frequency limit of signal band (f_1') $\omega_2' = 2\pi \times$ high-frequency limit of signal band (f_2')

$$\alpha' = \frac{\omega_2'}{\omega_1'} = \frac{f_2'}{f_1'}$$

 $G'_{max} =$ total incremental capacitance of each section of the ganged capacitors between signal frequencies f_1' and f_2' $T' =$ T less the incremental capacitance of each section of the ganged tuning capacitors between signal frequencies f_2 and f_2' $T'_c =$ T_c less the incremental capacitance of each section of the ganged tuning capacitors between signal frequencies f_2 and f_2' .**Signal circuits :**

For the tracking points coincident with the band limits.

$$T = \frac{G_{max}}{\alpha^2 - 1};$$

$$L = \frac{1}{T\omega_2^2} \text{ (or } L = \frac{25\,330}{Tf_2^2} \mu\text{H where } T \text{ is in } \mu\mu\text{F and } f \text{ is in Mc/s)}$$

Oscillator circuit :

For the tracking points coincident with the band limits.

$$P_{max} = \frac{G_{max}}{r - 1}$$

$$T_{c_{max}} = \frac{G_{max}}{r\beta^2 - 1}$$

$$\text{and } r = \frac{\alpha^2}{\beta^2} \cdot \frac{1 + \frac{2(\alpha - \beta)}{(\beta - 1)(\alpha + \gamma)}}{1 + \frac{2(\alpha - \beta)}{(\beta - 1)(1 + \gamma)}}$$

For the case of arithmetical-mean tracking

$$\left(\text{i.e. } f_3 = \frac{f_1 + f_2}{2} \right)$$

$$r = \rho = \frac{\alpha^2}{\beta^2} \cdot \frac{3 + \alpha}{3 + \beta} \cdot \frac{1 + 3\beta}{1 + 3\alpha}$$

For geometrical-mean tracking (i.e. $f_3 = \sqrt{f_1 f_2}$)

$$r = R = \frac{\alpha^2}{\beta^2} \cdot \frac{2\beta + (1 + \beta)\alpha^{\frac{1}{2}}}{2\alpha + (1 + \beta)\alpha^{\frac{1}{2}}}$$

(a) General formulae for padding and trimming capacitances.

(1) T_c given.

$$P = P_{max} - T_c = P_{min} + T_{c_{max}} - T_c$$

$$T_L = \frac{P}{P_{min}} [T_{c_{max}} - T_c]$$

(2) T_L given.

$$P = \frac{P_{min}}{2} \left(1 + \sqrt{\frac{P_{min} + 4T_L}{P_{min}}} \right)$$

$$T_c = P_{max} - P = P_{min} + T_{c_{max}} - P.$$

Formulae when $T_L \ll P$

$$P = P_{min} + T_L$$

$$T_c = T_{c_{max}} - T_L$$

error in P is given by $-\left(\frac{T_L}{P}\right)^2 \times 100$ per cent.

error in T_c is given by $\frac{T_L^2}{P \times T_c} \times 100$ per cent.

(b) Formulae for inductance of oscillator coil

$$L_0(\omega_2 + \omega_1)^2 = \left(\frac{P_{max}}{P}\right)^2 \cdot \frac{1}{T_{L_{max}}} = \frac{P_{min}P_{max}}{T_{c_{max}}} \cdot \frac{1}{P^2}$$

$$\text{or } L_0 = \frac{25\,330 \times P_{min}P_{max}}{T_{c_{max}} P^2 (f_2 + f_1)^2}$$

(capacitances in $\mu\mu\text{F}$, frequencies in Mc/s)

(c) Relations between P_{max} , P_{min} , $T_{c_{max}}$, and $T_{L_{max}}$

$$P_{max} = P_{min} + T_{c_{max}}$$

$$\frac{P_{max}}{P_{min}} = \frac{T_{L_{max}}}{T_{c_{max}}}$$

(d) Relations between oscillator-circuit components.

The effect of a change in value of one component of the oscillator circuit on the values required for the other components can be found from the following expressions :

$$\delta T_c = -\delta P$$

$$\delta T_L = \left(1 + \frac{2T_L}{P}\right) \delta P$$

$$\delta L_0 = -\frac{2L_0}{P} \delta P$$

where δL_0 , etc. means a small change in L_0 , etc. These changes must give values of P , T_c , etc. which lie between the limits of the maximum and minimum values (P_{max} , P_{min} , etc.) of the components considered.

(e) Auxiliary formulae when the outer tracking frequencies do not coincide with the band limits

$$G_{max} = \left(\frac{\omega_2'}{\omega_2}\right)^2 \cdot \frac{\alpha^2 - 1}{(\alpha')^2 - 1} \cdot G'_{max}$$

$$\frac{T'}{T} = \left(\frac{\omega_2'}{\omega_2}\right)^2$$

$$T_c - T_c' = T - T'$$

(B) Worked examples

To illustrate the application of the equations and charts, worked examples are appended.

A tuning capacitor is available having a capacitance range of 12-432 $\mu\mu\text{F}$. It is required to tune over the range of frequencies 530 to 1620 Kc/s , and the i-f of the receiver is 455 Kc/s . Determine the component values for the signal and oscillator circuits.

For ease of working the outer tracking frequencies will be made coincident with the band limits, and the third tracking frequency (f_3) will be taken as the geometrical-mean of the outer frequencies ($\sqrt{f_1 f_2} = 926.6$ Kc/s).

Signal circuits

$$G_{max} = 432 - 12 = 420 \mu\mu F$$

$$\alpha^2 = \left(\frac{1620}{530}\right)^2 = 9.342$$

$$T = \frac{420}{9.342 - 1} = 50.24 \mu\mu F \text{ (includes } 12 \mu\mu F \text{ gang min. cap. so that actual trimmer would be } 38.24 \mu\mu F)$$

$$L = \frac{25\,330}{50.24 \times 1.62^2} = 192.2 \mu H$$

Oscillator circuit

$$\alpha^2 = \left(\frac{1620}{530}\right)^2 = 9.342; \alpha^{\frac{1}{2}} = 1.748;$$

$$\beta = \frac{1620 + 455}{530 + 455} = 2.107; \beta^2 = 4.440;$$

$$(1 + \beta)\alpha^{\frac{1}{2}} = 5.431$$

$$r = R = \frac{9.342}{4.44} \left[\frac{(2 \times 2.107) + 5.431}{(2 \times 3.056) + 5.431} \right] = 1.758$$

$$P_{max} = \frac{432 - 12}{1.758 - 1} = 554 \mu\mu F$$

$$T_{c_{max}} = \frac{(432 - 12)}{(1.758 \times 4.44) - 1} = 61.7 \mu\mu F$$

(a) A value for T_L (about $8 \mu\mu F$) will be assumed, after preliminary calculation, as this is the usual case.

As obviously $T_L \ll P$ (Compare $8 \mu\mu F$ with P_{max})

$$P_{min} = P_{max} - T_{c_{max}} = 492.3 \mu\mu F$$

$$T_{L_{max}} = \frac{554 \times 61.7}{492.3} = 69.42 \mu\mu F.$$

From this it is permissible to estimate T_L as $8 \mu\mu F$ since this is about the order of stray capacitances likely to be across L_0 . Any small error here is unimportant, as long as the value chosen for T_L is less than $T_{L_{max}}$, since this is taken up during circuit alignment.

$$\text{Hence } P = 492.3 + 8 = 500.3 \mu\mu F$$

$$T_c = 61.7 - 8 = 53.7 \mu\mu F \text{ (includes gang min. cap. of } 12 \mu\mu F. \text{ Actual trimmer would be } 41.7 \mu\mu F)$$

$$(b) L_0 = \frac{25\,330 \times 492.3 \times 554}{61.7 \times 500.3^2 \times (1.62 + 0.455)^2} = 103.9 \mu H$$

(c) and (d)

Suppose now that it is required to make a change in the value of one of the oscillator components. What should be the new values of the other components?

A good example is the padder; a more suitable value may be $510 \mu\mu F$ (which lies between the maximum and minimum values of $554 \mu\mu F$ and $492.3 \mu\mu F$).

Then

$$\delta T_c = -9.7 \mu\mu F$$

$$\delta T_L = \left(1 + \frac{2 \times 8}{500.3}\right) 9.7 = 10 \mu\mu F$$

$$\delta L_0 = -\frac{2 \times 103.9 \times 9.7}{500.3} = -4.03 \mu H.$$

So that the new values for the oscillator components are $P = 510 \mu\mu F$

$$T_c = 53.7 - 9.7 = 44 \mu\mu F$$

$$T_L = 8 + 10 = 18 \mu\mu F$$

$$L_0 = 103.9 - 4.03 = 99.87 \mu\text{H}$$

and these values all lie within the permissible range of values, set by the maximum and minimum values calculated for P , T_L and T_c ; denoted by P_{max} , P_{min} etc.

A table showing a series of values between the calculated maxima and minima is often very useful. In this way the most suitable component values can be selected. Also, three point tracking is still maintained at the selected frequencies with the range of component values determined, as the change in values is independent of the tracking and intermediate frequencies provided these remain unaltered.

The same design problem, previously solved algebraically, will now be carried out using the tracking charts.

Signal circuits

Procedure exactly as before.

Oscillator circuit

$$\alpha = \frac{1620}{530} = 3.056$$

$$\beta = \frac{1620 + 455}{530 + 455} = 2.107$$

$$G_{max} = 432 - 12 = 420 \mu\mu\text{F}$$

(a) From the charts :

$$\frac{T_{c_{max}}}{G_{max}} = 0.15; \text{ therefore } T_{c_{max}} = 63 \mu\mu\text{F}$$

$$\frac{P_{min}}{G_{max}} = 1.2, \text{ therefore } P_{min} = 504 \mu\mu\text{F}$$

$$\frac{T_{L_{max}}}{G_{max}} = 0.17, \text{ therefore } T_{L_{max}} = 71 \mu\mu\text{F}$$

$$P_{max} = 504 + 63 = 567 \mu\mu\text{F}$$

Using $T_L = 8 \mu\mu\text{F}$ (as previously)

$$\bar{P} = 504 + 8 = 512 \mu\mu\text{F}$$

$$T_c = 63 - 8 = 55 \mu\mu\text{F}$$

$$(b) L_0 = \frac{25\,330 \times 504 \times 567}{63 \times 512^2 \times (1.62 + 0.455)^2} = 102 \mu\text{H}$$

(c) and (d) Any circuit component changes are made exactly as before.

Suitable practical values are then selected after allowing for strays.

(iii) (A) Padded signal circuits

The case of the multi-band all-wave receiver is of interest to designers. It can hardly be said that the receiver covering the complete short wave band (6 — 18 Mc/s) in one step gives very satisfactory performance, particularly in the hands of an unskilled operator.

Consider first the case where bandspreading is obtained merely by loading additional parallel capacitance across the tuned circuits. The scale calibration will become non-linear with frequency and the scale will be crowded towards the low-frequency end of the band. If, instead of using parallel capacitance, a small capacitance is inserted in series with the tuning capacitor so as to restrict the tuning range, the scale will be crowded towards the high frequency end. From this it should be clear that a combination of the two methods can probably be made to give very much improved scale linearity. The method is not restricted, however, to producing a linear scale calibration.

The circuit arrangement for the padded signal circuit takes the same form as the oscillator circuit. The analysis of these circuits, due to Green (Ref. 103), is based on tracking the padded signal and oscillator circuits to a (non-existent) pilot circuit (which also determines the form of scale calibration) at three points, and thereby making the padded circuits track with one another at the same three points. The error at frequencies between tracking points is usually not serious as the range of frequencies to be covered is generally fairly small.

The design problem is to select values for the padder P and the two trimming capacitances T_L and T_c such that simultaneously the following conditions are fulfilled :—

- (a) The desired frequency ratio is attained.
- (b) The scale calibration is linear, or, more generally, corresponds to a desired form.
- (c) The L/C ratio is maintained at a high value in order to achieve adequate gain in the signal circuits.

To simplify notation the virtual pilot circuit takes the same form as the original signal circuit shown in Fig. 25.33 and the same notation is retained, for both the padded signal and oscillator circuits, as was previously used for the oscillator circuit alone. The design equations are limited to the cases of arithmetical-mean and geometrical-mean tracking. Charts are available (in Ref. 103) covering the arithmetical-mean case.

Summary of formulae

Pilot circuit :

$$T = \frac{G_{max}}{\alpha^2 - 1}$$

$$\left(\frac{\omega_2}{\omega}\right)^2 = 1 + (\alpha^2 - 1) \frac{G}{G_{max}}$$

Padded circuit :

$$P + T_c = \frac{G_{max}}{r - 1}$$

$$T_{c_{max}} = \frac{G_{max}}{r\beta^2 - 1}$$

$$T_{L_{max}} = \frac{G_{max}}{r(\beta^2 - 1)}$$

$$P + T_c = P_{max} = P_{min} + T_{c_{max}}$$

where r is limited to the values given by ρ and R .

T_c specified :

$$P = P_{max} - T_c$$

$$T_L = \frac{P}{P_{min}} T_{c_{max}} - T_c$$

where P is first evaluated.

T_L specified :

$$P = \frac{P_{min}}{2} \left[1 + \sqrt{1 + \frac{4T_L}{P_{min}}} \right]$$

$$T_c = T_{c_{max}} - T_L \cdot \frac{P_{min}}{P}$$

where P is first evaluated.

When $T_L \ll P$

$$T_c = T_{c_{max}} - T_L$$

$$P = P_{min} + T_L$$

Gain is proportional to the dynamic impedance Z of the circuit and

$$Z = \frac{Q}{\omega C};$$

$$C = \frac{P^2}{P_{min}} \cdot \frac{G + T_{c_{max}}}{G + P_{max}} \text{ (effective capacitance across inductance).}$$

When $G = G_{max}$ then $C = C_{max}$. The value of P is obtained from the appropriate equations, according to whether T_c or T_L is specified.

Inductance

$$L_0 = \frac{1}{(\omega_1 + \omega_j)^2} \cdot \frac{P_{min}}{P^2} \cdot \frac{1 + \frac{P_{max}}{G_{max}}}{1 + \frac{T_{c_{max}}}{G_{max}}}$$

$$\text{or for numerical computation } L_0 = \frac{25\,330\,P_{min}(G_{max} + P_{max})}{(f_1 + f_j)^2 P^2 (G_{max} + T_{c_{max}})}$$

using μH , μF , Mc/s .

in which $(\omega_1 + \omega_j)$ is the known low frequency tracking point of the padded signal circuit. For a padded oscillator circuit replace $(\omega_1 + \omega_j)$ by $(\omega_1 + \omega_j \pm \omega_i)$. The value for P is derived from the appropriate equation according as to whether T_c or T_L is specified.

For an unpadded signal circuit

$$L = \frac{\alpha^2 - 1}{\alpha^2 \omega_1^2 G_{max}}$$

The notation is identical with that given previously, with the addition of

$\omega = 2\pi \times$ any frequency in the tuning range

$\omega_1 = 2\pi \times$ low frequency tracking point of pilot circuit

$\omega_2 = 2\pi \times$ high frequency tracking point of pilot circuit

$\omega_3 =$ arithmetical- or geometrical-mean tracking point of pilot circuit

$\omega_i = 2\pi \times$ true intermediate frequency of receiver

$\omega_j = 2\pi \times$ virtual intermediate frequency for the combination of a padded signal circuit with a virtual pilot circuit

$$\alpha = \frac{\omega_2}{\omega_1} = \frac{f_2}{f_1} = \text{frequency ratio of pilot circuit}$$

$$\beta = \frac{\omega_2 + \omega_j}{\omega_1 + \omega_j} = \text{frequency ratio of padded signal circuit}$$

$G =$ incremental capacitance of each section of the ganged tuning capacitors, measured from its value at ω_2

$G_{max} =$ value of G at ω_1

$C =$ total effective capacitance across L_0

$C_{max} =$ value of C when $G = G_{max}$

$Q = \omega L_0 / R$ where L_0 and R apply to the signal circuit, and this R is the r-f resistance of the circuit.

(B) Worked example

The method will be applied to the design of a receiver tuning from 6 to 9 Mc/s, using an i-f of 455 Kc/s, with a capacitor having a straight line frequency characteristic and a capacitance range of 12-432 μF . Arithmetical-mean tracking will be used.

Pilot circuit

For the pilot circuit assume that the required scale calibration is given by

$$\alpha = 2 \quad (\text{A sufficient range of values for most receiver calibration curves is from about 3 to 1.5})$$

$$\alpha^2 = 4$$

Signal circuits

$$\beta = 9/6 = 1.5$$

$$\beta^2 = 2.25$$

$$r = \rho = \frac{4}{2.25} \cdot \frac{3 + 2}{3 + 1.5} \cdot \frac{1 + (3 \times 1.5)}{1 + (3 \times 2)} = 1.552$$

$$P_{max} = P + T_c = \frac{432 - 12}{1.552 - 1} = 760.8 \mu\text{F}$$

$$T_{c_{max}} = \frac{432 - 12}{(1.552 \times 2.25) - 1} = 168.7 \mu\text{F}$$

$$T_{L_{max}} = \frac{432 - 12}{1.552 (2.25 - 1)} = 216.5 \mu\text{F}$$

$$P_{min} = 760.8 - 168.7 = 592.1 \mu\mu F$$

Take the case where T_c is specified. Draw up a table of component values, and select the most suitable.

T_c	T_L	P	L_0
50	19.3	710.8	2.24
100		660.8	
150		610.8	
200		560.8	
250		510.8	
300		460.8	

From this it seems that a convenient padder value is $610.8 \mu\mu F$. Then find T_L and L_0 to complete the table. If the values so found, using the first selection for P , are considered as being suitable, only those need be computed

$$T_L = \frac{610.8}{592.1} [168.7 - 150] = 19.3 \mu\mu F$$

$$L_0 = \frac{25330 \times 592.1 \times (420 + 760.8)}{6^2 \times 610.8^2 \times (420 + 168.7)} = 2.24 \mu H$$

So that the signal circuit components are

$$L_0 = 2.24 \mu H$$

$$T_L = 19.3 \mu\mu F$$

$$P = 610.8 \mu\mu F$$

$$T_c = 250 \mu\mu F \text{ (which includes } 12 \mu\mu F \text{ gang min. cap.)}$$

(Suitable practical values are selected after due allowance for strays).

An estimate can now be made of the circuit dynamic impedance (Z), as this will serve as a guide to the possible circuit gain. Improvement can often be effected by a redistribution of the component values, and the most favourable L/C ratios can be determined by completing the table set out earlier.

However the L/C ratio and the component values selected are usually a compromise forced on the designer by considerations of practical convenience.

Oscillator circuit

It will be taken that the oscillator frequency is higher than the signal frequency.

$$\beta = \frac{9 + 0.455}{6 + 0.455} = 1.464$$

$$\beta^2 = 2.145$$

$$r = \rho = \frac{4}{2.145} \cdot \frac{3 + 2}{3 + 1.464} \cdot \frac{1 + (3 \times 1.464)}{1 + (3 \times 2)} = 1.609$$

$$P_{max} = \frac{432 - 12}{1.609 - 1} = 689.6 \mu\mu F$$

$$T_{c_{max}} = \frac{432 - 12}{(1.609 \times 2.145) - 1} = 171.4 \mu\mu F$$

$$T_{L_{max}} = \frac{1.609 (2.145 - 1)}{432 - 12} = 228 \mu\mu F$$

$$P_{min} = 689.6 - 171.4 = 518.2 \mu\mu F.$$

Take the case, this time, where T_L is specified and draw up a table of component values. T_L is not necessarily very much smaller than P .

T_L	T_c	P	L_0
50	85.6	564.1	1.619
100		604	
150		639.7	
200		1072	

Then for the tabulated values of T_L we have

$$P = \frac{518.2}{2} \left[1 + \sqrt{1 + \frac{4T_L}{518.2}} \right]$$

These values are listed above.

Taking the padder of 604 $\mu\mu\text{F}$ as being suitable, then T_L is 100 $\mu\mu\text{F}$, and now find T_c and L_0 .

$$T_c = 171.4 - 100 \left(\frac{518.2}{604} \right) = 85.6 \mu\mu\text{F}$$

$$L_0 = \frac{25\,330 \times 518.2 (420 + 689.6)}{(6 + 0.455)^2 \times 604^2 (420 + 171.4)} = 1.619 \mu\text{H}$$

So that one suitable set of oscillator component values would be

$T_L = 100 \mu\mu\text{F}$, $P = 604 \mu\mu\text{F}$, $L_0 = 1.619 \mu\text{H}$
and $T_c = 85.6 \mu\mu\text{F}$ (including 12 $\mu\mu\text{F}$ gang min. cap.).

The signal and oscillator circuits should track at 6, 9 and 7.5 Mc/s.

SECTION 1 : CHOICE OF FREQUENCY

(i) *Reasons for selection of different frequencies* (ii) *Commonly accepted intermediate frequencies.*

(i) Reasons for selection of different frequencies

The choice of a particular intermediate frequency in a receiver is governed by a number of factors.

(a) If the frequency is very low the circuits will be generally too selective, resulting in side-band cutting. Very high selectivity will also make a receiver more difficult to tune, and imposes severe requirements on oscillator, and other circuit, stability.

(b) The lower the intermediate frequency the more difficult it becomes to eliminate image interference. This difficulty becomes greater as the carrier frequency is increased.

(c) The intermediate frequency should not fall within the tuning range of the receiver, as this would lead to instability and severe heterodyne interference. Also lower harmonics (principally second and third) of the i-f should not fall within the tuning range if this can be avoided. This requirement is not always easy to meet because of the other factors discussed in this section.

(d) Too high a value of intermediate frequency should be avoided as it generally leads to a serious reduction in selectivity and, usually, gain.

(e) The intermediate frequency should not be such that it approaches the range of frequencies over which the receiver is required to tune.

(f) If the intermediate frequency is made too high, tracking difficulties between the signal and oscillator circuits may be experienced.

(g) In some cases, where the intermediate frequency is higher than the highest received signal frequency (as in single span receivers), it is possible to tune the oscillator only and use low-pass filters for the signal circuits. However, it is generally preferable to use tunable signal circuits.

(ii) Commonly accepted intermediate frequencies

As a result of the experience gained over a number of years in addition to the considerations stated previously the values selected for the intermediate frequencies of most commercial receivers have become fairly well standardized. For the majority of broadcast receivers tuning the bands 540-1600 Kc/s and 6-18 Mc/s, an i-f of about 455 Kc/s is usual. A frequency of 110 Kc/s has been extensively used in Europe where the long wave band of 150-350 Kc/s is in operation. Receivers for use only on the short wave bands commonly employ an i-f of 1600 Kc/s or higher. Frequency modulation receivers covering the 40-50 Mc/s band generally use a 4.3 Mc/s i-f, and for the 88-108 Mc/s band they use 10.7 Mc/s. This latter value has been adopted as standard in U.S.A., and some other countries, for v-h-f receivers.

SECTION 2 : NUMBER OF STAGES

The number of stages required in the i-f amplifier is generally a compromise between the factors of selectivity, gain, and cost. For the usual broadcast receiver having a 455 Kc/s i-f, one stage employing two transformers is generally considered as being adequate (when using an i-f valve with a g_m of about 2000 micromhos). The transformers in common use are two parallel tuned circuits coupled by mutual inductance and stray capacitance. The windings are arranged so that any capacitive coupling aids the mutual inductance. Care should be taken to keep capacitive coupling small as it alters the symmetry of the overall response curve of frequency versus attenuation.

Common values of capacitance tuning the primary and secondary windings in commercial transformers are from about 50 $\mu\mu\text{F}$ to 120 $\mu\mu\text{F}$ to which must be added valve and circuit stray capacitances. Values as high as 800 $\mu\mu\text{F}$ are used in special circumstances, however. This point will receive further discussion in Section 7 of this chapter. Unloaded values for the primary and secondary Q 's are from about 70 to 130. The transformer windings are in most cases coupled from 0.8 of critical to critical. The amount of coupling when the transformer is wired into the receiver is the important factor as stray coupling (including regeneration and alteration of tuning slug positions) will often alter any value of k or conditions for critical k measured external to the receiver.

It should be noted particularly that the second i-f transformer usually feeds into a diode detector and this will appreciably affect the selectivity and gain of the preceding stage because of the loading across the transformer secondary. This loading is commonly taken as half the d.c. diode load resistance, which in most cases does not exceed 0.5 megohm because of the detector circuit requirements. If improved selectivity is required then the secondary of the i-f transformer may be tapped and the diode circuit fed from this tapping point to reduce loading on the tuned circuit ; but this generally involves a loss in stage gain.

For small battery receivers of the portable type it may be advantageous to employ three i-f transformers (i.e. two stages) rather than a r-f stage and one i-f stage. Although there is some reduction in signal-to-noise ratio with this arrangement, additional gain is often the main requirement. Further, it is possible to operate the two i-f valves in a very economical condition, e.g. by using reduced screen voltage, as the full gain available can seldom be utilized without difficulties arising from instability. The Q 's of the i-f's need not be more than 60 or 70 with this arrangement as the selectivity is more than adequate for ordinary reception.

With receivers using higher intermediate frequencies at least two stages (three transformers) are often required to give improved selectivity. Another important consideration, however, is that the dynamic impedance of the load presented by the transformer to the valve is lower, and stage gain is decreased. Valves used in the i-f stages of receivers having a high value of i-f generally have a mutual conductance

(g_m) of the order of 4000 micromhos to allow additional gain to be obtained to offset the loss due to the lower circuit dynamic impedance. These conditions apply particularly in F-M receivers using an i-f of 10.7 Mc/s. Short wave receivers using 1600 Kc/s i-f transformers commonly employ two stages (3 transformers) although one stage is often used and generally, but not always, the valves are similar to those used at lower frequencies and have a g_m of about 2000 micromhos or less. The pass-band and gain requirements will largely determine the values of the constants for the transformers.

A 10.7 Mc/s transformer in a F-M receiver has to pass a band of frequencies about 240 Kc/s wide and at the same time must not introduce such an appreciable amount of amplitude modulation (due to the selectivity of the transformers) that the limiter (or whatever device is used that is insensitive to amplitude variations) cannot give substantially constant output. To secure these results, some designers use combinations of overcoupled and critically-coupled transformers, while others prefer to use only critically-coupled transformers because of the simplification in the alignment procedure. For the type of F-M receiver using a ratio detector, two i-f stages are generally considered as being adequate (although this may lead to difficulties because of insufficient adjacent channel selectivity) with the second i-f valve feeding into a discriminator transformer. For most F-M receivers using limiters, three 10.7 Mc/s i-f transformers are used in cases where one limiter stage is included; or for two limiter stages an additional very wide band i-f transformer may be incorporated. The purpose of the additional i-f transformer is to provide interstage coupling, but at the same time the design must be such as to introduce no appreciable amplitude modulation of the signal after it has passed through the first limiter stage. If a locked oscillator type of F-M detector (such as the Bradley circuit) is employed, then it is common practice to use three normal i-f transformers plus a fourth transformer giving a voltage step down of about 6 to 1 to provide a low impedance voltage source for driving the detector. An additional i-f stage is included in receivers using limiters for the purpose of giving the greater gain required to obtain satisfactory amplitude limiting with very weak signals; the additional i-f stage also provides improved selectivity outside the required passband.

The number, and type, of stages used in any i-f amplifier is decided, of course, by the various requirements of the particular receiver and the selectivity and gain are under the control of the designer. Discussion as to the number of i-f stages used in typical A-M and F-M broadcast receivers is meant only to serve as a guide to common practice. However, it should not be overlooked that although gain and pass band requirements can sometimes be met with fewer stages than suggested above, adjacent channel selectivity will generally call for additional transformers. It is important that both pass band and adjacent channel selectivity be considered during the design, and if this is done there is usually little difficulty in selecting the number of i-f stages required.

Special i-f requirements can be fulfilled by making preliminary calculations for any number of stages which a designer may consider necessary. In Section 4 it is proposed to carry out the complete design of several transformers showing the various factors to which attention must be paid to meet a given set of conditions.

SECTION 3 : COMMONLY USED CIRCUITS

(i) *Mutual inductance coupling* (ii) *Shunt capacitance coupling* (iii) *Composite i-f transformers.*

In this section it is proposed to confine attention, particularly, to the most commonly used i-f transformer arrangement which uses mutual inductance coupling. Shunt capacitance coupling is not very widely used, but is included here as being of some interest because of its occasional application in F-M receivers. Details of various coupled circuit arrangements are given in Chapter 9; the references should be consulted for a more comprehensive survey of circuit arrangements, and analysis of their

properties. Of course, almost any type of coupling can be used in i-f circuits but transformers other than those using two windings coupled by mutual inductance are the exception rather than the rule in ordinary broadcast and communications receivers.

(i) Mutual inductance coupling

Fig. 26.1 shows the most widely used circuit arrangement for an i-f coupling transformer; C_1 , L_1 and C_2 , L_2 are the primary and secondary capacitances and inductances respectively. The two windings are coupled together by mutual inductance. The total capacitances tuning the circuits are due to valve input and output, wiring and coil capacitances as well as C_1 and C_2 .

The transformer is set to the required i-f by using powdered iron "slugs" which are moved inside the primary and secondary windings to vary the inductance values. Variable capacitance trimmers are often used as an alternative, and in some cases this may be advantageous since the inductance values can be pre-set fairly accurately and the capacitance, which is not known accurately because of additional strays, can be set to give the required resonant frequency; this arrangement also allows close control on the coefficient of coupling. However, capacitance trimmers are not always completely reliable and it is often of greater practical convenience to use variable iron cores in transformer windings. Further, the fixed capacitors C_1 and C_2 can be of high quality (e.g. silvered mica) to improve the circuit stability.

FIG. 26.1 TYPICAL TRANSFORMER COUPLED I.F. STAGE

FIG. 26.2 SHUNT CAPACITANCE COUPLED I.F. CIRCUIT

The type of circuit being considered is discussed also in Chapter 9 Sect. 6(iii), (iv), (v). Graphical methods of determining selectivity are given in Chapter 9 Sect. 10.

Section 4 below gives detailed design methods and examples for several transformers of this type.

(ii) Shunt capacitance coupling

This type of coupling arrangement is illustrated in Fig. 26.2. Circuits of this type can be conveniently arranged to give a fairly wide pass band and are sometimes used in F-M receivers, in particular, to couple two cascaded limiter stages. Some discussion of this type of circuit is given also in Chapter 9 Sect. 8(ii).

The design of circuits of this type is carried out in a similar manner to those using mutual inductance coupling. Usually the values selected for C_1 and C_2 are about $50 \mu\text{F}$ and the value for C_M is determined by the required coefficient of coupling. However, C_M is generally fairly large, being of the order of 1000 to 2000 μF in typical cases. L_1 and L_2 (which usually have equal values) are determined from:

$$L_1 = L_2 = 25330/f^2 C$$

where L_1 is in microhenrys

C is in μF and is equal to $\frac{C_1 C_M}{C_1 + C_M}$ (or $\frac{C_2 C_M}{C_2 + C_M}$) + stray capacitance across the primary circuit

and f is in Mc/s, and is taken as the intermediate frequency.

The resistors R_1 and R_2 are for the purpose of lowering the Q of the tuned circuits to the values required for the bandwidth desired.

The coefficient of coupling is given by

$$k = \sqrt{\frac{C_1 C_2}{(C_1 + C_M)(C_2 + C_M)}}$$

$$\approx \frac{\sqrt{C_1 C_2}}{C_M} \quad \text{when } C_M \gg (C_1, C_2).$$

(iii) Composite i-f transformers

Receivers used for F-M and A-M reception, on the 88-108 Mc/s and the 540-1600 Kc/s bands respectively, generally have the i-f amplifiers arranged so that the intermediate frequency is 10.7 Mc/s for the F-M band and 455 Kc/s for the A-M range. For reasons of economy many manufacturers use the same amplifier valves for both i-f's, and so it is necessary to find a solution to this problem which does not require elaborate circuit arrangements.

FIG. 26.3 ARRANGEMENT FOR F-M AND A-M I-F STAGE

One solution is the circuit shown in Fig. 26.3. The 10.7 Mc/s transformer is represented by C_p , L_p etc. and the 455 Kc/s transformers by L_1 , C_1 etc. When the carrier output from the converter stage is 10.7 Mc/s, the primary and secondary circuits of the 455 Kc/s i-f act as capacitances which allow the lower ends of the 10.7 Mc/s i-f to be effectively earthed. At 455 Kc/s the 10.7 Mc/s i-f transformer tuned circuits act as inductances in series with the transformers in use. The effective inductance, in series with the 455 Kc/s transformer, tends to offset any loss in gain due to the voltage drop across it because it reduces the loading on the valve input circuit. Any possible loss in gain is not important, however, as the g_m of the amplifier valves is about 4000 micromhos, and there are usually two i-f stages. The problem is generally one of getting rid of excess gain on the lower frequency channel; it is for this reason that very low L/C ratios are used in the 455 Kc/s i-f transformers, in receivers for this purpose, and the primary and secondary capacitances are often of the order of 750 $\mu\mu\text{F}$. This system of gain reduction is sometimes preferred to tapping down on 455 Kc/s i-f transformers using the more conventional component values as discussed in Sect. 2.

In receivers using a common converter, for F-M and A-M, it is usual to short out whichever transformer is not in use. It is not considered necessary, in most cases, to use switching with all i-f stages. Receivers adopting the method of using separate converters for improved oscillator stability on the v-h-f band, and a common i-f channel, do not require any switching in the i-f amplifier; the converter not in use having the high tension removed. Switching of detector circuits is also unnecessary; the last 455 Kc/s A-M transformer can be connected directly to a diode in the first a-f voltage amplifier valve, and a separate double diode, connected to the discriminator transformer, is used for detection in the F-M channel after F-M to A-M conversion has been carried out. Some valves, such as type 6T8, incorporate three diodes, a triode, and two separate cathodes, and so will allow all the detection and first a-f voltage amplification functions to be performed with one valve without switching being required. An alternative arrangement, common in receivers using ratio detectors, is to use the grid-cathode circuit of the last i-f valve (the driver stage) as a diode for A-M detection. When the receiver has a.v.c. applied to the driver stage, it is possible to select suitable values for the a.v.c. load resistor and the i-f by-pass capacitor to provide a satisfactory $R-C$ combination for A-M detection.

The two transformers may have all the windings in one can, or two cans may be used for each i-f, one for the 10.7 Mc/s i-f, and the other for the 455 Kc/s i-f. This latter arrangement has the advantage that it reduces interaction between the windings,

and also permits both transformers to be "slug" tuned without using elaborate mechanical arrangements. In some cases where the transformers are both mounted in one can, combinations of "slug" and capacitance adjustment are provided; an example of this is illustrated in Ref. 12.

Many arrangements have been suggested for combined i-f transformers, and some of these are described in Ref. 22. However, the circuit shown, or modifications of it, has received fairly wide acceptance as providing quite a good solution to the problem.

- (vii) *Appendix : Calculation of coupling coefficients.*

(i) General

The design procedure for i-f transformers can be greatly simplified by the use of charts and tables. If certain assumptions are made, which approximate to practical conditions, the design procedure can be reduced to a few routine operations. Here we will consider only the two winding transformer using mutual inductance coupling; the added capacitance coupling, which is always present, does not seriously affect the results particularly as its presence is taken into account when setting the coefficient of coupling (k).

The methods given below can be applied to inductive or capacitive coupling provided that the coefficient of coupling (k) is suitably interpreted [see appendix (vii) below for methods of calculating coupling coefficients]. The practical two winding transformer, as previously mentioned, has mixed coupling but this does not cause any difficulty when the two forms of coupling assist each other [suitable connections are given in (vi) below]. However, if the two forms of coupling are in opposition a rejection frequency is possible which can occur within the pass band of the transformer. This effect is well known to receiver designers who have accidentally reversed the connections of one of the i-f transformer windings, and found that the i-f stage gives practically no gain. This fact can also be made the basis of a useful method for measuring k , the capacitive coupling being increased (using a calibrated capacitor) until it equals the inductive coupling and zero voltage transfer then occurs at the working frequency. For further data on mixed coupling see Ref. 4.

The initial assumptions will be that the primary and secondary inductances L_1 and L_2 are given by $L = \sqrt{L_1 L_2}$. Also, it will be assumed that the values of Q do not alter appreciably over the range in which the selectivity curves are taken. We will not always take the primary and secondary Q 's as being equal, and the advantages

to be gained will become clear as we proceed. The magnification factor, or Q , will be defined as

$$Q = \sqrt{Q_1 Q_2}$$

and provided the ratio of Q_1/Q_2 or Q_2/Q_1 is not greater than 2, the error in the usual design equations is negligible for most practical purposes.

As long as $\sqrt{Q_1 Q_2} \approx (Q_1 + Q_2)/2$ the error in any of the usual approximate design equations will be small. If Q_1 and Q_2 differ by large amounts then the exact design equations are necessary and can be obtained from Refs. 2, 3, 6 and 8, or the design can be modified by using the universal selectivity curves to obtain the required results. It is of interest to note that the simplified equations given by Kelly Johnson (Ref. 1), Ross (Ref. 2) and Maynard (Ref. 6 and Figs. 9.17 and 9.18 of this book) are identical when it is assumed that $Q = Q_1 = Q_2$ and the various notations are made the same.

It may be thought that writing $Q = \sqrt{Q_1 Q_2}$ and $L = \sqrt{L_1 L_2}$ will be inconvenient since the i-f transformer, as constructed, will have its primary and secondary inductances and Q 's equal. However, in the majority of cases $L = L_1 = L_2$ is applied, and the method is extended to fulfil the condition that the unloaded primary and secondary Q 's should be equal while allowing the required $Q = \sqrt{Q_1 Q_2}$ to be obtained in the receiver, without further adjustment.

Critical-coupling, or a close approach to it, is most often employed in i-f transformers but there is little difficulty in designing transformers for almost any degree of coupling. All cases will be treated.

Universal selectivity and phase shift curves are given in Chapter 9, Sect. 10 (Figs. 9.17 and 9.18). Additional charts and tables are given, to be used as described in the appropriate sections.

The design procedure generally consists of finding values of Q , k and stage gain for given bandwidths at some value of i-f; or of finding the required bandwidth for values of Q and k previously determined. For clarity the cases of critical-, over-, and under-coupled transformers will be dealt with separately. Single tuned circuits are also included as they are sometimes required in i-f amplifiers. Additional data for the design of F-M transformers will be given in Sect. 4(v).

Stagger tuning (Refs. 8, 13, 17 and 38) of i-f transformers (e.g. tuning primary and secondary to different frequencies) to give substantially the same bandwidths as over-coupled transformers, does not have a very wide application in F-M and A-M receivers (except in cases where variable selectivity is to be used) and will not be discussed in detail.

Stagger tuning of single and double tuned circuits is widely used in television receivers, but this is a different application from the case where it is applied to the comparatively narrow bandwidths of ordinary sound receivers. In this case the transformer primary and secondary are tuned to the same frequency, but this is not necessarily the intermediate frequency.

Since i-f transformers for television receivers involve special problems they are not treated here (see Refs. 27, 28, 94, 95, 96 and 97). Also, triple tuned transformers are not discussed, but the article of Ref. 26 gives an excellent treatment.

Finally, the design methods do not make allowance for regenerative effects, nor should they be applied for finding the shape of resonance curves at frequencies far removed from resonance. The selectivity curve shapes are assumed to be perfectly symmetrical although in practice it will be found that this is seldom true.

(ii) Critically-coupled transformers

(A) Design equations and table

In general the procedure given is similar to that due to Kelly Johnson (Ref. 1) and Ross (Ref. 2). However, these procedures assume that $Q = Q_1 = Q_2$; we shall take $Q = \sqrt{Q_1 Q_2}$. For most cases it is not advisable to use the equations given below for Q_1/Q_2 or Q_2/Q_1 greater than about 2, unless some additional adjustment is made from the universal selectivity and phase shift curves.

For N critically-coupled transformers,

$$\rho = \left(1 + \frac{X^4}{4}\right)^{N/2} \quad (1)$$

$$X = \sqrt{2(\rho^{2/N} - 1)} \quad (2)$$

$$Q = \frac{Xf_0}{2\Delta f} \quad (3)$$

$$\text{and } \theta = \tan^{-1} \frac{2X}{2 - X^2} \quad (4)$$

where ρ = attenuation at Δf c/s off resonance

N = number of identical transformers used ($N = 1$ for one transformer)

f_0 = resonant frequency (the i-f in our case)

$Q = \sqrt{Q_1 Q_2} = 1/k_c$ (in which Q_1 and Q_2 are actual primary and secondary Q 's; k_c is critical-coupling coefficient)

$2\Delta f$ = total bandwidth for a given attenuation (ρ)

and θ = phase shift between secondary current at resonance and secondary current at Δf c/s off resonance.

The required design information is given in equations (1) to (4). Usually either ρ is stated for a given bandwidth and a known i-f, or X can be found to allow ρ to be determined. Once these two factors have been found, the determination of k and/or Q is a simple matter.

Table 1 lists various values of ρ and X . Suppose ρ is known, then X is read from the table and used in equation (3) to find Q (since $2\Delta f/f_0$ is already known). The coefficient of coupling is then $k_c = 1/Q$.

If complete resonance and/or phase shift curves are required, then the universal curves of Figs. 9.17 and 9.18 (Chapter 9, Sect. 10) are used. These curves apply to one transformer only. For N identical transformers the attenuation in decibels is multiplied by N ; for transformers which are not identical, the individual attenuations (in db) are added. Resonance and phase shift curves can also be determined directly, by using table 1 and eqns. (1) to (4).

In the application of the universal curves take $D = X = Q2\Delta f/f_0$ (this Q being $\sqrt{Q_1 Q_2}$ as determined) and $b = k/k_c = Qk$ (for critical coupling $b = 1$, in this case); which are the same as for $Q_1 = Q_2$. If the values of Q_1 and Q_2 differ by more than about 2 to 1, then the more exact expressions for D and b^2 are applied to check how closely the required conditions are approached, it being carefully noted that in all expressions on the curves involving a that the Q shown is Q_2 .

TABLE 1 CRITICALLY-COUPLED TRANSFORMERS

For use with equations (1), (2) and (3)

N = Number of Transformers

Attenuation (ρ)		$N = 1$	$N = 2$	$N = 3$
Times Down	db Down	X	X	X
$\sqrt{2}$	3	1.41	1.14	1.01
2	6	1.86	1.41	1.25
4	12	2.76	1.86	1.57
7	17	3.73	2.21	1.81
10	20	4.46	2.46	1.95
20	26	6.32	2.96	2.26
40	32	8.96	3.54	2.56
70	37	11.9	4.08	2.82
100	40	14.1	4.46	3.02
1000	60	—	7.96	4.46
10 000	80	—	14.1	6.66

The maximum stage gain is given by

$$\text{Gain} = g_m Q \omega_0 L / 2 \quad (5)$$

where g_m = mutual conductance of i-f valve (if conversion gain is required, conversion conductance (g_c) is substituted for g_m)

$\omega_0 = 2\pi \times$ resonant frequency (f_0) i.e. $f_0 = i\text{-f}$

$L = \sqrt{L_1 L_2}$; L_1 and L_2 are primary and secondary inductances

and $Q = \sqrt{Q_1 Q_2}$; Q_1 and Q_2 are primary and secondary magnification factors.

A condition, not specifically stated in the equations, is that $L_1 C_1 = L_2 C_2$ in all cases.

The maximum gain is usually converted to decibels, so that the gain at any point on the resonance curve can be found by subtraction of the attenuation, also expressed in decibels.

(B) Example and additional design extension

A 455 Kc/s i-f transformer, using critical-coupling, is required to give a total bandwidth of 20 Kc/s for an attenuation of 20 db (10 times).

(a) $f_0/2\Delta f = 455/20 = 22.75$.

(b) From table 1 we have $X = 4.46$ (since $N = 1$).

(c) From eqn. (3), $Q = 4.46 \times 22.75 = 101$.

(d) $k_e = 1/Q = 0.0099$.

(e) Select a suitable value for $C_1 (= C_2)$; a capacitance of $100 \mu\text{F}$ is satisfactory (made up of fixed + stray capacitances).

$$\text{Then } L = \frac{25.33}{f^2 C} = \frac{25.33}{0.455^2 \times 100} = 1.22 \text{ mH}$$

(f in Mc/s; C in μF)

and take $L = L_1 = L_2$ since this is convenient in this case.

(f) The i-f valve (e.g. type 6SK7) has $g_m = 2 \text{ mA/volt}$ ($= 2000 \mu\text{mhos}$).

From equation (5),

$$\text{Max. stage gain} = \frac{2 \times 10^{-3} \times 101 \times 2\pi \times 455 \times 10^3 \times 1.22 \times 10^{-3}}{2} \\ = 352 \text{ times (or 51 db).}$$

(g) Some designs might stop here and the magnification factor would be taken as $Q = Q_1 = Q_2 = 101$. It would be realized that valve loading would have an effect although possibly nothing more would be done (or else some attempt would be made to allow for the plate and grid resistances by finding new values of Q_1 and Q_2).

Let us proceed further and ask whether the transformer as it stands fulfils the design conditions in a radio receiver. The answer is that obviously it does not, since it would be connected in most cases between two i-f valves, a converter and i-f valve or between an i-f valve and a diode detector. Suppose the connection between two i-f amplifier valves (type 6SK7 would be representative) is considered since this appears a fairly innocuous case. The plate resistance (r_p) of a type 6SK7 under the usual conditions of operation is 0.8 megohm. The short circuit input resistance, also under one set of operating conditions, is 6.8 megohms (this is calculated from the data given in Chapter 23, Sect. 5); other effects, which would alter this value, will be ignored for simplicity, although they may not be negligible. It is first required to determine what values of Q_1 and Q_2 are required to give $Q = Q_1 = Q_2 = 101$.

This is found from

$$Q_u = \frac{QR}{R - Q\omega_0 L} \quad (6)$$

where Q_u = unloaded Q

Q = loaded Q

R = parallel resistance across winding

$\omega_0 = 2\pi f_0$; (resonant frequency = f_0)

and L = inductance.

For the primary

$$Q = 101; R = r_p = 0.8 \text{ M}\Omega;$$

$$\omega_0 = 2\pi \times 455 \times 10^3; L = L_1 = 1.22 \text{ mH}$$

$$\text{and } Q\omega_0 L = 101 \times 2\pi \times 455 \times 10^3 \times 1.22 \times 10^{-3} = 0.352 \text{ M}\Omega.$$

$$\text{Then } Q_u = \frac{101 \times 0.8}{0.8 - 0.352} = 180.$$

For the secondary

$$Q_u = \frac{101 \times 6.8}{6.8 - 0.352} = 106.8.$$

(C) Design extension

The value $Q_u = 180$ could not be obtained very easily, if at all, with a normal type of i-f transformer. In addition, the disadvantage of unequal primary and secondary Q 's should be apparent. For values of Q only about 10% higher than that given, or where the transformer is coupled to a diode detector, the situation becomes so much worse that it is clear that a revised approach is necessary. What is actually needed is

- (1) A transformer with equal values of primary and secondary Q 's when unloaded. These will be denoted by $Q_u = Q_{u1} = Q_{u2}$.
- (2) The values of Q_{u1} and Q_{u2} to be such that when the transformer is connected into the i-f amplifier, and loaded by the valve output and input resistances, the desired value of $Q = \sqrt{Q_1 Q_2}$ will be obtained.
- (3) The required coefficient of coupling (k) (critical for this particular example) to be unchanged. It will be described later how k can be pre-set to any desired value for any two circuits coupled together.
- (4) Excessive values of Q_{u1} and Q_{u2} are to be avoided (see the previous method of determining Q_{u1}) as far as possible, because of the practical difficulties involved.
- (5) The response curve of frequency versus attenuation to be that specified (or very close to it).

All of these conditions can be fulfilled very closely, provided the approximations made in deriving the design equations hold. A simple analysis of the circuits involved, and including the required conditions, gives

$$Q_u = \frac{\alpha + \sqrt{\alpha^2 + 2Q^2 R_1 R_2 \beta}}{\beta} \quad (7)$$

where $Q_u = Q_{u1} = Q_{u2}$ (unloaded primary and secondary Q)

$Q = \sqrt{Q_1 Q_2}$ (in which Q_1 and Q_2 are loaded primary and secondary Q 's)

R_1 = parallel resistance (r_p in our case) shunted across trans. primary

R_2 = parallel resistance (grid input in our case) shunted across trans. secondary

$\alpha = Q(Q\omega_0 L)(R_1 + R_2)$; in all cases it will be taken that $L = L_1 = L_2$
and $\beta = 2[R_1 R_2 - (Q\omega_0 L)^2]$.

For our example:

$$Q = 101; Q^2 = 1.02 \times 10^4; R_1 = 0.8 \text{ M}\Omega; R_2 = 6.8 \text{ M}\Omega$$

$$Q\omega_0 L = 0.352 \text{ M}\Omega \text{ (found previously)}$$

$$\alpha = 101 \times 0.352 \times 7.6 = 270; \alpha^2 = 7.29 \times 10^4$$

$$\beta = 2[5.44 - 0.124] = 10.63 \text{ (M}\Omega)^2$$

$$Q_u = \frac{270 + \sqrt{7.29 \times 10^4 + 2 \times 1.02 \times 10^4 \times 5.44 \times 10.63}}{10.63} = 131$$

so that $Q_{u1} = Q_{u2} = 131$.

To check that the transformer, when placed in the receiver, gives the desired value of $Q = \sqrt{Q_1 Q_2}$ use

$$Q = \frac{Q_u R}{Q_u \omega_0 L + R} \quad (8)$$

from which

$$Q_1 = \frac{131 \times 0.8}{0.458 + 0.8} = 83.4$$

$$Q_2 = \frac{131 \times 6.8}{0.458 + 6.8} = 123$$

and so

$Q = \sqrt{Q_1 Q_2} = \sqrt{83.4 \times 123} = 101$, which is the desired value (as determined previously).

(D) Conclusions

All that is required to design the specified transformer is to go through the simple steps (a) to (e) and, knowing R_1 and R_2 , apply eqn. (7). Overall response and phase shift are determined from the universal curves, as explained previously.

It should be obvious that eqn. (7) will not hold under all practical conditions, but it is not limited by the ratio of Q_1/Q_2 or Q_2/Q_1 , and failing cases can be checked by the condition for $\beta = 0$. It has been assumed for simplicity that $L = L_1 = L_2$ but this is not essential, and the design equation could be extended to the case of $L = \sqrt{L_1 L_2}$. In some failing case, if it is essential to fulfil the specified conditions, Q_1 and Q_2 (and if necessary L_1 and L_2) can be selected to give the desired values of Q and L ; this will be illustrated in the section on the design of variable bandwidth crystal filters.

(E) k Measurement

The coefficient of coupling, k , for two circuits resonant at the same frequency, can be set on a Q meter (provided Q_b lies within the useful working range) using the relationship

$$Q_b = \frac{Q_{u1}}{1 + Q_{u1} Q_{u2} k^2} \quad (9)$$

If $Q_{u1} = Q_{u2} = Q_u$

$$\text{then } Q_b = \frac{Q_u}{1 + (Q_u k)^2} \quad (9A)$$

where Q_{u1} = primary Q (sec. o/c or detuned by large amount)

Q_{u2} = secondary Q (pri. o/c or detuned by large amount)

Q_b = Q to be obtained when primary and secondary are coupled and the secondary tuned to make the primary Q a minimum.

(Usual precautions as to can and earthy side of secondary winding being grounded to be observed—it is preferable to use the same order of connections for measurement as those to be used in the receiver.)

When the transformer has different primary and secondary Q 's, it is often advantageous to use the higher Q winding as the primary when setting the coefficient of coupling; this applies particularly when the coupling is very loose.

The actual capacitance values tuning the primary and secondary for Q meter measurements should include the allowance made for stray capacitance otherwise incorrect slug positions (i.e. incorrect inductance values) will give rise to an error which can be avoided.

In our example we desire a value for $k = 0.0099$ (for critical-coupling when $Q = \sqrt{Q_1 Q_2} = 101$); $Q_u = 131$.

Then from (9A)

$$Q_b = \frac{131}{1 + (1.297)^2} = 48.9.$$

All that is required is to adjust the spacing between the two resonant circuits until the Q meter reads 48.9. The desired co-efficient of coupling has then been obtained. Alternatively, by transposing terms in the equation, k is given for any values of Q_b , Q_{u1} , and Q_{u2} ,

$$\text{so that } k = \sqrt{\frac{Q_{u1} - Q_b}{Q_{u1} Q_{u2} Q_b}} \quad (9B)$$

The method applies directly to under-, over-, or critically-coupled transformers and is useful within the limits set by the usable range of the Q meter. For over-coupled transformers additional methods are sometimes required, and the procedure will be indicated in Sect. 5.

It is sometimes required to measure k in terms of critical or transitional coupling. In this case the circuits are loaded to give the values of Q_1 and Q_2 required when the transformer is connected into the receiver, and the following expressions can be applied:

$$\frac{k}{k_c} = \sqrt{\frac{Q_1 - Q_2}{Q_2}} \quad (9C)$$

$$\text{and } \frac{k}{k_t} = \sqrt{\frac{2Q_1Q_2(Q_1 - Q_2)}{Q_2(Q_1^2 + Q_2^2)}} \quad (9D)$$

It might be noted that when $Q_1 = Q_2$ the expressions (9C) and (9D) are identical, as would be expected.

(iii) Over-coupled transformers

(A) Design equations and table

Here the method to be followed is based on that due to Everitt (Ref. 3).

Fig. 26.5 illustrates the terms used regarding bandwidth.

It should be noted that when the primary and secondary Q 's differ appreciably, two peaks of secondary output voltage do not appear immediately critical-coupling is exceeded. The actual value of k , which corresponds to the condition for two peaks of secondary voltage, is called the transitional-coupling factor [see Chapter 9, Sect. 6(v)], and Ref. 8.

In what follows we shall use $Q = \sqrt{Q_1Q_2}$ and $L = \sqrt{L_1L_2}$, as was done for critically-coupled transformers, but this is not an approximation in the derivation of the design equations (10), (11) and (12) provided that $L_1C_1 = L_2C_2$. It will also be assumed, for simplicity, that the peaks of the response curve are of equal height and symmetrically placed in regard to f_0 .

$$Q_k = A + \sqrt{A^2 - 1} \quad (10)$$

$$A = \frac{(Qk)^2 + 1}{2Qk} \quad (11)$$

$$\frac{24f_p}{f_0} = k \sqrt{1 - \frac{1}{(Qk)^2}} \quad (12)$$

$$\theta = \tan^{-1} \frac{2X}{1 - X^2 + (Qk)^2} \quad (13)$$

where $Q = \sqrt{Q_1Q_2} = \frac{1}{k_c}$ (in which Q_1 and Q_2 are primary and secondary Q 's respectively; k_c is coefficient of critical-coupling)

k = any coefficient of coupling equal to or greater than critical

A = gain variation from peak to trough (i.e. difference in transmission level)

$24f_p$ = bandwidth between peaks; $\sqrt{2(24f_p)}$ is the total bandwidth for two other points on the resonance curve with the same amplitude as at f_0

θ = phase shift between the secondary current at resonance and the secondary current at $4f$ c/s off resonance

$X = (24f/f_0)Q$

and f_0 = resonant frequency of transformer (i-f).

The universal resonance and phase shift curves of Figs. 9.17 and 9.18 (Chapter 9 Sect. 10) are directly applicable, using the exact expressions if desired and taking Q as Q_2 for all terms involving a . It is more convenient, and sufficiently accurate, to use the conditions for $Q_1 = Q_2$ when Q_1/Q_2 or $Q_2/Q_1 > 2$; in this case $b = Qk$ (or k/k_c), $D = (24f/f_0)Q$ and since these expressions do not involve a , the value $Q = \sqrt{Q_1Q_2}$ as determined in the design problem is used. A check will reveal that it is difficult to read any difference from the curves whichever method is used.

It should be observed that five points on the resonance curve are given directly from the design equations.

To find the maximum stage gain which occurs at the peaks, the equation (5) as given for critically-coupled transformers, is applied directly. Generally it is the average gain in the pass band ($\sqrt{2} \times 24f$) which is required and this is given by multiplying eqn. (5) by

$$\frac{(Qk + 1)^2}{2[(Qk)^2 + 1]} \quad (14)$$

If the gain at f_0 (i.e. at the trough of the curve) is required, equation (5) is multiplied by

$$\frac{2Qk}{(Qk)^2 + 1} \quad (15)$$

which is the same as multiplying equation (5) by $1/A$, since equation (15) is equivalent to $1/A$.

Equations (14) and (15) can be evaluated directly from Fig. 26.4 when Qk is known; the dotted line being for eqn. (14) and the solid line for eqn. (15). Equation 5 is multiplied by the gain reduction factor so found. The gain reduction indicated by eqn. (15) can also be read directly from the $1/A$ column in table 2.

FIG. 26.4 GAIN REDUCTION FACTORS FOR COUPLING OTHER THAN CRITICAL

TABLE 2. OVER-COUPLED TRANSFORMERS

For use with equations (10), (11), (12), (14), (15)

A (= peak to trough gain variation)		Qk	$\sqrt{1 - \frac{1}{(Qk)^2}}$	$(Qk)^2$	$\frac{1}{A}$
db	Times Down				
0	1.00	1.00	0.000	1.00	1.00
0.25	1.03	1.27	0.616	1.61	0.971
0.50	1.06	1.41	0.707	2.00	0.943
1	1.12	1.73	0.817	3.00	0.893
1.9	1.25	2.00	0.866	4.00	0.800
2	1.26	2.02	0.869	4.08	0.794
3	1.41	2.41	0.910	5.81	0.709
3.1	1.43	2.45	0.913	6.00	0.670
4	1.59	2.81	0.935	7.90	0.629
4.4	1.67	3.00	0.943	9.00	0.599
5	1.78	3.25	0.952	10.56	0.562
6	2.00	3.72	0.963	13.84	0.500
6.6	2.13	4.00	0.968	16.00	0.469
7	2.24	4.24	0.972	17.98	0.446

(B) Example

A 455 Kc/s i-f transformer is required to pass a band of frequencies 16 Kc/s wide (i.e. ± 8 Kc/s). The variation in gain across the pass band is not to exceed 0.5 db.

(a) From Fig. 26.5 it is reasonable to take the **total** bandwidth as 16 Kc/s and so the peak separation is $16/\sqrt{2} = 11.3$ Kc/s.

(b) $2\Delta f/f_0 = 11.3/455 = 0.0248$.

(c) From Table 2, $\sqrt{1 - 1/(Qk)^2} = 0.707$.

(d) From eqn. (12), $k = 0.0248/0.707 = 0.035$.

(e) From Table 2, $Qk = 1.41$

$$Q = 1.41/0.035 = 40.2.$$

(f) Assuming a value for $C_1 (= C_2)$ of $80 \mu\text{F}$ (including strays)

$$L = 25.33/0.455^2 \times 80 = 1.53 \text{ mH}$$

and take $L = L_1 = L_2 = 1.53 \text{ mH}$.

(g) To determine the average stage gain in the pass band. From Fig. 26.4 (or eqn. 14), with $Qk = 1.41$, reading from the dotted curve, gain reduction factor equals 0.97. Assuming we use a type 6J8-G converter valve having a conversion conductance of $290 \mu\text{mhos}$ (0.29 mA/volt), then from eqn. (5) and the gain reduction factor,

$$\begin{aligned} \text{Average stage gain} &= 0.97 \times \pi \times 0.29 \times 40.2 \times 0.455 \times 1.53 \\ &= 24.7 \text{ times (or 27.9 db).} \end{aligned}$$

(h) Assume that the transformer is connected between a type 6J8-G converter and a type 6SK7 voltage amplifier and that both valves are working under a particular set of operating conditions.

For type 6J8-G the conversion plate resistance $r_p = 4\text{M}\Omega = R_1$ and for the type 6SK7 the short circuit input resistance $= 6.8 \text{ M}\Omega = R_2$ (as determined from Chapter 23, Sect. 5).

From Equation (7)

$$\alpha = 40.2 \times 0.17 \times 10.8 = 73.8; \alpha^2 = 0.544 \times 10^4$$

$$\beta = 2[27.2 - 0.17^2] = 54.4 \text{ approximately}$$

$$Q_u = \frac{73.8 + \sqrt{0.544 \times 10^4 + 4.76 \times 10^6}}{54.4} = 41.4,$$

so that $Q_u = Q_{u1} = Q_{u2} = 41.4$ which is the unloaded value for primary and secondary Q 's before the transformer is connected between the two valves; the additional refinement in design is hardly necessary here, and it would be sufficient to make $Q = Q_1 = Q_2 = 40$ (approx.).

FIG. 26.5 ILLUSTRATION OF TERMS USED FOR OVER-COUPLED TRANSFORMERS

It can easily be checked, using the procedure set out for critically-coupled transformers, that the geometrical-mean of the loaded values Q_1 and Q_2 is 40.2 as required. Complete resonance and phase shift curves are plotted as previously explained. The values for k can be set in exactly the same way as explained in the section on critically-coupled transformers, if this is convenient. If k is high it is preferable to apply one of the following methods.

(C) k measurement (when k is high)

When k is high, one of the following methods may be used

The first of these uses the relationship

$$\Delta C = C_1 k^2 / (1 - k^2)$$

$$\text{or } k = \sqrt{\frac{\Delta C}{\Delta C + C_1}}$$

where C_1 = capacitance required to tune the primary to resonance with the secondary open circuited.

k = coefficient of coupling required (say k greater than 0.1 or so)
and ΔC = increment in capacitance required to tune the primary to resonance when the secondary is short circuited.

As an illustration suppose $k = 0.2$ and $C_1 = 200 \mu\text{F}$ (the exact working frequency may not always be convenient) then $\Delta C = 8.34 \mu\text{F}$. Using a "Q" meter, the spacing between primary and secondary is adjusted until this increment in capacitance is obtained; this gives the required value of k .

With some transformers, neither of the two methods given previously will be convenient, and a third method is required. In this case a "Q" meter is again used, and the two transformer windings are connected firstly "parallel aiding" and then "parallel opposing." Any convenient resonance frequency may be selected, and the two capacitance values (C_1 and C_2) required to resonate the coils with the two different connections are noted. The coefficient of coupling is then given by

$$k = \left(\frac{1 + a^2}{2a} \right) \left(\frac{C_1 - C_2}{C_1 + C_2} \right)$$

where $a^2 = L_2/L_1$. (This result was determined by J. B. Rudd).

For a pre-determined value of k the relationship

$$\Delta C = \frac{4akC_2}{1 + a(a - 2k)}$$

is applied; where ΔC = change in capacitance = $C_1 - C_2$.

As an example, suppose $L_1 = L_2$ (i.e. $a^2 = 1$) the capacitance $C_2 = 100 \mu\text{F}$ and $k = 0.1$ is required. Then

$$\Delta C = \frac{4 \times 1 \times 0.1 \times 100}{1 + 1(1 - 2 \times 0.1)} = 22.2 \mu\text{F}.$$

This method should not be used for small values of k (say below about 0.02) as it does not take into account capacitive coupling. For k equal to 0.02 or less the method of Sect. (ii)E should always be used. For k greater than about 0.2 the short-circuit/open-circuit method, given previously, is usually the most convenient. All measurements must be made with the transformer in its can, and the can should be earthed.

In cases where a "Q" meter is not available, the operation of the transformer can be checked using a single stage amplifier and measuring the selectivity curve with a signal generator and a valve voltmeter. Alternatively, measurements can be made in the receiver, and a typical case is illustrated in Chapter 27 Sect. 2(iv) in connection with measurements on ratio detectors (see also Chapter 14 of Ref. 17).

(iv) Under-coupled transformers and single tuned circuits

It is sometimes necessary to use combinations of single tuned circuits or under-coupled transformers in conjunction with over-coupled circuits to give a substantially level response over the pass band. Another application for the under-coupled transformer often arises when an improvement in selectivity is needed, without an excessive loss in stage gain. It has been shown by Adams (Ref. 9) that the optimum conditions for selectivity and gain for a given Q , are obtained when the coefficient of coupling is approximately 0.82 of critical. However, it is readily shown for a transformer having k equal to $0.5 k_c$ that the loss in gain is only about 2 db (approx. 0.8 of maximum gain).

The design equations (Ref. 1) that follow are applicable to single tuned circuits, which will be considered first:

(A) Single Tuned Circuits

$$\rho = (1 + X^2)^{N/2} \quad (16)$$

$$X = (\rho^{2/N} - 1)^{\frac{1}{2}} \quad (17)$$

$$Q = \frac{Xf_0}{2\Delta f} \quad (18)$$

$$\text{and } \theta = \tan^{-1} \frac{2\Delta f}{f_0} Q = \tan^{-1} X \quad (19)$$

where ρ = attenuation at Δf c/s off resonance

N = number of identical tuned circuits (for a single tuned circuit $N = 1$)

f_0 = resonant frequency

and θ = phase shift between current at resonance and the current at Δf c/s off resonance.

The design of the single tuned circuit presents no difficulty, and it is only necessary to use Table 3 in conjunction with eqns. (16), (17) and (18). Selectivity and phase shift can be found from the universal curves of Figs. 9.17 and 9.18 (Chapter 9 Sect. 10), or selectivity can be evaluated directly from eqns. (16), (17) and (18) used in conjunction with Table 3.

TABLE 3. SINGLE TUNED CIRCUITS

For use with equations (16), (17) and (18)

N = number of identical tuned circuits

Attenuation (ρ)		$N = 1$	$N = 2$	$N = 3$
Times Down	db Down	X	X	X
$\sqrt{2}$	3	1.00	0.644	0.509
2	6	1.73	1.00	0.767
4	12	3.87	1.73	1.23
7	17	6.93	2.45	1.63
10	20	9.95	3.00	1.91
20	26		4.36	2.52
40	32		6.25	3.27
70	37		8.31	4.00
100	40		9.95	4.53
1000	60			9.95

(B) Example

Two single tuned circuits are required to give an attenuation of 17 db for a total bandwidth of 10 Kc/s. The i-f is 455 Kc/s.

(a) From Table 3, $X = 2.45$ (since $N = 2$).

(b) $Q = 2.45 \times 455/10 = 111.5$ from eqn. (18).

(c) Assuming $C = 200 \mu\text{F}$ (including all strays)

$$L = 25.33/0.455^2 \times 200 = 0.611 \text{ mH.}$$

(d) The unloaded Q required depends on the combined effects of valve input and output resistance. Take the loading for the two transformers as being the same, for simplicity.

Then suppose $r_p = 0.8 \text{ M}\Omega$ and grid input resistance = $6.8 \text{ M}\Omega$ the effective shunt resistance is $0.715 \text{ M}\Omega$.

From eqn. (6)

$$Q_u = 111.5 \times 0.715/(0.715 - 0.194) = 153.$$

(e) The gain of each stage (twice that for a critically-coupled transformer) is $g_m Q \omega_0 L$, so that taking $g_m = 2 \text{ mA/volt}$ ($2000 \mu\text{mhos}$) in each case, stage gain = $2\pi \times 2 \times 111.5 \times 0.455 \times 0.611 = 390$ times (or 51.8 db).

(f) Suppose we have the loaded Q given as 111.5 (as in our previous problem using $N = 2$), and we require the bandwidth for 6 db attenuation; from table 3 obtain $X = 1.0$ and from eqn. (18) the total bandwidth ($2\Delta f$) is 4.08 Kc/s. In a similar manner the attenuation can be found when the bandwidth is stated. The resonance curves could also be used to find X ($= D$ in Chapter 9, in this case) and ρ .

(C) Under-coupled transformers

If the transformers use very loose coupling, the methods for single tuned circuits could be applied ($N = 2$ for each transformer) in conjunction with eqn. (7). This

approach does not lead to very accurate results since the values of coupling are seldom less than 0.1 of critical and more often are of the order of 0.5 to 0.8 of critical.

General design equations applicable to transformers having any degree of coupling are given below, but it will be seen that they are not quite as tractable as in previous cases unless an additional factor such as Q , k , or Qk (i.e. a given proportion of critical-coupling) is specified. However, this will offer little difficulty.

$$X' = \{[(1 - \alpha^2)^2 + (\rho^{2/N} - 1)(1 + \alpha^2)^2]^{\frac{1}{2}} - (1 - \alpha^2)\}^{\frac{1}{2}} \quad (20)$$

$$\rho = \left[\frac{(1 + \alpha^2 - X'^2)^2 + 4X'^2}{(1 + \alpha^2)^2} \right]^{N/2} \quad (21)$$

$$X = (2\Delta f/f_0)Q \quad (22)$$

$$Qk = \alpha = \left[\frac{X\{X^2 + (X^2 + 4)(\rho^{2/N} - 1)\}^{\frac{1}{2}} - (X^2 + \rho^{2/N} - 1)}{\rho^{2/N} - 1} \right]^{\frac{1}{2}} \quad (23)$$

$$\theta = \tan^{-1} 2X/[1 - X^2 + \alpha^2] \quad (13)$$

where ρ = attenuation at Δf c/s off resonance

$$\alpha = Qk = k/k_c$$

$Q = \sqrt{Q_1 Q_2} = 1/k_c$ (in which Q_1 and Q_2 are the primary and secondary Q 's and k_c is critical coupling coefficient)

k = any coefficient of coupling

N = number of identical transformers

f_0 = resonant frequency

and θ = phase shift between secondary current at and off resonance.

The restriction of Q_1/Q_2 or $Q_2/Q_1 \geq 2$ is applied, as previously explained.

It may be observed that these equations are the most general ones, e.g. if $Qk = 1$ the equations reduce to those for critical-coupling.

Stage gain is given by evaluating eqn. (5) and multiplying by eqn. (15) (or reading the gain reduction factor from Fig. 26.4).

The coefficient of coupling can be set as described for critically-coupled transformers.

(D) Example

A 455 Kc/s i-f transformer is required to give a total bandwidth of 20 Kc/s for an attenuation of 4 times. The transformer is to be connected between a voltage amplifier, having a plate resistance of 0.8 M Ω (e.g. type 6SK7), and a diode detector having a load resistance of 0.5 M Ω .

In this case other loading effects due to the a.v.c. system etc. will be neglected. For a typical case where the a.v.c. diode plate is connected by a fixed capacitor to the i-f transformer primary, there will be appreciable damping of the primary circuit due to the diode circuit (approx. $R_L/3$ when diode is conducting). This damping will not be constant for all signal input voltages, particularly if delayed a.v.c. is used.

- (a) The difficulty first arises in evaluating X . If we select a suitable value for Q the problem becomes quite straightforward.

To select a value for Q it is necessary to realize that an unloaded value of 150 would be about the absolute maximum with normal types of construction, and even this figure is well on the high side unless an "iron pot" or a fairly large can and former are used. Assume $Q = 150$ for this problem (so far as the procedure is concerned it is unimportant if a lower value is selected).

The next point is that circuit loading will set a limit to the value of $Q\omega_0 L$ ($= Q/\omega_0 C$). Now L will be set, normally, by the minimum permissible value of C . Suppose $C = 85 \mu\text{F}$ including strays, then $L = 1.44 \text{ mH}$; and we will take $L = L_1 = L_2$ and $C = C_1 = C_2$ for practical convenience. Better performance would be possible by making $L_1 > L_2$ but the improvement is only small, and hardly worthwhile unless the secondary load is very small.

- (b) For our problem

$$\omega_0 L = 1/\omega_0 C = 4120 \Omega; \text{ also } R_1 = 0.8 \text{ M}\Omega \text{ and}$$

$$R_2 = 0.5/2 = 0.25 \text{ M}\Omega \text{ (half the d.c. diode load resistance).}$$

Then applying eqn. (8)

$$Q_2 = \frac{150 \times 0.25}{0.25 + (150 \times 4.12 \times 10^{-3})} = 43.3$$

$$\text{and } Q_1 = \frac{150 \times 0.8}{(0.8 + 0.618)} = 84.6$$

so that

$$Q = \sqrt{Q_1 Q_2} = \sqrt{84.6 \times 43.3} = 60.5.$$

(c) From eqn. (22)

$$X = \frac{20 \times 60.5}{455} = 2.66.$$

(d) From eqn. (23)

$$Qk = \left[\frac{2.66\{2.66^2 + (2.66^2 + 4)(4^2 + 1)\}^{\frac{1}{2}} - (2.66^2 + 4^2 - 1)}{4^2 - 1} \right]^{\frac{1}{2}} = 0.93$$

$$\text{and } k = 0.93/60.5 = 0.0154.$$

(e) From eqns. (5) and (15) (the solid curve of Fig. 26.4)

$$\begin{aligned} \text{Stage gain} &= \frac{(2 \times 60.5 \times 4.12)}{2} = 0.996 \\ &= 249 \text{ times or } 47.9 \text{ db.} \end{aligned}$$

(f) The completed transformer has primary and secondary Q 's of 150 (before connection into the receiver), a coefficient of coupling equal to 0.0154 (which is 0.93 of critical-coupling when the transformer windings are loaded) primary and secondary inductances of 1.44 mH and tuning capacitances of 85 $\mu\mu\text{F}$ (including strays). The stray capacitances across the primary would be valve output (7 $\mu\mu\text{F}$ for type 6SK7) plus distributed capacitance of winding, plus capacitances due to wiring and presence of shield *etc.*; across the secondary there would be diode input capacitance (about 4 $\mu\mu\text{F}$ for a typical case), plus distributed capacitance of secondary winding plus wiring and shield can capacitances. The total capacitances can be measured in the receiver or estimated using previous experience as a guide; typical values would be 10-20 $\mu\mu\text{F}$ depending on the type of i-f transformer, valves *etc.* If the second valve is not a diode, the input capacitance should also include that due to space charge, Miller effect *etc.* as discussed in Chapter 2 Sect. 8; Chapter 23 Sect. 5 and Sect. 7 of this chapter. However, in most practical cases the total capacitance across the secondary is estimated by adding a suitable value to the valve input capacitance. Changes in input resistance which would affect the loading across the i-f transformer secondary, are also discussed in these same sections. Input capacitance changes with a.v.c. are considered in Sect. 7 of this chapter.

(g) A complete resonance curve can be obtained from Fig. 9.17 (Chapter 9 Sect. 10), by taking

$$D = Q2A/f_0 (= X) \text{ and } b = Qk = k/k_c,$$

or directly from the design equations (20), (21) and (22).

(v) F-M i-f transformers

(A) Design data

The design methods given so far are applicable to both F-M and A-M transformers, but there are additional data available which will be of assistance (see also Sect. 9(ii) of this chapter for an alternative design procedure based on permissible non-linear distortion).

Bandwidth requirements are of importance, and it is fairly generally accepted that the i-f amplifier should be capable of passing all significant sideband frequencies of the frequency modulated wave; where significant sidebands are taken as those having amplitudes which are greater than about 1% of the unmodulated carrier amplitude. The bandwidths for this condition can be found from Table 4 (see also Ref. 19) for commonly occurring values of modulation index.

TABLE 4. BANDWIDTHS FOR USE WITH F-M TRANSFORMERS

$$\text{Modulation Index} = \frac{\Delta F}{f} = \frac{\text{carrier frequency deviation}}{\text{audio modulating frequency}}$$

Values for $\frac{\Delta F}{f}$ may be interpolated with sufficient accuracy

$\Delta F/f$	= 0.01-0.4	0.5	1.0	2.0	3.0	4.0	5.0	6.0
Bandwidth	= $2f$	$4f$	$6f$	$8f$	$12f$	$14f$	$16f$	$18f$
$\Delta F/f$	= 7.0	8.0	9.0	10.0	12.0	15.0	18.0	21.0
Bandwidth	= $22f$	$24f$	$26f$	$28f$	$32f$	$38f$	$46f$	$52f$

As an example, for the F-M broadcast band $\Delta F = \pm 75$ Kc/s and the highest audio frequency is 15 Kc/s, then $\Delta F/f = 75/15 = 5$.

Then the required bandwidth is $16 \times 15 = 240$ Kc/s.

The highest audio frequency is chosen because this imposes the most severe requirements on bandwidth ; e.g. suppose we had taken $f = 7.5$ Kc/s, then the modulation index would be 10, and the bandwidth $= 28f = 28 \times 7.5 = 210$ Kc/s.

The bandwidths actually employed in a receiver should also make allowance for possible drift in the oscillator frequency. A reasonably good oscillator should not drift by more than about ± 20 Kc/s when operating around 110 Mc/s ; so that an additional 40 Kc/s should be added to the bandwidth. Of course, this is only a rough approximation, since the oscillator frequency variation is random and would introduce additional frequency modulation ; the determination of the true bandwidth would be quite a difficult problem, unless several simplifying assumptions are made.

From what has been said, it appears that the receiver total bandwidth should be about 280 Kc/s to fulfil the most severe requirements. However, most practical receivers limit the total bandwidth to about 200 Kc/s, which is not unreasonable since the average frequency deviation is about ± 50 Kc/s.

For such large bands of frequencies to be passed through tuned circuits which do not give transmission (for the bandwidth desired) without attenuation it is necessary to have some criterion which will allow the permissible amount of attenuation to be estimated. To eliminate non-linear distortion the circuits should provide a uniform amplitude and a linear phase characteristic over the operating range. Curvature of the phase characteristic of the tuned circuits will cause non-linear a-f distortion, while curvature of the amplitude characteristic may cause additional distortion if the amplitude happens to drop below the operating voltage range of the amplitude limiting device incorporated in the receiver. A suitable criterion can be determined from the phase angle/frequency characteristics of the tuned circuits (the phase angle being that between the secondary current at resonance to that at Δf c/s off resonance). Inspection of universal phase shift curves will show that the greatest range of linearity of phase shift versus frequency change, is given by critically-coupled transformers (Ross, Ref. 2) ; but slight overcoupling does not lead to excessive non-linearity. Overcoupling has some advantages, in particular slightly greater adjacent channel selectivity can be obtained ; but there is the disadvantage of more difficult circuit alignment. As an extension of this work, Ross (Ref. 2) has also shown that for a critically-coupled transformer a suitable criterion of permissible non-linearity is that

$$X \gg 2 \quad (24)$$

where we will take

$$X = (2\Delta f/f_0)Q \quad (\text{this is the same } X \text{ as previously})$$

$2\Delta f$ = total bandwidth

f_0 = central carrier frequency

and $Q = \sqrt{Q_1 Q_2}$ (where Q_1 and Q_2 are the primary and secondary magnification factors).

The amount of introduced amplitude modulation can be estimated from

$$m = \frac{\rho - 1}{\rho + 1} \quad (25)$$

where m = amplitude modulation factor

and ρ = attenuation at bandwidth of twice deviation frequency (i.e. $2\Delta f = 2\Delta F$).

Fig. 26.6 shows directly values of m for various values of X . Values of m are of importance since they allow an estimate to be made of the amplitude limiting requirements demanded from whatever device is incorporated in the receiver to "iron out" amplitude variations.

Many F-M receiver designs allow anything from 20% to 50% of introduced amplitude modulation, but these figures should always be considered in connection with the amount of non-linear distortion introduced by the tuned circuits [see Sect. 9(8)]. Good designs often allow considerably less than 20% of introduced amplitude modulation.

It is also worth noting, before leaving this section, that the carrier frequency should be regarded as a reference point only, since, unlike amplitude modulation, its amplitude varies and becomes zero under some conditions of modulation. This is the basis of a method due to Crosby (Ref. 25) used for measuring frequency deviation.

FIG. 26.6 PERCENTAGE OF INTRODUCED A-M IN AN F-M CURRENT FOR N CRITICALLY COUPLED TRANSFORMERS

(B) Example

A F-M i-f amplifier is required using three critically-coupled transformers. The i-f is 10.7 Mc/s and the frequency deviation ± 75 Kc/s; the highest a-f modulating frequency is 15 Kc/s (critical-coupling has been selected in this case but a combination of critical and over-coupled transformers might lead to a better solution).

The converter valve to be used has a conversion r_p of $1.5 M\Omega$ and a conversion conductance of $475 \mu\text{mhos}$; and the two i-f valves each have plate resistances of $2 M\Omega$ and $g_m = 5000 \mu\text{mhos}$.

- (a) For simplicity it will be taken that any additional selectivity, due to the other tuned circuits in the receiver, is negligible. Also, as will be illustrated, the dynamic impedances of the i-f transformers will be so low as to render additional damping due to plate and grid input resistances negligible; this is not true, however, if the final transformer is connected to a limiter stage because of grid current damping—some consideration will be given to this later.

- (b) From previous considerations regarding bandwidth, in connection with Table 4, we will adopt 220 Kc/s as a compromise.

If we design on the limit of $X = 2$, then from eqn. (3)

$$Q = \frac{2 \times 10.7 \times 10^6}{220 \times 10^3} = 97.4$$

and $k_c = 1/Q = 0.0103$.

- (c) Taking $2\Delta f = 2\Delta F = 150$ Kc/s, for maximum frequency deviation, since $Q = 97.4$ and $N = 3$, then, from eqn. (3), $X = 1.365$ and, from equation (1), $\rho = 2.55$, whence from eqn. (25) or Fig. 26.6,

$$m = \frac{2.55 - 1}{2.55 + 1} = 0.436 \text{ or } 43.6\% \text{ amplitude modulation.}$$

- (d) This is a severe additional requirement for limiters etc., and could also lead to high distortion, although the condition for linearity of phase shift with frequency is fulfilled. The distortion can be found from eqn. (54) for each of the transformers.

- (e) Select suitable values for C_1 and C_2 . To obtain the highest possible dynamic impedance these are usually made rather small. Take

$$C_1 = C_2 = 60 \mu\text{F} \text{ (including strays)}$$

$$L (= L_1 = L_2) = \frac{25330}{10.7^2 \times 60} = 3.68 \mu\text{H.}$$

There would be an advantage in making $C_1 < C_2$ and $L_1 > L_2$ but this is awkward for winding i-f's on a machine.

- (f) The dynamic impedance of each winding (considered uncoupled from one another) is

$$R_0 = Q\omega_0 L = 97.4 \times 2\pi \times 10.7 \times 3.68 = 24\,000 \, \Omega$$

which is very much less than the valve plate or input resistances in typical stages.

- (g) To find the overall gain of the i-f stages :—For the first stage, connected to the converter, we are concerned with conversion gain.

From eqn. (5) and step (f),

Conversion gain = $475 \times 10^{-6} \times 24\,000/2 = 5.7$ times (15.1 db). For the second and third stages in each case, gain = $5.7 \times 5/0.475 = 60$ times (35.6 db). Hence the overall gain is $15.1 + (2 \times 35.6) = 86.3$ db.

- (h) If the third transformer connects to a limiter its design should be modified for best results ; however, this is not done in many receivers. Grid current will alter the effective input capacitance of the limiter valve and cause very appreciable detuning of the transformer secondary. To overcome this detuning it may be necessary to make the pass band of this transformer somewhat greater than for the other two, or else to use a very large capacitance (of the order of 600 $\mu\mu\text{F}$) to tune the secondary (tapping down is also effective). It has also been suggested that Q_1 should equal Q_2 in this case (Ref. 21). The important point, apart from possible distortion, is that the susceptibility to certain types of impulse noise is increased if the tuned circuits are not accurately aligned to the centre frequency of the discriminator. Further, when the i-f circuit is detuned, additional amplitude modulation will be introduced, and this increases the difficulty of obtaining effective limiting. Grid current damping, of course, would tend to offset the effect to some extent (see also Refs. 21, 24). Since this transformer would probably be non-standard in any case, it would be advantageous to make L_1 as large as possible, to assist in keeping the stage gain high. This follows as a result of the stage gain being directly proportional to $\sqrt{L_1 L_2 Q_1 Q_2} = LQ$.

- (i) It is important to check whether the i-f transformers will provide sufficient adjacent channel selectivity. This will depend on the frequency allocations of the various transmitters. In the U.S.A. local F-M transmissions are usually spaced 400 Kc/s apart, and the past experience of some designers has indicated that adjacent selectivity is adequate if the receiver bandwidth is not more than about 800 Kc/s for a relative attenuation of 60 db.

In the example above there are three critically-coupled transformers each having a nominal Q of 97 :

From Table 1, $X = 4.46$ for 60 db attenuation.

From eqn. (3)

$$2\Delta f = \frac{Xf_0}{Q} = \frac{4.46 \times 10.7 \times 10^6}{97} = 494 \text{ Kc/s.}$$

However, commercial F-M receivers have given reasonably satisfactory performance with two i-f transformers with Q 's of about 75 leading to a bandwidth of 1140 Kc/s for 60 db attenuation. It might also be noted that larger commercial receivers generally use three transformers with Q 's of about 70 to 75 and not 97 as found in the worked example, which is not to be taken as indicating good design practice.

Whether the selectivity performance is entirely adequate will depend very largely on the relative field strengths of the desired and undesired transmissions at the point of reception, and it is to be expected that more exact figures will only be decided on after a number of years' experience with practical operating conditions. The problem is similar to that of the A-M broadcast receivers (using 455 Kc/s i-f transformers) where it is usually taken that adjacent channel selectivity will be adequate if the overall band-

width does not exceed about 40 Kc/s for 60 db attenuation relative to the response at the centre frequency, although many commercial receivers have bandwidths of less than 30 Kc/s for the same attenuation.

(vi) I-F transformer construction

The methods of (i) to (v) in this section will allow the necessary design data for an i-f amplifier to be collected together. The final step is to determine the winding details and physical arrangement of the transformers. It is not proposed to discuss the merits of various types of windings, but merely to give a few details which have proved helpful in practice.

For transformers working at the higher frequencies, the windings are quite often solenoids and the determination of the number of turns required is a simple matter. Satisfactory results can be obtained by applying Hayman's modification of Wheeler's formula as given in Chapter 10. Methods are also set out for determining the number of turns per inch, and suitable wire diameters for obtaining optimum values of Q . Usually wire gauges between 18 and 28 s.w.g. are suitable as they are not so heavy as to be awkward to bend and they do not tear the usual type of coil former when the construction requires the leads to be passed through the inside of the former down to the base connections. Some error in the calculated number of turns will be apparent unless allowance is made for the inductance of leads. The number of turns required is finally determined experimentally in any case so that the calculated number of turns provides a good starting point.

Measurements must always be made with the coils in the cans because the effects of the can, brass mounting bosses, slugs etc. on inductance and Q are quite large.

Powdered iron "slugs" are commonly used for setting the inductance values and, for 10.7 Mc/s in particular, the iron must be very finely divided if the coil Q is not to be seriously changed as the cores are moved through the windings. Sufficient inductance variation also requires that the "slugs" have a certain minimum size.

Silvered mica fixed capacitors are to be preferred for good frequency stability with temperature changes, particularly at high frequencies such as 10.7 Mc/s, and temperature compensation using negative temperature coefficient capacitors is essential if the best results are to be obtained. Cheaper mica types are very often used at the lower frequencies around 455 Kc/s. If capacitance trimmers are to be used, care must be taken in their choice as pressure types are often mechanically unstable and sometimes have very low Q values. Suitable wax or other treatment should be applied to fixed capacitors to offset the effects of changes in humidity.

Coils should be baked* to remove moisture and then given suitable wax or varnish treatment to prevent humidity changes altering their properties. The electrical characteristics of the coils will be altered by wax etc. and it is essential to check the final values for Q , k etc. after the treatment is complete.

Typical former diameters for i-f transformers range from about $\frac{3}{8}$ in. to $\frac{1}{2}$ in., and the grade of material used for the former will affect the stability of the transformer directly when variations in temperature and humidity occur.

The design of transformers with pie windings (a larger number of pies generally reduces distributed capacitance and increases Q) is not as simple as for solenoids since most equations require a knowledge of coil dimensions which are not always available. There are also optimum sizes of winding to give the highest possible Q —see Chapter 10. A method which has proved satisfactory in practice is to make measurements on various types of coils which are likely to be used fairly often and apply the relationship

$$N = B\sqrt{L} \quad (26)$$

where N = turns per pie

L = inductance in μH

and B = experimentally determined constant.

As an example : A winding is to be made to have an inductance of 1.44 mH. Previous experiments have shown that, in the frequency range of 300-900 Kc/s and for

*See also Chapter 11 Sect. 7.

an inductance of about 0.5-2 mH, a two pie winding on a 9/16 in. former (each pie 5/32 in. wide, with 3/32 in. spacing between the pies and using 5/44 A.W.G. Litz wire) has the factor $B = 4.33$. Then from eqn. (26)

$$N = 4.33\sqrt{1440} = 165 \text{ turns per pie ;}$$

the two pies each of 165 turns, being connected series aiding. The same method can be applied in cases where it is convenient, to any type of winding.

Since the presence of the iron "slug" will affect inductance (and r-f resistance) it is necessary to determine its effect and also to calculate the variation in inductance which can be made. The turns required are found for the condition with the "slug" in the winding and in the position giving the mean inductance value. This means that the value of L used in eqn. (26) will be less than the calculated value by the increase due to the iron.

The value of the inductance (L) using a powdered iron core (e.g. magnetite) can be found from

$$L = L_0 \left[1 + a \left(\frac{r_1}{r_2} \right)^2 \left(\frac{l_1}{l_2} \right) (\mu_{eff} - 1) \right] \quad (27)$$

where L_0 = inductance of air cored coil

r_1 = radius of iron core

r_2 = mean radius of coil

l_1 = length of core

l_2 = length of coil

μ_{eff} = effective permeability of iron core (Refs. 88 and 89 list values for μ and μ_{eff} for various types of iron powders ; typical values for μ_{eff} are from 1.5 to 3, depending on the type of iron)

$a = 0.8$ when $l_1 < l_2$

and $a = 1$ when $l_2 < l_1$.

The iron cores in common use are about $\frac{3}{8}$ in. to $\frac{1}{2}$ in. in diameter and range in length from about $\frac{1}{4}$ in. to 1 in. An inductance change of about $\pm 10\%$ when the "slug" is moved through the winding, is generally sufficient for most requirements. The dimensions required for solving eqn. (27) are available if the experimental procedure previously suggested has been carried out on air cored coils ; or the whole procedure can be carried out experimentally.

Some manufacturers make up 455 Kc/s i-f transformers completely enclosed in powdered iron pots. There is often little difficulty with this construction in obtaining Q 's in the order of 150. Stray capacitances are often large, however, and sometimes lead to very unsymmetrical resonance curves.

At the lower frequencies (up to about 1 or 2 Mc/s) Litz wire is advantageous for obtaining high Q values and 3, 5, 7 and 9 strands of about 44 A.W.G. (or near S.W.G. or A.W.G. gauges) wire are common ; Q values greater than about 120 will require some care in the transformer construction, and the size of can selected will materially affect the value obtainable (see Ref. 91 for illustration).

The required values of L_1 , L_2 , k , etc. for developmental purposes are conveniently found using a Q meter. Methods for setting k , using a Q meter, have already been outlined in this section. For an experimental transformer it is of assistance to place the windings on strips of gummed paper (sticky side outwards) wrapped around the former. In this way the windings can be moved quite readily along the former.

It should be noted that some variation in k can be expected when the transformer is connected in the receiver because of alteration of "slug" position, added top capacitance coupling (this occurs for example because of capacitance between the a.v.c. and detector diodes) etc. Regeneration is also troublesome as it alters the effective Q values, and hence the conditions for critical k . To avoid overcoupling it is sometimes desirable to make the value of k somewhat less than is actually required (often about 0.8 to 0.95 of the critical value depending on the receiver construction and i-f). If all added coupling is accounted for and the Q values are those specified then no difficulty arises. Some slight increase in coupling, in the receiver, is not necessarily serious, because the loaded primary and secondary Q 's are not always equal. In this

case a double hump in the secondary voltage does not appear until transitional coupling has been exceeded, and the k required for this to occur is always higher than k critical; transitional and critical k are the same, of course, when primary and secondary Q 's are equal.

For the capacitance and mutual inductance coupling to be aiding, the primary and secondary windings are arranged so that if the plate connects to the start of the primary, then the grid (or diode plate) of the next stage connects to the finish of the secondary winding; both coils being wound in the same direction. This method of connection also assists in keeping the undesired capacitance coupling to a minimum. The order of base connections is also important in reducing capacitance coupling and the grid and plate connections should be as far from one another as possible.

The cans to be used with i-f transformers should be as large as is practicable. They are generally made from aluminium, although copper was extensively used at one time. Cans should preferably be round and seamless. Perfect screening is not obtained, in general, and care is necessary in the layout of the various stages to ensure that the transformers are not in close proximity to one another. When mounting the transformer into a can, if there is a choice as to the position of the leads (although this is largely determined by the valve type available) it is always preferable to bring the connections for each winding out to opposite ends, as this reduces stray capacitance coupling. The effects of the coil shield on inductance and r-f resistance can be calculated (see Chapter 10 and Ref. 4, p. 134) and the results serve as a useful guide, but direct measurement on the complete transformer is the usual procedure. Mechanical considerations generally ensure that the can is thick enough to provide adequate shielding (for considerations of minimum thickness see Ref. 4, p. 135).

Methods for determining gear ratios, winding pitch and so on, for use with coil winding machines are discussed in the literature (Refs. 29, 30, 31, 32); see also Chapter 11, Sect. 3(iv) in particular.

Finally, the measure of the success of any i-f transformer design will be how closely the predicted performance approaches the actual results obtained when the transformer is connected into the receiver.

(vii) Appendix : Calculation of Coupling Coefficients

For the calculation of the coefficient of coupling (see also Chapter 9) it is helpful to use the following rules of procedure:

(a) If the coupling circuit is drawn as a T section, the coefficient of coupling is given by the ratio of the reactance of the shunt arm divided by the square root of the product of the sum of the reactances of the same kind in each arm including the shunt arm,

$$\text{i.e. } k = \frac{X_m}{\sqrt{(X_1 + X_m)(X_2 + X_m)}}.$$

(b) If the coupling circuit is drawn as a Π section, the coefficient of coupling is given by the ratio of the susceptance of the series arm divided by the square root of the product of the sum of the susceptances of the same kind in each arm including the series arm,

$$\text{i.e. } k = \frac{B_m}{\sqrt{(B_1 + B_m)(B_2 + B_m)}}.$$

A few examples will now be given to illustrate the procedure. From rule (a) applied to Fig. 9.15,

$$k = \frac{X_m}{\sqrt{(X_1 + X_m)(X_2 + X_m)}} = \frac{L_m}{\sqrt{(L_1 + L_m)(L_2 + L_m)}}.$$

For Fig. 9.12 using rule (b)

$$k = \frac{B_m}{\sqrt{(B_1 + B_m)(B_2 + B_m)}} = \frac{C_m}{\sqrt{(C_1 + C_m)(C_2 + C_m)}}.$$

For Fig. 9.14 using rule (a)

$$k = \frac{1/C_m}{\sqrt{\left(\frac{1}{C_1} + \frac{1}{C_m}\right)\left(\frac{1}{C_2} + \frac{1}{C_m}\right)}} = \sqrt{\frac{C_1 C_2}{(C_1 + C_m)(C_2 + C_m)}}.$$

For Fig. 9.13 using rule (b)

$$k = \frac{1/L_m}{\sqrt{\left(\frac{1}{L_1} + \frac{1}{L_m}\right)\left(\frac{1}{L_2} + \frac{1}{L_m}\right)}} = \sqrt{\frac{L_1 L_2}{(L_1 + L_m)(L_2 + L_m)}}.$$

It is sometimes helpful to make use of the obvious relationship in the form of k for the two types of circuit, by drawing dual networks and writing down the value of k for the duals as though capacitances were inductances and vice versa, e.g. the inductances of Fig. 9.13 are the duals of the capacitances of Fig. 9.14, and so the value of k is written down for, say, Fig. 9.14 and if k is required for Fig. 9.13 we merely substitute the symbols $L_1 L_2 L_m$ for $C_1 C_2 C_m$.

As a more difficult example the coefficient of coupling for Fig. 9.16(A) will be calculated. Firstly redraw the two coupled circuits as two T sections and then combine the two directly connected series arms. The complete coupling circuit now comprises a series arm $L_1 - M_1$; a Π section made up from M_1 , $L_1' - M_1 + L_2' - M_2$, M_2 ; a series arm $L_2 - M_2$. Transforming the Π section to a T section and adding the two series arms of the previous circuit to the new series arms, we have a single T section in which the first series arm is

$$\frac{M_1(L_1' - M_1 + L_2' - M_2)}{L_1' + L_2'} + L_1 - M_1 = \frac{L_1(L_1' + L_2') - M_1(M_1 + M_2)}{L_1' + L_2'}$$

the second series arm is

$$\frac{M_2(L_1' - M_1 + L_2' - M_2)}{L_1' + L_2'} + L_2 - M_2 = \frac{L_2(L_1' + L_2') - M_2(M_1 + M_2)}{L_1' + L_2'}$$

and the shunt arm is $\frac{M_1 M_2}{L_1' + L_2'}$.

Applying rule (a), and writing $L_m = L_1' + L_2'$,

$$\begin{aligned} k &= \frac{M_1 M_2}{\sqrt{[L_1 L_m - M_1(M_1 + M_2) + M_1 M_2][L_2 L_m - M_2(M_1 + M_2) + M_1 M_2]}} \\ &= \frac{M_1 M_2}{\sqrt{(L_1 L_m - M_1^2)(L_2 L_m - M_2^2)}} \\ &= \frac{k_1 k_2}{\sqrt{(1 - k_1^2)(1 - k_2^2)}} \end{aligned}$$

where $k_1 = \frac{M_1}{\sqrt{L_1 L_m}}$ and $k_2 = \frac{M_2}{\sqrt{L_2 L_m}}$.

As a further example a bridged T coupling section will be considered, made up from inductances bridged by a capacitance. This corresponds to the familiar case of a mutual inductance coupled transformer with added top capacitance coupling (e.g. Fig. 9.16D) and also refers to any practical i-f transformer because of the presence of stray capacitance affecting the coupling between the primary and secondary windings.

The procedure in this case is to use rule (a) and determine the coupling coefficient due to mutual inductance (the inductances are considered as forming a T network); call this k_m . Next use rule (b) to determine the coupling coefficient due to capacitance coupling (the capacitances form a Π network); call this k_c . Then if the connections are such that the two forms of coupling aid each other, the resultant coupling coefficient is

$$k_T = \frac{k_m + k_c}{1 + k_m k_c}$$

and if $k_m k_c \ll 1$ then

$$k_T = k_m + k_c \text{ (approximately).}$$

For the case of the two forms of coupling being in opposition

$$k_T = \frac{k_m - k_c}{1 - k_m k_c}$$

and if $k_m k_c \ll 1$ then

$$k_T = k_m - k_c \text{ (approximately).}$$

The above expressions for k_T can be derived quite simply from data given in Ref. 101, or directly using a similar method to that set out below. The results are most helpful in determining rapidly the effect of additional top capacitance coupling e.g. an i-f transformer is connected between the last i-f amplifier valve and a diode detector, and the a.v.c. diode is connected to the primary of the transformer in the usual manner. Then clearly there is top capacitance coupling added across the i-f transformer due to the direct capacitance between the two diodes, and a knowledge of the value of this capacitance will allow the added coupling to be taken into account when designing the transformer. If the capacitance value is not known its effect can be estimated when a response curve is taken.

This method for finding k_T can be applied in exactly the same way to a bridged T coupling network in which the two main series arms are inductances with mutual inductance coupling between them, the shunt arm is a capacitance and the T is bridged by a capacitance.

An alternative procedure, and a most important one, for determining k will now be discussed. This method can be applied quite generally to determining coupling coefficients for Π and T networks which have $L_1 C_1 = L_2 C_2$. The method is due to Howe and the reader should consult Refs. 99 and 100 for a more detailed explanation. This procedure uses the relationship

$$k = \frac{\omega_1^2 - \omega_2^2}{\omega_1^2 + \omega_2^2}$$

where ω_1 is the higher angular frequency of free oscillation in the circuit and ω_2 is the lower angular frequency of free oscillation.

FIG. 26.6 A

FIG. 26.6 B

ω_1 is calculated from Fig. 26.6A, which shows a symmetrical T network with mixed coupling, by considering the capacitors C to be charged as shown. During the discharge of the capacitors it is clear that $L_m C_m$ have no effect on the resonant frequency in this case, and

$$\omega_1^2 = 1/LC.$$

ω_2 is calculated from Fig. 26.6B in which the capacitors C are charged as shown. In this case, when the capacitors are discharging, it is convenient to consider the shunt arm as being made up of two equal parts each carrying the primary and secondary current alone; the reactances of L_m and C_m being doubled to allow for the single current. Then

$$\omega_2^2 = \frac{1}{(L + 2L_m) \left(\frac{CC_m/2}{C + C_m/2} \right)}$$

$$\text{so that } k = \frac{L_m C_m - LC}{L_m C_m + LC + LC_m}.$$

A somewhat similar procedure can be applied to a Π network, or an equivalent T network can be found and the above procedure applied.

For cases where the sections are unsymmetrical some modification in the procedure is necessary. Taking the case of a T section using inductance coupling (with $L_1C_1 = L_2C_2$) the shunt arm is replaced by two inductances (x_1 and x_2) in parallel such that their combined inductance equals that of the shunt arm (L_m) and such that the values selected will give equal resonant frequencies for the two circuits

$$\text{i.e. } \frac{L_1 + x_1}{L_2 + x_2} = \frac{C_2}{C_1}.$$

The case of capacitance coupling is treated in a similar way. The procedure is then exactly as before for the symmetrical coupling network. There would be little difficulty in extending this procedure to the case of the unsymmetrical T section using mixed coupling, but it is worth noting that numerical solutions are much easier to handle than a general algebraic solution even in the case of simple coupling.

For the two mesh network just considered, using mixed coupling and in which $L_1C_1 = L_2C_2$ it is usually simpler to use the relationship

$$k_T = \frac{k_m \pm k_c}{1 \pm k_m k_c}$$

as was done for the bridged T network. Taking the example just considered,

$$k_m = \frac{L_m}{L + L_m}$$

$$k_c = \frac{C}{C + C_m}$$

$$\text{and } k_T = \frac{\frac{L_m}{L + L_m} - \frac{C}{C + C_m}}{1 - \frac{L_m C}{(L + L_m)(C + C_m)}} \\ = \frac{L_m C_m - LC}{L_m C_m + LC + LC_m}$$

exactly as before.

It should be carefully noted that in all cases of mixed coupling the sign of L_m is most important. For the example just given L_m was taken as being positive; this is the case of the two forms of coupling being in opposition, and zero voltage transfer occurs when the shunt arm is series resonant. With L_m negative the two forms of coupling aid each other and there is no series resonant frequency. The aiding condition, which is the one usually required, is possible only when the coupling between the two inductances is due to mutual induction, as a physical coupling inductance would act so as to oppose the capacitive coupling.

The methods given so far, for determining the coupling coefficient, are useful for the types of circuit considered. However, it should be observed that they can be applied directly only to the following cases:

(1) Circuits having coupling elements all of the one kind i.e. all capacitances or all inductances (simple coupling).

(2) Circuits having mixed coupling in which the primary and secondary circuits are tuned to the same frequency. However, it is only necessary that $L_1C_1 = L_2C_2$ and the primary and secondary circuit elements need not be identical.

Determination of k for the cases just stated usually presents little difficulty and is simplified by choosing one or other of the procedures outlined; these cases cover most practical requirements. A real difficulty does arise when the primary and secondary are tuned to different frequencies and the coupling is mixed.

It may now be of interest to consider the procedure given below which makes use of the result obtained by Howe (Ref. 98) and follows from the definition that the coupling between two circuits is the relation between the possible rate of transfer of energy and the stored energy of the circuits; by the possible rate of energy transfer is meant the rate of energy transfer in the absence of all resistance other than that utilized for coupling.

The definition leads to the relationship

$$k = \frac{1}{\sqrt{\omega_1 \omega_2}} \sqrt{\frac{E_{12}}{W_1} \cdot \frac{E_{21}}{W_2}}$$

where we have taken for our purposes that

$\omega_1 = 2\pi \times$ resonant frequency of primary circuit with sec. o/c

$\omega_2 = 2\pi \times$ resonant frequency of secondary circuit with pri. o/c

E_{12} = voltage transferred from primary to secondary

= $Z_{m_{12}}$ for a primary alternating current of 1 amp. and angular frequency ω_1

E_{21} = voltage transferred from secondary to primary

= $Z_{m_{21}}$ for a secondary alternating current of 1 amp. and angular frequency ω_2

W_1 = maximum energy stored in primary circuit for an alternating current of 1 amp.

W_2 = maximum energy stored in secondary circuit for an alternating current of 1 amp.

This method can be applied to any two oscillatory circuits coupled together in any manner, when all the elements are linear and bilateral.

As a simple example consider the case covered previously of an unsymmetrical T section of inductances. Then

$$Z_{m_{12}} = \omega_1 L_m; Z_{m_{21}} = \omega_2 L_m; W_1 = L_1 + L_m; W_2 = L_2 + L_m$$

$$\begin{aligned} \text{and } k &= \frac{1}{\sqrt{\omega_1 \omega_2}} \sqrt{\frac{\omega_1 L_m \omega_2 L_m}{(L_1 + L_m)(L_2 + L_m)}} \\ &= \frac{L_m}{\sqrt{(L_1 + L_m)(L_2 + L_m)}} \text{ exactly as before.} \end{aligned}$$

It can be seen that the primary and secondary frequencies need not be considered in cases of this type involving simple coupling only.

Now consider an unsymmetrical T section with mixed coupling, and different primary and secondary resonant frequencies :

$$Z_{m_{12}} = \omega_1 L_m - \frac{1}{\omega_1 C_m} = \omega_1 \left(L_m - \frac{1}{\omega_1^2 C_m} \right)$$

$$Z_{m_{21}} = \omega_2 L_m - \frac{1}{\omega_2 C_m} = \omega_2 \left(L_m - \frac{1}{\omega_2^2 C_m} \right)$$

$$W_1 = L_1 + L_m$$

$$W_2 = L_2 + L_m$$

$$\begin{aligned} k &= \frac{1}{\sqrt{\omega_1 \omega_2}} \sqrt{\frac{\omega_1 \omega_2 \left(L_m - \frac{1}{\omega_1^2 C_m} \right) \left(L_m - \frac{1}{\omega_2^2 C_m} \right)}{(L_1 + L_m)(L_2 + L_m)}} \\ &= \sqrt{\frac{\left(L_m - \frac{1}{\omega_1^2 C_m} \right) \left(L_m - \frac{1}{\omega_2^2 C_m} \right)}{(L_1 + L_m)(L_2 + L_m)}} \end{aligned}$$

and since

$$\omega_1^2 = \frac{C_1 + C_m}{(L_1 + L_m)C_1 C_m}$$

$$\omega_2^2 = \frac{C_2 + C_m}{(L_2 + L_m)C_2 C_m}$$

the expression for k can be rewritten as

$$k = \sqrt{\frac{(L_m C_m - L_1 C_1)(L_m C_m - L_2 C_2)}{(L_1 + L_m)(L_2 + L_m)(C_1 + C_m)(C_2 + C_m)}}$$

It should be carefully noted that the ω_1 and ω_2 used here are not the same as found previously for the natural resonant frequencies of the coupled circuits.

If now we take $L_1 = L_2 = L$ and $C_1 = C_2 = C$,

$$k = \frac{L_m C_m - LC}{(L + L_m)(C + C_m)}.$$

Since this case corresponds to that used in connection with Figs. 26.6A and 26.6B it would be expected that the results would correspond. However, it is seen that there is an additional term $L_m C$ in the denominator of the second solution. This is explained by the method used for determining ω_1 and ω_2 in the latter case, and so the method as given here cannot be considered exact. The approximation involved in this particular example is that the result is equivalent to

$$k_T = k_m \pm k_c \text{ and not } k_T = \frac{k_m \pm k_c}{1 \pm k_m k_c}.$$

This is seen quite readily because

$$k_m = \frac{L_m}{L + L_m}; \quad k_c = \frac{C}{C + C_m}$$

and so $k_T = \frac{L_m(C + C_m) - C(L + L_m)}{(L + L_m)(C + C_m)} = \frac{L_m C_m - LC}{(L + L_m)(C + C_m)}$ which is the result just obtained.

A rather similar difficulty occurs when determining the central reference frequency for the transformer of Fig. 26.2. The angular frequency (ω) is determined exactly as above by considering the secondary on open circuit, and for this case

$$\omega = \sqrt{\frac{\omega_1^2 + \omega_2^2}{2}}$$

where ω_1 and ω_2 are now determined in the same way as for Figs. 26.6A and 26.6B.

SECTION 5: VARIABLE SELECTIVITY

(i) *General considerations* (ii) *Automatic variable selectivity.*

(i) General considerations

Any method giving variable-coupling may be used to provide variable selectivity.

Variable-coupling by means of pure mutual inductance is the only system in which mistuning of the transformer does not occur without introducing compensation of other component values. As the coupling is increased above the critical value, the trough of the resonance curve remains at the intermediate frequency (Ref. 8).

FIG. 26.7

With any other type of coupling which has no mutual inductance component, one of the two humps remains at the intermediate frequency. The mistuning is then half the frequency bandwidth between humps.

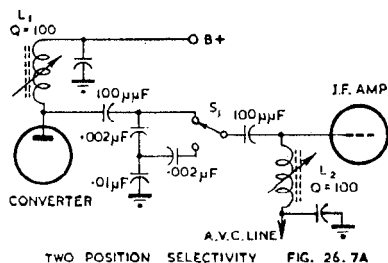

The method of switching tertiary coils approximates far more closely to the curve for pure mutual inductance (M in Fig. 26.7) than it does to the other curve. The

tertiary coil may have no more than 5% of the turns on the main tuning coil and less than 0.5% ratio of inductance. The symmetry of the overall selectivity curves is usually good.

Variable capacitance coupling may be used and the coupling capacitor may be either a small capacitor linking the top end of the primary to the top end of the secondary or it may be a common capacitor in series with both primary and secondary circuits. This latter arrangement is commonly known as "bottom coupling."

For "top coupling" very small capacitances are required and the effect of stray capacitances is inclined to be serious, particularly in obtaining low minimum coupling. It may be used, however, with a differential capacitor arrangement whereby continuously variable selectivity is obtained (Refs. 41, 42). The differential capacitance in this case adds to or subtracts from the capacitance in the primary and secondary circuits to give the requisite tuning. The disadvantage of this arrangement is that sufficiently low minimum coupling is very difficult to obtain and the capacitor is a non-standard type.

"Bottom coupling" has results similar to "top coupling," but is easier to handle for switching and also has advantages for low coefficients of coupling. A two or three step tapping switch may be used to give corresponding degrees of bandwidth provided that simultaneously other switch contacts insert the necessary capacitances in the primary and secondary circuits, for each switch position, to give correct tuning.

One such bottom coupling method which requires the minimum of switching for two degrees of coupling is shown in Fig. 26.7A (Ref. 42a). The two coils L_1 and L_2 should each be in a separate shield can. With switch S_1 in the position shown, the selectivity is broad; in the lower position the selectivity is normal. Capacitances as shown are only illustrative. The same principle can be used for three values of coupling, using seven capacitors.

In most cases, the second i-f transformer is slightly under-coupled and its peak is used to fill in the "trough" between the peaks of the first transformer in its broad position.

A wide variety of circuit arrangements for obtaining variable selectivity has been described in the literature. Design methods and practical constructional details for many of these can be found in the references listed at the end of this chapter. Further discussion is also given in Chapter 11, Sect. 3(iii).

(ii) Automatic variable selectivity

Automatic variable selectivity allows the bandwidth of the i-f amplifier to be varied with signal strength, the pass band being a maximum for the strongest signal.

Many types of circuits have been developed using variable circuit damping, varying coupling reactance and circuit detuning. A number of the circuits are not very practical arrangements since they involve the addition of a number of valves whose sole function is to provide variable bandwidth.

One interesting circuit arrangement (Ref. 46), which does not require any additional valves, is shown in Fig. 26.8.

To understand the operation of the circuit it is first necessary to consider what happens in an ordinary mutual inductance coupled transformer. It is well known,

when two circuits are coupled together, that there is a back e.m.f. induced in the primary winding from the secondary which will have a marked effect on the magnitude and phase characteristics of the primary current as a function of frequency. The primary current response curve exhibits a double peak at values of k even less than critical, because the back e.m.f. represents a voltage drop that decreases rapidly on either side of the resonant frequency. Double peaking of the primary current is masked in its effect on the secondary current by the selectivity of the secondary circuit. When the coupling exceeds critical (actually transitional) coupling the secondary current exhibits two peaks, but to a lesser extent than the primary current.

FIG. 26-8 AUTOMATIC SELECTIVITY ARRANGEMENT

If the magnitude of the counter e.m.f. is increased by increasing the mutual inductance, and at the same time a voltage of almost equal magnitude and opposite phase is added in series with the primary circuit, a single peak of output current can be obtained in the transformer secondary. The additional series voltage, so introduced, will increase the stage gain and selectivity from the condition which existed prior to its introduction; in our case the prior condition is that the stage gain is less and the secondary current has two peaks, i.e. the transformer is initially over-coupled.

In the circuit of Fig. 26.8 the valve V_2 performs the dual functions of amplification and production of the series voltage to be added to the primary circuit. A resistance in the cathode of V_2 produces an a.c. voltage drop, which is proportional to the g_m of the valve and the secondary current of the transformer; this voltage drop across the cathode resistor is the one applied back to the transformer primary. When a strong signal is being received a.v.c. will increase the bias on the grid of V_2 and so its g_m is reduced. When the g_m (and consequently the voltage drop across the cathode resistor) is sufficiently small, peak separation is obtained; the width between the peaks depending on the value of mutual inductance. Weak signals reverse the process and narrow down the overall response curve.

A quantitative analysis (setting out design data and instability conditions) is given in the Ref. (46). For the circuit of Fig. 26.8 the peak separation is given as 8 Kc/s for an i-f of 450 Kc/s. Other designs are shown for peak separations of 15 Kc/s and also for obtaining two position automatic selectivity; the latter arrangement necessitates the use of a relay.

Other types of automatic selectivity are discussed in the references listed.

SECTION 6 : VARIABLE BANDWIDTH CRYSTAL FILTERS

(i) Behaviour of equivalent circuit (ii) Variable bandwidth crystal filters (iii) Design of variable bandwidth i-f crystal filter circuits (A) Simplifying assumptions (B) Gain (C) Gain variation with bandwidth change (D) Selectivity (E) Crystal constants (F) Position of filter in circuit (G) Other types of crystal filters (iv) Design example.

(i) Behaviour of equivalent circuit

Fig. 26.9 shows the generally accepted equivalent electrical circuit for a quartz crystal of the type used in the i-f stage of a communications receiver.

In this network suppose we consider that R is zero, then between terminals 1 and 2 there is a reactance

$$X = \frac{\omega L - 1/\omega C}{\omega C_0 \left[\omega L - \frac{1}{\omega} \left(\frac{1}{C} + \frac{1}{C_0} \right) \right]} \quad (28)$$

When $\omega L = 1/\omega C$ the reactance is zero and the circuit is series resonant.

When $\omega L = \frac{1}{\omega} \left(\frac{1}{C} + \frac{1}{C_0} \right)$ the reactance is infinitely large, and the circuit is parallel resonant (anti-resonant).

The difference in frequency between f_p and f_r is given approximately by

$$\Delta f = \frac{C}{2C_0} f_r.$$

From the values of the 455 Kc/s crystal constants which are given in (iii)E below, it will be seen that Δf is about 250 c/s in a typical case.

The presence of R will slightly modify the conditions for which parallel resonance occurs. For our purposes the conditions given are near enough.

It should be clear from the circuit that the parallel resonance frequency (f_p) will be higher than the series resonance frequency (f_r). For frequencies above f_r the resultant reactance due to L and C in series is inductive, and this is connected in parallel with a capacitive reactance due to C_0 . A typical curve of output voltage versus frequency change, for this type of circuit, is shown in Fig. 26.10.

If the value of C_0 could be altered as required, then the position of f_p would be variable. Suppose by some means we are able to connect a negative capacitance C_N (or a parallel inductance will give somewhat similar results) across C_0 ; then the value of the capacitance shunted across the series circuit will be

$$C' = C_0 - C_N. \quad (29)$$

FIG. 26.9

FIG. 26.10 RESPONSE CURVE FOR CIRCUIT OF FIG. 26.9

From this, it follows that C' can be reduced from its initial value of C_0 (when C_N is zero) until it becomes zero, and C_N has then exactly neutralized C_0 . The response curve would now be that for the series circuit (made up from L , R and C) alone, which behaves as a pure series resistance at f_r . If the magnitude of C_N is further increased, then C' becomes negative and the series circuit is shunted by a negative capacitance; which is equivalent to shunting an inductance across the series circuit (which behaves like a capacitive reactance for frequencies below f_r). This means that the parallel resonance frequency (f_p) will now be lower than the series resonance frequency (f_r). Any frequency above or below the series resonance frequency can now be chosen as the rejection, or parallel resonance, frequency and the current through the circuit, at this point, will be reduced; the values for f_p and the current depending on the circuit constants.

To achieve the variation in C' the circuit of Fig. 26.9 (i.e. the crystal) is incorporated in the bridge circuit of Fig. 26.11, in which C_N is made variable to achieve the results discussed. In this circuit Z_L is the load impedance; Z_s is the impedance of the voltage source; Z_1 and Z_2 are any two impedances used to make up the resultant

bridge circuit. It will be realized that the presence of Z_s and Z_L would have some modifying effect on our previous discussion, but the general principles remain unchanged; these impedances will be taken into account when the design of the crystal filter stage is carried out.

The arrangement of any practical circuit using a single crystal can be reduced to the general form of Fig. 26.11.

Two typical circuit arrangements are shown in Fig. 26.12. Fig. 26.12(A) shows that Z_1 and Z_2 are obtained by using two capacitances C_1 and C_2 for the bridge arms. Fig. 12(B) uses a tap on the i-f transformer secondary (L_1 and L_2) to obtain the bridge arms Z_1 and Z_2 .

In any circuit arrangement such as those shown, the best overall selectivity is obtained when C' is zero (i.e. $C_N = C_0$). Under this condition, if the circuit is designed with some care, the response curve of output voltage with frequency change will be reasonably symmetrical. If C_N is varied to place f_p above or below f_s , although we may improve the selectivity (and so the rejection) against an unwanted signal at f_p , the resonance curve is no longer symmetrical and the selectivity is decreased on the opposite side of the curve.

FIG. 26.11 CIRCUIT ARRANGEMENT FOR VARYING C' ($=C_0-C_N$)

FIG. 26.12 PRACTICAL CIRCUIT ARRANGEMENTS FOR QUARTZ CRYSTAL FILTERS

(ii) Variable bandwidth crystal filters

It is often necessary, in practical receivers, to have means available for varying the bandwidth of the crystal filter circuit. This can be achieved in a number of ways, such as detuning the input and (or) output circuits or varying their resonant impedances. Also, as well as having variable bandwidth it is desirable that there should not be appreciable change in stage gain as the bandwidth is altered. Further, the overall response curve of voltage output versus frequency should remain as symmetrical as possible with changes in bandwidth when the bridge circuit is arranged so that C_0 is neutralized by C_N .

To fulfil all of the conditions above, a simple solution is to use a tuned circuit as the load for the filter circuit, and to alter its dynamic impedance by switching-in either series or parallel resistors. Simple detuning of the input circuit, or the output circuit, is not very satisfactory and the best results can only be achieved by detuning both the input and output circuits in opposite directions by an amount depending on their relative Q 's. (For a description of circuits using the latter method see Refs. 48 and 63). To obtain constancy of gain it is necessary that the voltage source impedance be low, and this again suggests the switched output circuit when the bandwidth is to be varied. The choice of series or shunt resistors to alter bandwidths is largely bound up in stray capacitances across switch contacts and the resistors themselves; careful consideration here suggests that resistors in series with the inductor, or the capacitor, of the tuned load will probably give the least detuning effects. Unless the values of the tuning capacitances for the input and load circuits are fairly large, alteration of C_N will have some appreciable effect on the resonant frequencies of these circuits, giving rise to asymmetry of the response curve and loss in sensitivity. This effect can sometimes be overcome, partly, by the use of a differential type of neutralizing capacitor. However, circuits using this arrangement should be carefully examined as usually there are still some detuning effects. For most practical cases it is sufficient to choose suitable values of tuning capacitance, particularly when

operation is confined to an i-f of 455 Kc/s, and to tap down on the circuit when this is possible.

Two other points are worth mentioning. The first is that the crystal stage gives high selectivity around resonance, but the "skirt" selectivity may be quite poor; for this reason the other stages in the receiver must provide the additional "skirt" selectivity required. In addition, good "skirt" selectivity is a requirement of the i-f amplifier to minimize any possible undesirable effects which may arise because of crystal subsidiary resonances. The other point is that having C_N as a variable control is not necessarily a great advantage, and simpler operation is obtained when C_N can be pre-set to neutralize C_0 . This cannot be done with all types of variable bandwidth circuits, since the conditions for neutralization may be altered as the bandwidth is changed.

(iii) Design of variable bandwidth i-f crystal filter circuits

(A) Simplifying assumptions

From Fig. 26.11, when a capacitance balance is obtained as far as C_0 is concerned,

$$C_N \approx C_0(Z_1/Z_2). \quad (30)$$

Since C_0 is generally about 17 μF it is convenient to make $Z_1 = Z_2$. Also, C_N must have very low losses if the attenuation at the rejection frequencies is to be high. The general design will call for all capacitors to be of the low loss type. When the condition of eqn. (30) is fulfilled, the equivalent circuit reduces to that of Fig. 26.13(A).

FIG. 26.13

EQUIVALENT CIRCUITS FOR CRYSTAL FILTER WHEN $C_0 = C_N$

For purposes of analysis it is convenient to rearrange Fig. 26.13(A) as shown in Fig. 26.13(B), and, if we take $Z_1 = Z_2$, the value of $Z's$ will be a quarter of the total dynamic impedance of the secondary circuit of the i-f input transformer. $E's$ will be half the voltage developed across the two series capacitors tuning the i-f transformer secondary.

(B) Gain

First we will derive an expression for the overall gain of the i-f stage.

From Fig. 26.13(B),

$$\frac{E_0}{E's} = \frac{Z_L}{Z_L + Z's + Z_x} \quad (31)$$

where E_0 = output voltage across load circuit applied to grid of following i-f amplifier valve

Z_L = load impedance

$Z's$ = voltage source impedance

Z_x = crystal impedance (C_0 neutralized)

$$= R + j\left(\omega L - \frac{1}{\omega C}\right)$$

$$= R \text{ at resonance (i.e. i-f)}$$

and $E's$ = available voltage developed at tap on input i-f transformer secondary.

To compute the complete stage gain we must now consider Fig. 26.14. Here, since we require maximum gain, a critically-coupled transformer is connected to a voltage amplifier valve (V_1) whose grid to cathode input voltage is E_g . Then since $E's$ is half the total voltage appearing across C_1 and C_2

$$E's = \frac{1}{2} \left(\frac{g_m E_g Q \omega_0 L}{2} \right) \quad (32)$$

FIG. 26.14 CIRCUIT FOR DETERMINING $E's$

where g_m = mutual conductance of V_1

$$Q = \sqrt{Q_1 Q_2} = 1/k_c$$

$$\omega_0 = 2\pi \times i\text{-f}$$

and $L = \sqrt{L_1 L_2}$ (always provided that $L_1 C_1 = L_2 C_2$).

Combining eqns. (31) and (32), the gain from the grid of V_1 to the grid of the next amplifier valve (V_2) is

$$\text{Stage gain} = \frac{E_0}{E'_s} \times \frac{E'_s}{E_g} = \frac{E_0}{E_g} = \left(\frac{Z_L}{Z_L + Z'_s + Z_x} \right) \left(\frac{g_m Q \omega_0 L}{4} \right). \quad (33)$$

Eqn. (33) gives a great deal of information about the circuit. For constancy of gain, it follows that Z_L should be very much greater than $(Z'_s + Z_x)$. Since Z_x (or R at resonance) cannot be altered by the receiver designer, it is necessary to make Z'_s as small as possible. However, as Z'_s is made smaller the overall gain will be affected since it is a centre tap on the output of the input i-f transformer. The maximum value for Z_L will be limited by the maximum bandwidth requirements, and the permissible values of circuit constants. The other factors affecting gain are g_m , Q and L . For a given valve under a fixed set of operating conditions, g_m is practically outside the designer's control; the value of $L (= \sqrt{L_1 L_2})$ is made as large as possible consistent with the requirements of minimum permissible tuning capacitance; $Q = \sqrt{Q_1 Q_2}$ is adjusted so that Q_1 is made as high as possible, and since we desire Z'_s to be low a suitable value is selected for Q_2 . The method of determining Q has a large effect on the stage gain which can be obtained, as will be seen later in the illustrative example.

(C) Gain variation with bandwidth change

For constancy of maximum gain at f_0 (i.e. the i-f) it has been suggested that Z'_s should be small. There is a limit, however, to the minimum gain variation that can be obtained for a given change from maximum to minimum bandwidth. From the preceding equations it may be deduced that the maximum stage gain (A_{max}) is obtained when the bandwidth is greatest, and the minimum gain (A_{min}) when the bandwidth is least. This limit in gain variation (since R for the crystal is fixed) is the condition for which the voltage source impedance (Z'_s) becomes zero, which occurs when

$$\alpha_0 = \frac{A_{min}}{A_{max}} = \frac{R_{T_2}(R_{T_1} - R)}{R_{T_1}(R_{T_2} - R)} \quad (34)$$

where R_{T_1} = total series resistance (at f_0) when the bandwidth is least

(= $R + Z'_s + Z_L$; in which Z_L has its smallest value)

and R_{T_2} = total series resistance (at f_0) when the bandwidth is greatest

(= $R + Z'_s + Z_L$; in which Z_L now takes up its largest value).

To determine the voltage source impedance (Z'_s) for the usual condition where Z'_s is not zero, we use

$$Z'_s = \frac{R_{T_2}(R_{T_1} - R) - \alpha R_{T_1}(R_{T_2} - R)}{R_{T_2} - \alpha R_{T_1}} \quad (35)$$

which, for convenience, is rewritten in terms of eqn. (34) as

$$Z'_s = \frac{\alpha_0 - \alpha}{\frac{\alpha_0}{R_{T_1} - R} - \frac{\alpha}{R_{T_2} - R}} \quad (35A)$$

where R_{T_1} and R_{T_2} have the values given immediately above,

R = equivalent series resistance of crystal

and $\alpha = \frac{A_{min}}{A_{max}}$ = gain variation desired, and must always be less than one.

If a value is selected for Z'_s then

$$\alpha = \frac{R_{T_2}(R_{T_1} - R) - Z'_s R_{T_2}}{R_{T_1}(R_{T_2} - R) - R_{T_1} Z'_s}. \quad (36)$$

(D) Selectivity

Selectivity around resonance can be calculated by the methods to be outlined, but for most purposes it is sufficient to determine the bandwidth for a given attenuation at the half power points (3 db attenuation or $1/\sqrt{2}$ of the maximum voltage output) on each of the required selectivity curves.

Considerable simplification in the design procedure is possible, if the bandwidths for 1 db attenuation (or less) are known. In this case it would be sufficiently accurate to take Z_L and Z_s equal to their dynamic resistances at resonance, at least for most practical conditions, without introducing appreciable error. The advantage obtained being that, in what follows, $R_{T_1} = R'_{T_1}$ and $R_{T_2} = R'_{T_2}$ for all conditions. The value of Q_x would be given by $Q_x = f_0/4\Delta f$ for 1 db attenuation, and this expression would be used in place of eqn. (38). However, the procedure given is more general and there should be little difficulty in applying the simplified procedure, if necessary. Further the method given illustrates (in reverse) how the bandwidths near resonance can be calculated for various amounts of attenuation.

To determine the bandwidth at the half power points proceed as follows: first it may be taken that the equivalent inductive reactance of the crystal is very much greater than the inductive reactance of the load and source impedances. Also, provided the variations in gain are not allowed to become excessive, at and near resonance the value of Z'_s is very closely R'_s . For very narrow bandwidths, near resonance, it is also sufficiently close to take $Z_L = R_L$; for large bandwidths the resistive component (R_L) of Z_L at the actual working frequency will have to be found. From these conditions, we have

$$Q_x = \frac{\omega_0 L}{R_L + R'_s + R} = \frac{\omega_0 L}{R'_{T_1}} = \frac{1}{\omega_0 C R'_{T_1}} \quad (37)$$

where Q_x = the equivalent Q of the circuit of Fig. 26.13(B)

L = equivalent inductance of the crystal

C = equivalent series capacitance of the crystal

R = equivalent series resistance of the crystal

R_L = resistive component of Z_L , the load impedance, at the frequency being considered (= Z_L at resonance)

R'_s = resistive component of Z'_s , the voltage source impedance

$R'_{T_1} = R_L + R'_s + R$ = total series resistance at frequencies away from f_0
(for very narrow bandwidths $R_L \approx Z_L$ and $R'_{T_1} \approx R_{T_1}$)

and $\omega_0 = 2\pi \times f_0$ (where f_0 is the i-f).

From the principles of series resonant circuits we know that the total bandwidth ($2\Delta f$) for the half power points (3 db atten.) is given by

$$2\Delta f = f_0/Q_x. \quad (38)$$

It follows from eqns. (38) and (37) that for large bandwidths Q_x should be small and so R'_{T_1} should be large. For narrow bandwidths the reverse is true, and the limiting case for the narrowest bandwidth would be when $R'_{T_1} = R$ (i.e. for the crystal alone); a condition impossible to achieve in practice because of circuit requirements.

Since $Z_L \gg (Z'_s + R)$ for constancy of maximum gain at f_0 , under conditions of varying bandwidth, it also follows that Q_x will mainly be determined by the magnitude of the resistive component of the dynamic impedance of Z_L .

Some additional selectivity is given by the input i-f transformer, and for more exact results the attenuation for a particular bandwidth would be added to that found for the crystal circuit. This additional selectivity is usually negligible around the "nose" of the resonance curve, but can be determined from the universal resonance curves of Chap 9 Sect. 10, evaluating D and b for unequal primary and secondary Q 's (Q_1 and Q_2) and noting that Q in these expressions is Q_2 .

The resonance curve for the complete circuit is seldom necessary for a preliminary design. The procedure is rather lengthy but not very difficult. First it is necessary to find the resistive component of Z_L (i.e. R_L) at frequencies off resonance. This is carried out from a knowledge of $|Z_L|$ (= Z'_L) at resonance, and by determining the reduction factors from the universal selectivity curves. Multiplying $|Z_L|$ by the

indicated attenuation factors gives the required magnitudes of load impedance $|Z'_L|$. To find the resistive component, values of θ corresponding to the various bandwidths (and values of $|Z'_L|$) are read from the universal phase-shift curves of Chapt. 9 Sect. 10. Then

$$R_L = |Z'_L| \cos \theta. \quad (39)$$

The resistive component of Z'_s can be found in a similar way from

$$R'_s = Z'_s \cos \phi$$

but since the impedance of Z'_s is generally small, and the circuit relatively unselective, R'_s can often be taken as equal to Z'_s for a limited range of frequencies near resonance. When Z'_s is very low, it can be neglected in comparison with $R_L + R$.

Then, since the resistance (R) and the inductance (L) of the crystal are known, eqn. (37) can be applied to determine the values of Q_x corresponding to the various bandwidths. (Strictly f_0 would be replaced by the actual operating frequency off resonance, but this is hardly necessary).

Knowing the different values of Q_x and since the bandwidths corresponding to each Q_x value are known, the various points for the complete selectivity curve can be found from the universal resonance curve for a single tuned circuit (it is unimportant that this is for a parallel tuned circuit rather than a series tuned circuit, since the conditions for parallel and series resonance are practically the same provided the Q is not less than about 10; there is, however, a reversal in sign of the phase angles for the two cases). Additional selectivity due to the input transformer can be taken into account if this degree of accuracy is thought to be necessary.

(E) Crystal constants

Before a complete design can be carried out, some data on the equivalent electrical constants of the quartz crystal must be available. In most cases details can be obtained from the crystal manufacturer.

Typical values for the electrical constants of 455 Kc/s quartz crystals widely used in Australian communications receivers are:

$$R = 1500\Omega; C = 0.018 \mu\mu\text{F}; C_0 = 17 \mu\mu\text{F}.$$

The crystals are a special type of X cut bar and have no subsidiary resonances for a range of at least ± 30 Kc/s from f_r . They are approximately 20 mils (0.02 in.) thick, $\frac{1}{8}$ in. wide, $\frac{1}{8}$ in. long and are mounted between flat electrodes with an air gap not greater than 1 mil. (0.001 in.).

FIG. 26.15 APPROXIMATE METHODS FOR DETERMINING EQUIVALENT ELECTRICAL CONSTANTS OF QUARTZ CRYSTALS

If the required data cannot be obtained, then details of methods for measuring, firstly, the value of Q for the crystal, can be found in Ref. 65. The experimental set-up is shown in Fig. 26.15(A) and Q is found from

$$Q = \frac{f_r}{2(f_p - f_r)} \sqrt{\frac{E_r}{E_p}} \quad (40)$$

where f_r = series resonance frequency

f_p = parallel resonance (or antiresonance) frequency

E_r = voltage across terminating resistance at series resonance

and E_p = voltage across terminating resistance at parallel resonance.

A knowledge of Q will allow the filter circuit to be designed, but if values for C and C_0 are required these can be readily measured (Ref. 64) by using the arrangement of Fig. 26.15(B) and the relations

$$\frac{C}{C_A + C_0} = \left(\frac{f_{p2} - f_{p1}}{f_r} \right)^2 \quad (41)$$

$$\text{and } f_{vA} = \frac{1}{2\pi\sqrt{L_A C_A}} \quad (42)$$

where C = series capacitance of crystal

C_A = parallel capacitance of circuit $L_A C_A$

L_A = parallel inductance of circuit $L_A C_A$

C_0 = shunt capacitance across crystal due to holder etc.

f_{v_1} and f_{v_2} = parallel resonance frequencies of combined circuits. The combination has two parallel resonance frequencies, one above and one below f_r .

f_r = series resonance frequency, measured with combined circuit.

and f_{vA} = parallel resonance frequency of circuit $L_A C_A$ alone.

C_0 is determined by disconnecting the crystal and adding capacitance to $L_A C_A$ to retune the circuit to the frequency f_r .

(F) Position of filter in receiver

In most receivers using crystal filters at least two i-f stages are included, since the gain of the crystal stage is usually well below that for a normal i-f stage. Low stage gain immediately after the converter valve may have an adverse effect on signal-to-noise ratio, and it is sometimes preferable to place the filter between the first and second i-f voltage amplifier valves; however, it is fairly common practice to place the selective crystal stage immediately after the converter to reduce the effects of spurious responses.

It would not be satisfactory to place the filter between the last i-f valve and the detector because of the low impedance of the load in this case.

Since it is common practice to incorporate at least one r-f stage in receivers of the type mentioned, it is unlikely that effects such as possible deterioration in signal-to-noise ratio would be of any consequence. However, good design suggests at least two i-f stages plus one or more r-f stages, depending on performance requirements.

(G) Other types of crystal filters

There are several types of crystal filters suitable for use in radio receivers other than the simple bridge circuit, to which attention has been confined. Typical examples are double-crystal and bridged T filters. These circuits are characterized by having two rejection frequencies, usually placed with geometric symmetry about f_r . Details can be found in Refs. 49, 54, 55 and 61.

Resistance balancing is sometimes applied to the complex types of crystal filters to increase attenuation at the rejection frequencies. This method has also been applied to wave filters using LC circuits only. Details are given in Refs. 59, 60 and 61.

(iv) Design example

Using the constants for the 455 Kc/s crystal given in (E) above, it is required to design a crystal filter circuit to have a total bandwidth ($2\Delta f$) for 3 db attenuation,

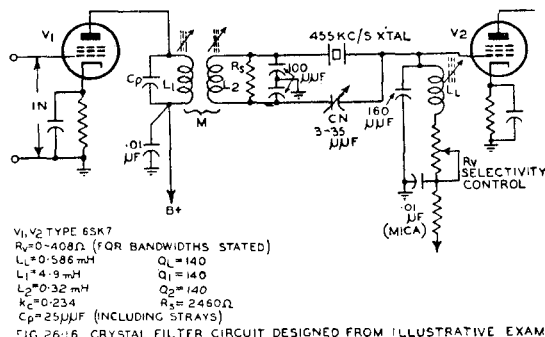

FIG. 26-16 CRYSTAL FILTER CIRCUIT DESIGNED FROM ILLUSTRATIVE EXAMPLE

which can be varied from 200 c/s to 3 Kc/s. The variation in maximum stage gain should not exceed about 2 db (± 1 db about the average gain) but it is desirable to

keep the stage gain as high as possible, consistent with stable operation with varying signal input voltages (i.e. large detuning of the i-f circuits should not occur when the signal voltages vary over a wide range).

To make the problem complete, it will be assumed that the filter is connected between two type 6SK7 pentode voltage amplifier valves. The complete circuit is shown in Fig. 26.16.

(1') Since $Z_1 = Z_2$ and $C_0 \approx 17 \mu\mu\text{F}$, let us select a suitable capacitance range for C_N . The smallest residual capacitance for C_N will be about $3 \mu\mu\text{F}$. From this, we have to increase C_N a further $14 \mu\mu\text{F}$ to neutralize C_0 . In addition, it is desired to move the rejection frequency (f_r) below f_s , so that it is reasonable to allow C_N to increase at least a further $14 \mu\mu\text{F}$. The total increment in C_N is thus $28 \mu\mu\text{F}$; which gives a range of 3 to $31 \mu\mu\text{F}$; for convenience this is made, say, 3 to $35 \mu\mu\text{F}$ (or whatever is the nearest standard capacitance range).

(2') From eqn. (38):

for 200 c/s total bandwidth, and 3 db attenuation,

$$Q_{x_1} = 455/0.2 = 2275;$$

for 3 Kc/s,

$$Q_{x_2} = 455/3 = 151.6.$$

(3') From eqn. (37) (and $C = 0.018 \mu\mu\text{F}$)

$$R'_{T_1} = \frac{10^{12}}{2275 \times 2\pi \times 455 \times 10^3 \times 0.018} = 8550 \Omega$$

$$\text{and } R'_{T_2} = \frac{8550 \times 2275}{151.6} = 0.128 \text{ M}\Omega.$$

So that (since $R = 1500 \Omega$)

$$R_{L_1} + Z'_s = 8550 - 1500 = 7050 \Omega$$

$$R_{L_2} + Z'_s = 0.128 - 15 \times 10^{-3} = 0.126 \text{ M}\Omega.$$

For narrow bands of frequencies, $R_{L_1} \approx Z_{L_1}$, and we may write

$$R'_{T_1} = R_{T_1} \text{ and } Z_{L_1} + Z'_s \approx 7050 \Omega.$$

(4') To find Z_{L_2} . It should be clear, from the values just given (Z'_s remains unchanged) that for fairly large bandwidths

$$R_{L_2} \gg Z'_s.$$

Assume that, for the load circuit, $Q_L = 140$. Then by calculation, or from the universal resonance curves, we have for a single tuned circuit and a frequency of 455 Kc/s,

Z_{L_2} at resonance

$$|Z'_{L_2}| \text{ at 3 Kc/s bandwidth} = 1.37.$$

Also, the phase shift $\theta = 42^\circ 43'$.

Using these factors in conjunction with eqn. (39),

$$|Z'_{L_2}| = \frac{R_L}{\cos \theta} = \frac{0.126}{0.735}$$

$$\text{and so } Z_{L_2} = \frac{1.37 \times 0.126}{0.735} = 0.235 \text{ M}\Omega.$$

(If the maximum bandwidth required is too large it will be found that Z_{L_2} cannot be obtained with ordinary circuit components).

From this, since $Z_{L_2} = Q_L \omega_0 L_L$,

$$L_L = \frac{0.235 \times 10^3}{140 \times 2\pi \times 0.455} = 0.586 \text{ mH}$$

$$\text{and } C_L = \frac{25330}{0.455^2 \times 586} = 208 \mu\mu\text{F} \text{ (see below).}$$

(5') If it is possible to make Z_L higher than 0.235 megohm then a voltage step-up is possible using the arrangement of Fig. 26.17, which also reduces detuning effects

when C_N is varied. Good circuit stability (which requires a large value for C_L) is most important since the circuit bandwidth and gain are very critical to detuning. The main causes of detuning are capacitance changes at the input of V_2 due to grid bias variations, and resetting of C_N ; this latter capacitance change is offset, to some extent, in the alternative circuit since it appears across only part of the tuned circuit capacitance. Any form of tapping down is helpful in reducing detuning variations due to C_N , but this is limited by the impedance required for the filter load circuit.

Fig. 26.17. Alternative load circuit for crystal filter stage.

FIG. 26.17

Methods of reducing detuning effects are discussed in Sect. 7(ii), and could be applied here to offset changes in valve input-capacitance. Connecting the grid to a tap on the tuned load is an obvious means of reducing the effects of valve input-capacitance variation. This method involves a loss in gain, but this is not necessarily serious as in some receivers the total gain is more than can usefully be employed.

The actual fixed capacitance for C_L is found approximately as follows :

Valve input capacitance	= $6.5 \mu\text{F}$
Strays across coil + wiring etc.	= $8.5 \mu\text{F}$
$C_N + C_0 = 2C_0 = 2 \times 17$	= $34 \mu\text{F}$ (when C_0 is neutralized by C_N)
Total strays	= $49 \mu\text{F}$

Fixed capacitance req. = $208 - 49 = 159 \mu\text{F}$ (say $160 \mu\text{F}$).

(6') From eqn. (34); and since $R_T = 8550 \Omega$ and $R_{T_2} = 0.237 \text{ M}\Omega$ (approximately; i.e. $Z_{L_2} + R$),

$$\alpha_0 = \frac{0.237 (7050)}{8550 (0.235)} = 0.83$$

(which shows that the gain variation is practicable).

Then, since $\alpha = 2 \text{ db down} = 0.794$, we have from eqn. (35A)

$$Z'_s = \frac{0.83 - 0.794}{0.83 - \frac{0.794}{\frac{7050}{0.235 \times 10^6}}} \approx \frac{0.036 \times 7050}{0.83} = 306 \Omega,$$

so that $Z_s = 4Z'_s = 1224 \Omega$.

(7') To determine the approximate range of the selectivity control R_v . For maximum bandwidth $R_v = 0$. For minimum bandwidth, since $Z_{L_1} (= R_{L_1}) = 7050 - 306 = 6744 \Omega$,

then $Q_{L_1} = \frac{Z_{L_1}}{\omega_0 L_L} = \frac{6744}{1680} = 4$ [This is an approximation only; see end of step (8')]

and $R'_v = \frac{\omega_0 L_L}{Q_L} = \frac{1680}{4} = 420 \Omega$.

Resistance already in circuit when Q is 140, is

$$R_L = 1680/140 = 12 \Omega.$$

Range of R_v required is from $0 - 408 \Omega$.

This is the range if R_v is connected in series with L_L . If R_v is to be connected in series with the capacitive arm of Z_L it should be realized that it would actually be in

series with the fixed capacitance of $160 \mu\mu\text{F}$ only, and not the total capacitance, so that new values for the range of R_p would have to be calculated in this case.

(8') The design of the input transformer is the next step. For maximum gain the transformer will be critically-coupled (this term is hardly a correct one in the design which follows and for this particular case it might be preferable to use other methods).

Consider first the secondary circuit. The total secondary capacitance, if we select $100 \mu\mu\text{F}$ capacitors (connected in series) for the ratio arms of the bridge circuit, will be $100/2 + 14.5 = 64.5 \mu\mu\text{F}$. The $14.5 \mu\mu\text{F}$ represents the approximate total for

$\frac{C_N}{4} + \frac{C_0}{4} = \frac{C_0}{2}$ (since $C_N = C_0$) = $8.5 \mu\mu\text{F}$ plus an allowance of $6 \mu\mu\text{F}$ for coil and circuit strays.

Then the apparent secondary inductance required is

$$L_2 = \frac{25.33}{0.455^2 \times 64.5} = 1.9 \text{ mH.}$$

From step (6') above, $Z_s = 1224 \Omega$. Since critical-coupling (see remarks above) will halve the actual value of Q_2 , we must use an uncoupled value for Z_s of 2448Ω . This allows us to determine the uncoupled secondary magnification factor

$$Q_2 = \frac{2448}{\omega_0 L_2} = \frac{2448}{5440} = 0.45.$$

Because of the low value for Q_2 , the condition of $\omega_0^2 L_2 C_2 = 1$ is no longer sufficiently accurate. For cases such as this, where Q is less than about 10, proceed exactly as before but modify the value of L_2 by a factor $Q^2/(1 + Q^2)$. This gives the true condition for resonance (unity power factor) if Q is assumed constant and L_2 is variable as it will be in most i-f transformers of the type being considered. The actual value required for L_2 is now

$$L_2 (\text{actual}) = 1.9 \left[\frac{0.45^2}{1 + 0.45^2} \right] = 0.32 \text{ mH.}$$

(9') Since the secondary Q is very low, and L_2 is fixed by other considerations, it should be clear that if we require reasonably high stage gain the primary $Q (= Q_1)$ and the primary inductance L_1 should be as high as possible; since this will allow $QL = \sqrt{Q_1 Q_2 L_1 L_2}$ to be increased.

As the minimum capacitance across L_1 will be about $25 \mu\mu\text{F}$ (valve output + strays, which will be fairly high for a large winding), then it is possible to make

$$L_1 = \frac{25.33}{0.455^2 \times 25} = 4.9 \text{ mH.}$$

Of course, it may not be advisable to resonate the primary with stray capacitances only, but there are practically no detuning effects present (except those due to temperature and humidity variations). The possibility of instability must not be overlooked, however, when the grid to plate gain is high, and for the case given it would probably be necessary to neutralize the i-f stage or to reduce the gain by increasing the capacitance value above $25 \mu\mu\text{F}$ (and so reducing L_1). However, L_1 will be made large here to illustrate the design procedure to be adopted in cases such as this, where L_1 is not equal to L_2 and also to bring out an additional useful point which could be overlooked in connection with the design of a.v.c. systems; see Chapter 27 Sect. 3(xv).

(10') Assume that unloaded Q values of 140 for the primary and secondary can be obtained. The plate resistance (r_p) for type 6SK7 is $0.8 \text{ M}\Omega$ for a set of typical operating conditions. Then the actual value of Q_1 is

$$Q_1 = \frac{Q_u r_p}{Q_u \omega_0 L_1 + r_p} = \frac{140 \times 0.8}{1.96 + 0.8} = 40.6.$$

(11') In order that the actual value of Z_s shall be 1224Ω (and so $Z'_s = 306 \Omega$) the secondary circuit must be loaded with a resistance R_s given by

$$R_s = \frac{Q_u Q_2 \omega_0 L_2}{Q_u - Q_2} = \frac{140 \times 2448}{140 - 0.45} = 2460 \Omega$$

where L_2 has the apparent value of 1.9 mH , and not its actual value, so as to make allowance for the use of approximate expressions which are normally only applicable

when Q exceeds about 10.

$$(12') Q = \sqrt{Q_1 Q_2} = \sqrt{40.6 \times 0.45} = 4.28.$$

$$\text{The coefficient of coupling} = k_c = 1/4.28 = 0.234.$$

$$L = \sqrt{L_1 L_2} = \sqrt{4.9 \times 0.32} = 3.06 \text{ mH.}$$

The actual value of L_2 is required here.

(13') It is now proposed to estimate the gain. To find the true gain for the conditions selected it would be necessary to solve the complete equivalent circuit. It should also be noted that the condition for secondary circuit series resonance does not coincide with the condition for parallel resonance. Correct circuit matching (i.e. that the value of Z'_s is the required one) can be readily checked from the equivalent secondary circuit. This has been done to ensure that the previous modifications to the transformer constants are quite satisfactory. Here the original gain equation (33) will be used, and then a suitable correction factor (namely X_{c_2}/X_{L_2}) will be applied for this special case where $X_{c_2} \neq X_{L_2}$. The results show an appreciable error, about + 20% in the worst practical cases, but the additional labour involved in a more exact analysis is hardly justified.

For the valve type selected $g_m = 2000 \mu\text{mhos}$ (2 mA/volt). Gain from grid of V_1 to grid of V_2 , using eqn. (33), is

$$\begin{aligned} \text{Gain (max. bandwidth)} &= \left[\frac{0.235}{0.235 + 306 \times 10^{-6} + 1500 \times 10^{-6}} \right] \times \\ &\quad \left[\frac{2 \times 4.28 \times 2\pi \times 0.455 \times 1.25}{4} \right] \\ &= 0.992 \times 7.7 = 7.6 \text{ times (17.6 db).} \end{aligned}$$

$$\text{Gain (min. bandwidth)} = 6744/8550 \times 7.7 = 6.07 \text{ times (15.6 db).}$$

The factor $X_{c_2}/X_{L_2} = 5470/917 = 5.95$ and so the maximum gain is about 45 times (33 db) and the minimum gain about 36 times (31 db). The calculated value from the equivalent circuit is 38 times.

Thus the maximum total gain variation (including all approximations) is about 2 db as specified i.e. ± 1 db about the average gain. Larger variations in gain, if permissible, would also allow increased overall gain; the disadvantages have been discussed previously.

(14') For some purposes a standard i-f transformer using fixed capacitances of about $100 \mu\mu\text{F}$, and the coupling increased to critical when the secondary and primary are correctly loaded, would give satisfactory results. The gain variation, and maximum gain, are largely controlled by the value of the damping resistor R_s connected across the secondary of the transformer.

To control bandwidth it is necessary to increase Z_L to increase the maximum bandwidth, R_s is increased to decrease the minimum bandwidth. If switched steps are required for bandwidth control, R_s can be calculated for each step; the remainder of the design is exactly as before.

The arrangement used for the input transformer is only one of many possible circuits. For cases such as the one given here (where the total gain is not a prime requirement) it may be preferable to leave the secondary circuit untuned and to use a tapped resistor to provide the ratio arms for the bridge circuit. The design procedure is readily developed from the usual coupled circuit theory.

SECTION 7 : DETUNING DUE TO A.V.C.

(i) Causes of detuning (ii) Reduction of detuning effects (A) General (B) Circuits.

(i) Causes of detuning

Detuning of i-f (and r-f) circuits is largely due to changes in valve input capacitance. The capacitance change is brought about when the grid bias on the valve is

altered, the bias change being due to the a.v.c. voltage altering with different signal inputs. This alteration in bias also leads to variation in the valve input conductance which will have to be considered in some circuits, since the conductance increases by about 2 : 1, from cut-off to normal operating conditions, with typical valve types operating at 100 Mc/s (see Ref. 68; also Chapter 2 Sect. 8 and Chapter 23, Sect. 5).

If all the factors which cause valve input capacitance and conductance changes are considered the problem is rather involved as can be seen from the discussions given in Chapter 2, Sect. 8 and Chapter 23, Sect. 5. We will confine attention here, mainly, to input capacitance changes which are most troublesome in receiver design.

One of the principal causes of change in valve input capacitance is the variation in position and density of the space charge distribution between grid and cathode, brought about by the change in grid bias.

Variation in grid-plate transconductance (g_m) is another principal cause of input capacitance change as will be seen later.

Short-circuit input capacitance changes are not very much affected by frequency, although the change in capacitance with transconductance is slightly greater at low frequencies than at high. The slight variation with frequency will not usually be important when compared with the changes due to alteration of transconductance, so that the data given in Chapter 2, Sect. 8 can be used directly. From this data, it is seen that the short-circuit input capacitance alters by about 1 to 2 μF in typical cases. It is interesting to compare these changes with that due to grid-to-plate coupling i.e. Miller effect (see Chapter 2, Sect. 8).

Suppose, for simplicity, that the plate load acts as a pure resistance. Then the input capacitance change is given by

$$\Delta C = C_g - C_{gp} = C_{gp} \left(\frac{g_m r_p R_L}{r_p + R_L} \right) \quad (43)$$

Taking a type 6SK7, with a plate load of 0.25 megohm, as a typical example. Then since $C_{gp} = 0.003 \mu\text{F}$, $r_p = 0.8 \text{ M}\Omega$ (this value is not constant, but it has been assumed so for simplicity) and g_m changes from 0-2000 μmhos , the input capacitance change is

$$\Delta C = 0.003 \frac{2 \times 0.8 \times 0.25 \times 10^3}{1.05} = 1.14 \mu\text{F}.$$

If C_{gp} is augmented by stray capacitances, such as those inevitably present due to the socket, wiring etc., this figure for ΔC will be very appreciably increased. The corresponding change in short-circuit input capacitance is 1.18 μF (see table Chapter 2 Sect. 8).

The effects are additive and cause an increase in input capacitance as the grid bias voltage becomes more positive.

(ii) Reduction of detuning effects

(A) General

There are a number of methods available for reducing the effects of valve input capacitance variations, and these methods (in most cases) also reduce input conductance variations. Usually the reduction of these effects will lead to a loss in stage gain unless additional circuit changes are made.

In the case of the ordinary broadcast receiver special circuits are not often used. The only precautions taken are :

(1) The total capacitance tuning the i-f transformer secondary, in particular, is made as large as is practicable consistent with other circuit requirements. Values of 200 μF , or so, should be used if possible, although values of the order of 100 μF , are generally used, since it is unlikely that the change in input signal will be such as to cause the maximum input capacitance change. Large values of tuning capacitance for the transformer are also helpful in increasing the attenuation at frequencies far removed from resonance. Also, with some types of converter valves (e.g. 6A8-G) a large tuning capacitance for the primary of the first i-f transformer can be of assistance in reducing degeneration in the signal input circuit connected to the converter; this applies particularly to signal frequencies which approach the intermediate frequency.

(2) The receiver is aligned on small input signal voltages, since detuning effects will be less serious when the input signal is large.

(3) The circuit layout is such as to minimize stray grid-to-plate capacitance.

The degree of circuit mistuning in terms of frequency shift can be determined by comparing the input capacitance change with the total capacitance across the valve input circuit. A number of helpful practical examples of circuit mistuning are given in Ref. 69.

There are several additional factors which are of importance.

(1) Detuning will cause sideband asymmetry and so lead to the possibility of increased distortion. This is of particular importance in high fidelity receivers.

When the carrier is received on the side of the i-f selectivity curve, one set of sidebands is almost completely eliminated (or at least substantially reduced in amplitude), and the amplitudes of the carrier and low frequency components of the other set of sideband frequencies are reduced. The tuned circuits will introduce phase and frequency distortion and the diode detector will give rise to non-linear distortion because of the absence of one set of sidebands. Experiment has shown that with the usual type of receiver the amount of detuning that can be tolerated before distortion becomes noticeable to a critical listener is about ± 1 Kc/s.

(2) Detuning of the r-f and converter input circuits can lead to a reduction in signal-to-noise ratio. This effect is not often very serious, when compared with the deterioration in signal-to-noise ratio caused by the reduction in gain of the r-f stages as the a.v.c. bias is increased; further discussion of this point will be given in connection with the design of a.v.c. systems in Chapter 27.

(3) Detuning can result in considerable loss in adjacent channel selectivity. This is not particularly serious if the receiver has been aligned on small signal input, since the deterioration occurs when the desired signal is large.

(4) The i-f stages lend themselves more readily to compensation methods than the r-f circuits; in the case of the r-f circuits exact compensation can usually be obtained at one frequency only. Since the r-f stages are often relatively unselective, detuning is not often a very serious factor and it is usual to compensate only in the i-f circuits.

(5) Even although exact compensation for input capacitance changes can be obtained at the resonant frequency, the compensation is not complete at frequencies removed from the i-f centre frequency, and there will always be some departure from symmetry on the "skirts" of the overall response curve. However, since compensation is required mainly at the centre frequency, this is not serious.

(6) The neutralization methods to be described in Section 8, in connection with stability, will affect input capacitance variations which are due to grid-to-plate coupling. If the amplifier is neutralized, then the input capacitance changes with grid bias will be due, mainly, to space charge effects.

(B) Circuits

Attention will be confined to the circuits of Fig. 26.18 (some discussion of which has already been given in Chapter 23, Sect. 5), since these allow satisfactory results to be obtained with a small number of components. Other types of compensating circuits can be found in Refs. 67, 71, 72.

In Figs. 26.18A and B, C_b is a by-pass capacitor and may be neglected in the discussion which follows. It is possible to show that, for complete compensation of the input capacitance variation, the condition required is

$$R_{gk} = \Delta C / C_{gk} \quad (44)$$

where R_{gk} = unbypassed cathode resistance

g_k = grid-to-cathode transconductance; which is given by $g_m(I_k/I_b)$ in which g_m is the mutual conductance; I_k is the total d.c. cathode current (for a pentode this is usually the sum of the plate and screen-grid currents); I_b is the d.c. plate current

ΔC = valve input capacitance change

and C_{gk} = grid-to-cathode capacitance.

For a typical case suppose $\Delta C = 3 \mu\mu\text{F}$, $C_{gk} = 6 \mu\mu\text{F}$ and $g_k = 2000$ (11.8/9.2) = 2560 μmhos , so that

$$R_k = (3/6) \times (10^6/2560) = 195 \, \Omega.$$

Since $\Delta C/C_{gk}$ determines the value of R_k for a particular valve, it is sometimes convenient to increase C_{gk} artificially to obtain a more suitable value for R_k . This is done by adding a small capacitance between the grid and cathode terminals. However, too large a total value for C_{gk} can have an undesirable effect on the valve input conductance, particularly at high frequencies, and so it is not advisable to increase C_{gk} to more than about twice its usual value or even less, at high frequencies (say 10 Mc/s or so). For typical results see Ref. 68. For 455 Kc/s i-f circuits it is often permissible to connect the whole of C_2 in parallel with C_{gk} .

Because of the presence of the unbypassed cathode resistor there will be a change in the effective mutual conductance (and consequently a loss in gain) given by

$$g_{m(\text{effective})} = \frac{g_m}{1 + R_k g_k} \quad (45)$$

In our example :

$$g_{m(\text{effective})} = \frac{2000}{1 + 195 \times 2.56 \times 10^{-3}} = 1330 \, \mu\text{mhos}.$$

If C_{gk} is increased to $20 \, \mu\mu\text{F}$ then $R_k = 58.5 \, \Omega$ and the effective $g_m = 1740 \, \mu\text{mhos}$. The actual cathode bias resistor required is approximately $260 \, \Omega$ so that about $200 \, \Omega$ ($= R'_k$) would be used and this is then by-passed in the usual manner by C_k , as shown in Fig. 26.18B. The increased value of C_{gk} would need some corresponding reduction in C_2 since the total capacitance tuning the i-f transformer secondary includes the resultant capacitive reactance due to C_{gk} and R_k in series if the reactances of C_b and C_k are neglected.

FIG. 26.18 METHOD FOR REDUCING VARIATIONS OF INPUT ADMITTANCE

The use of an unbypassed cathode resistor results in an increase of the short-circuit feedback admittance, and this effect can be used to increase the stage gain so as to offset the loss in g_m and, also, the reduction in Q of the input transformer due to the cathode resistor forming part of the tuned circuit. Two methods are available for increasing the feedback admittance; the first is to connect the plate and screen by-pass capacitors back to the cathode; the second is to add a small capacitance between plate and cathode, the plate and screen by-pass capacitors being connected to ground in the usual manner. These methods of increasing gain need to be treated with some care as they can easily lead to oscillation and particular attention is needed if instability is to be avoided. With some valve types (e.g. 6SG7, 6SH7, 9001, 9003, 6AG5, 6AK5) the plate-to-cathode capacitance is already relatively high because of the internal connections between the suppressor grid, beam confining electrodes, and the cathode; this can lead to oscillation difficulties without external capacitance being added.

In the majority of cases it is preferable to return plate and screen by-pass capacitors (also the suppressor grid) to ground, and add a capacitance from plate to cathode if this is thought to be desirable.

With any circuit the capacitances can be measured and the value for R_k accurately calculated, but in a practical case it is generally much simpler to determine an approximate value for R_k and then find the exact value experimentally.

SECTION 8 : STABILITY

(i) *Design data* (ii) *Neutralizing circuits.*(i) **Design data**

The discussion of Chapter 23, Sect. 7 should be used in conjunction with the data to be given here ; also, the detuning effects discussed in the previous section are closely bound up with the data which follow.

For stages using single tuned circuits the expression given in Chapter 23 is more conveniently arranged as

$$\text{Max. stable impedance} = \sqrt{\frac{2}{g_m \omega_0 C_{gp}}} \quad (46)$$

from which it immediately follows that the

$$\text{Max. stable gain} = \sqrt{\frac{2g_m}{\omega_0 C_{gp}}} \quad (47)$$

For double tuned circuits which are critically-coupled—the usual case—Jaffe (Ref. 74) has shown that

$$\text{Max. stable impedance} = \sqrt{\frac{0.79}{g_m \omega_0 C_{gp}}} \quad (48)$$

$$\text{and max. stable gain} = \sqrt{\frac{0.79 g_m}{\omega_0 C_{gp}}} \quad (49)$$

where g_m = mutual conductance of amplifier valve

$\omega_0 = 2\pi \times f_0$ (and f_0 is operating frequency ; i-f in this case)

C_{gp} = total grid-to-plate capacitance made up from that due to the valve, wiring and valve socket etc.

Additional data are given in Ref. 75 for cases where the input and output circuits are not identical. This reference also shows that greater gain is possible when the impedance of the input circuit is less than that of the output circuit ; a condition which is fulfilled only in special cases in practical i-f circuits.

The equations given above, and in the references, are useful in forming an estimate of the possible maximum gain obtainable and in indicating some of the causes of instability ; but detailed calculations for various circuit possibilities hardly seem to be justified.

It may be helpful to note that when selecting a particular type of valve for maximum gain combined with stability, the most suitable is that having the greatest value of g_m/C_{gp} consistent with other circuit requirements (and cost). For an i-f valve, g_m/C_{gp} is of considerable importance but for a r-f valve operating at v-h-f it is also very important to consider the factor $g_m\sqrt{R_i}$, as pointed out in Chapter 23, Sect. 5.

(ii) **Neutralizing circuits** (See Supplement page 1498)

A simple neutralizing circuit, which requires only the addition of one capacitor, is shown in Fig. 26.19(A). The equivalent capacitance bridge is shown in Fig. 26.19(B). It is assumed that the cathode by-pass capacitance is large.

The condition for the effects of the grid-to-plate capacitance to be neutralized is

$$C_N = C_{gp} \quad (50)$$

where C_N = neutralizing capacitance required

C = a.v.c. by-pass capacitance (usually about 0.01 μF)

C_{gp} = total grid-to-plate capacitance including strays

and C_{gk} = total grid-to-cathode capacitance including strays.

For a typical case $C = 0.01 \mu\text{F}$, $C_{gp} = 0.01 \mu\text{F}$ and $C_{gk} = 15 \mu\mu\text{F}$.

Then $C_N = 0.01 \times 10^{-6} (0.01/15) = 6.7 \mu\mu\text{F}$.

The exact value for C_N is determined experimentally. For receiver production it is generally sufficient to use a fixed value for C_N which is reasonably close to the

FIG. 26-19

I-F NEUTRALIZATION CIRCUIT

value required. The neutralization is generally not sufficiently critical to require different capacitance values in different receivers of the same type, as even partial neutralization is helpful and often sufficient.

Other circuits using various arrangements of inductance and capacitance for neutralization and stabilization can be found in the references. Two interesting alternatives (Refs. 79 and 80) to that of Fig. 26.19 are shown in Fig. 26.20.

Circuit (1) will be briefly discussed; circuit (2) should be self-explanatory. In both cases all the components have their usual values except C_3 in circuit (1), and L_a is an added inductance (in i-f and some r-f circuits) in circuit (2); the latter arrangement is of interest when the cathode is grounded for d.c. To obtain complete neutralization in circuit (1) it is required to make

$$C_3 = C_1(C_{pk}/C_{gp}) \quad (51)$$

where C_1 = i-f tuning capacitor

C_{pk} = total plate-cathode capacitance including all strays

and C_{gp} = total grid-plate capacitance including all strays.

In a typical case for a 455 Kc/s i-f transformer $C_1 = 100 \mu\text{F}$, $C_{pk} = 10 \mu\text{F}$, $C_{gp} = 0.01 \mu\text{F}$.

Then $C_3 = 100 \times (10/0.01) = 0.1 \mu\text{F}$, which is used as the by-pass capacitor across the cathode resistor. Also, remember that exact neutralization may not be necessary.

BOTH CIRCUITS ARE DEGENERATIVE, BUT ARE RE-GENERATIVE WHEN AA', BB' ARE REVERSED

FIG. 26-20 METHODS FOR STABILISING R-F AND I-F AMPLIFIERS

This circuit requires no additional components and C_3 is set to the value required for neutralization. It will be noted that the capacitance of C_3 is somewhat larger than is generally used for a by-pass capacitor. The only disadvantage is that an additional lug is required on the i-f transformer base and care is necessary to keep critical leads as short as possible. The advantage of the circuit in a r-f stage should be apparent.

Receivers which combine the detector diode in the i-f amplifier valve sometimes require additional neutralization because of feedback (which may be either regenerative or degenerative) caused by the grid-to-diode capacitance. A typical circuit is shown in Fig. 26.21. This requires two capacitors, C_{N1} and C_{N2} , in addition to the usual circuit components.

system, the distortion is materially reduced ; this can be confirmed experimentally. As a compromise between distortion and a.v.c. action, the screen supply voltage can be obtained by means of a high resistance voltage divider arrangement if so desired. Detailed measurements of distortion have been made on typical i-f voltage amplifier valves for various methods of screen voltage supply and some of the results can be found in Ref. 83. In cases where the range of bias voltage is limited, a high resistance voltage divider can be arranged to give less distortion than that given by the series feed arrangement. A total increase in non-linear distortion of the order of 2% for 90% amplitude modulation is to be expected in typical cases using a series screen resistor. Because of the internal construction of remote cut-off valves, such as those used in i-f and r-f amplifiers, the screen current is often rather variable and this suggests a voltage divider in cases where variations in screen voltage are important (see Ref. 84).

For methods of measuring the signal handling capabilities of i-f amplifier valves and the non-linear distortion from this cause, the reader is referred to Ref. 4 (page 335) and Ref. 83.

Frequency distortion, caused by sideband cutting due to the selectivity of the tuned circuits, is always present to some extent ; this should be obvious from the discussion on the design of i-f transformers and it is not proposed to treat the matter further here.

(ii) Frequency modulation i-f stages

With frequency modulation receivers, distortion of the amplitude (in itself) of the frequency modulated wave is generally not of great importance, provided the amplitude limiting device is capable of smoothing out the variations. Non-linearity in i-f and r-f valve characteristics are of secondary importance, with this system of reception, and the non-linear distortion appearing in the receiver output from this cause is usually negligible ; this is the reverse of the case for amplitude modulation.

The amount of distortion caused by the non-linearity of phase shift/frequency characteristics of the tuned circuits is of considerable importance, however, and poorly designed i-f transformers will lead to non-linear distortion in the receiver output. If the criterion for non-linearity given in eqn. 24 [Sect. 4(v) of this chapter] is fulfilled, then the distortion in the receiver output due to the i-f circuits preceding the discriminator (or whatever detection system is used) will be quite small, and in most cases less than that introduced by the detection and audio systems.

When a F-M receiver is accurately tuned to the centre frequency of the carrier, the non-linear distortion of the modulating signal introduced by the tuned circuits will consist mainly of odd order harmonics. Of these the third harmonic (H_3) is the largest and a method of estimating its magnitude is helpful when i-f transformers are being designed. The required expression is (Ref. 82),

$$H_3 = \frac{4A^3}{\beta} (1 + A^2)^{\frac{1}{2}} \left[\frac{3Q^2k^2 - 4A^2 - 1}{(1 + Q^2k^2)^3} \right]. \quad (53)$$

For a critically-coupled transformer $Qk = 1$ and so

$$H_3 = \frac{A^3}{\beta} (1 + A^2)^{\frac{1}{2}} (1 - 2A^2) \quad (54)$$

where $A = \frac{\Delta F}{f_0} Q$

ΔF = frequency deviation

f_0 = central carrier frequency

Q = magnification factor ($Q_1 = Q_2$)

β = modulation index = $\Delta F/f$

f = a-f modulating frequency

and k = coefficient of coupling (the coupling may be inductive or capacitive and either shunt or series).

For 1 db attenuation it is known that, for a critically-coupled transformer with identical primary and secondary circuits, $Q = f_0/\text{total bandwidth}$. From this we

may write $A = \Delta F/\text{total bandwidth}$. If it is taken that the total frequency deviation ($2\Delta F$) is equal to the total bandwidth for 1 db attenuation, then we obtain

$$A = \frac{1}{2} \text{ and } H_3 = \frac{\sqrt{5}}{32\beta} = \frac{7}{\beta} \% \quad (55)$$

The Q required for this condition is given from the previously stated relationship $Q = f_0/\text{total bandwidth}$.

Suppose $Q = 71$ is obtained, for a critically-coupled transformer, with $f_0 = 10.7$ Mc/s, $2\Delta F = 150$ Kc/s and $\beta = 5$. Then the third harmonic audio distortion introduced by each transformer is 1.4% (approx.); using either eqns. (54) or (55).

If $Q = 80$ is obtained from the procedure of Sect. 4, then eqn. (54) gives $H_3 = 1.57\%$; eqn. (55) is not applicable in this case.

It should be clear that a simple approximate design procedure can be developed from the conditions leading to eqn. (55).

The distortion given in the examples is somewhat higher than that experienced under normal operating conditions. The third harmonic of 15 Kc/s will hardly trouble the listener, but harmonics of the lower audio frequencies would be serious if their amplitudes are appreciable, and the possibility of intermodulation effects should not be neglected.

Applying eqn. (54) for $Q = 71$, $\Delta F = 50$ Kc/s (more nearly the usual operating condition) and a modulation frequency of 5 Kc/s, then $H_3 = 0.074\%$. (See also Chapter 27, Sect. 2 under heading "Non-linear distortion").

It should be carefully noted that eqn. (55) applies only for the special conditions under which it was derived. Distortion is normally calculated from eqns. (53) and (54).

Only a few of the significant factors have been mentioned here, and for more detailed information the reader is referred to Refs. 82, 85, 86 and 87.

(i) Diodes

(A) General

A diode has two electrodes namely plate and cathode. It is therefore identical in structure with a power rectifier but the term is generally restricted to valves which are used for detection or a.v.c. as distinct from rectifiers which are used for power supply. The operation of diodes with a.v.c. is considered in detail in Sect. 3 of this chapter. The operation of a diode on a modulated wave is rather different from the operation of a power rectifier, and it is necessary to consider the characteristic curves of a diode valve if a full understanding of the operation is to be obtained. The operation of diodes on a modulated input is considered in (B) below. Fig. 27.1 shows typical distortion curves for a diode operating firstly under ideal conditions with no a.c. shunting (curve B) and secondly the distortion resulting when a load of 1 megohm is shunted across a diode load resistance of 0.5 megohm (curve A). The respective percentages of harmonic distortion at 100% modulation are approximately 6% and 12% so that the presence of such shunting has a very marked effect on performance ; these curves apply only for the particular conditions under which they were derived.

The design of a diode detector for low distortion is based on the following requirements :

- (1) That the input voltage should not be less than 10 volts peak.
- (2) That no appreciable a.c. shunting should be present.

The first of these two requirements is easily met for local stations and a voltage from 10 to 20 volts is quite common in receivers fitted with a.v.c. The second requirement is one which is difficult to satisfy. Shunting of the diode load may be due to :

FIG. 27.1

- (1) The a.v.c. system.
- (2) The following grid resistor.
- (3) An electron ray tuning indicator.

The circuit of a typical diode detector is shown in Fig. 27.2 in which the diode load resistance is R_2 together with R_1 ; the latter, in conjunction with C_1 and C_2 , form a r-f filter so that the r-f voltage passed on to the a-f system may be a minimum. R_1 is generally made about 10% of R_2 and typical values are 50 000 ohms and 0.5 megohm. The capacitances of C_1 and C_2 depend upon the frequency of the carrier; for an intermediate frequency of 455 Kc/s they may both be $100 \mu\text{F}$.

If the volume control (R_2) is turned to maximum the shunting effect due to R_3 will be appreciable, since R_3 cannot exceed 1 or 2 megohms with most types of valves. If, however, grid leak bias is used on a high- μ triode valve, R_3 may be approximately 10 megohms and the input resistance of the valve will then be of the order of 5 megohms. This is sufficiently high to be unimportant but for lower values of R_3 the distortion with the control set near maximum may be severe. It is found in most conventional receivers that the a-f gain is considerably higher than that required for strong carrier voltages and under these conditions the control will be turned to a low setting. The a.c. shunting effect due to R_3 is practically negligible provided the control is below one-fifth of the maximum position. A good method of overcoming the a.c. shunting due to the audio amplifier is shown in Fig. 27.3. The diode may be in the same envelope as the i-f amplifier valve. Negative feedback is applied across

FIG. 27.2 DIODE DETECTOR CIRCUIT

part of the cathode bias resistor for the a-f voltage amplifier valve. For the component values shown, the measured input resistance between points A and B is in excess of 10 megohms for frequencies up to about 10 Kc/s. A possible disadvantage is the reduction in overall gain because of the negative feedback, although this is not generally serious. Increasing the feedback resistance R increases the overall gain, but reduces the input resistance. Intermediate values of gain and input resistance may be selected as desired. For further details of receivers using this arrangement see Refs. 6 and 7.

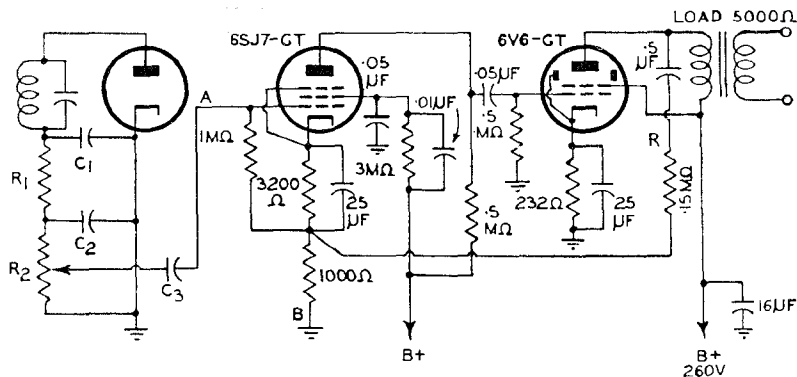

FIG. 27-3 AUDIO AMPLIFIER GIVING LOW A.C. SHUNTING ACROSS DIODE LOAD.

Another useful method of reducing a.c. shunting effects is to use a cathode follower stage between the detector and the a-f voltage amplifier. This is often conveniently accomplished by employing a double triode valve, one section serving as the cathode follower and the other as an a-f voltage amplifier.

Distortion due to the a.v.c. system will be discussed in detail in Sect. 3 below. One type of distortion often encountered is caused by delayed a.v.c. systems at the point where the a.v.c. diode just starts to conduct. This form of distortion is called differential distortion and may be kept to low values by making the delay voltage small. The conventional arrangement for obtaining a.v.c. voltage from the primary of the last i-f transformer is generally preferred, as it reduces the a.c. shunting effect across the detector diode circuit.

The a.c. shunting due to the addition of an electron ray tuning indicator to the diode detector circuit is serious and difficult to avoid. In order to reduce the distortion to a minimum the resistor feeding the grid of the tuning indicator may be made 2 megohms and the effect will only then be apparent at high percentages of modulation. If the tuning indicator is connected to the a.v.c. system it will not operate at low carrier levels unless the delay voltage is extremely small. One possible method, where the utmost fidelity is required, is to use the same circuit as for delayed a.v.c. but with a delay voltage of zero, and to connect the tuning indicator to this a.v.c. circuit. With this arrangement a.c. shunting due to the a.v.c. circuit and the tuning indicator is eliminated, while differential loading no longer occurs.

FIG. 27-4 COMPENSATED DIODE DETECTOR.

An interesting arrangement (Ref. 8) for counteracting the effect of a.c. loading, and so increasing the maximum percentage of modulation which can be handled without excessive distortion is accomplished by the use of the circuit of Fig. 27.4. In this arrangement a positive bias is applied to the diode plate in such a way as to be proportional to the carrier input. A fixed positive bias would not be satisfactory since it would only give low distortion at one carrier level.

FIG. 27.5

TYPICAL DIODE CHARACTERISTICS.

(B) Diode curves

Typical diode characteristics are shown in Fig. 27.5. Each curve corresponds to the peak voltage of a constant unmodulated carrier voltage. On this graph may be drawn loadlines corresponding to diode load resistances in a similar manner as for triodes. The intersection of the applied loadline (OA) with the peak input voltage curve indicates the d.c. voltage developed by the diode and available for a.v.c. As the load resistance increases, so the d.c. voltage approaches the peak input voltage.

For example, if the carrier input is 10 volts peak and the diode load resistor 0.5 megohm, the diode current will be $17\ \mu\text{A}$, and the d.c. voltage — 8.7 volts. If 100% modulation is applied to the carrier, the operating point will move at audio frequency along the loadline from the intersection with the "0" curve, through X to the intersection with the 20 volt curve. The distortion over this excursion is small (about 5% second harmonic) and may be reduced still further by operating with a higher carrier input voltage.

Typical diode curves with loadlines already drawn are shown in valve data books. Average curves are shown in Fig. 27.6 and these are applicable to the diodes incorporated in standard types of Radiotron diode-triode and diode-pentode valves. It has become the usual practice to show the signal input voltages in r.m.s. values rather than the peak voltages indicated in Fig. 27.5.

If the d.c. load resistance of 0.5 megohm, represented by OA in Fig. 27.5, is shunted by an a.c. load (such as would occur due to the grid resistor of the following valve) the dynamic loadline will be similar to BC, which passes through the static point X but which has a slope corresponding to the total effective a.c. load resistance. This loadline (BC) reaches cut-off at about 75% modulation and the distortion at higher percentages of modulation will consequently be severe. For any combination of d.c. and a.c. loads it is possible to draw the loadlines and determine the limiting percentage of modulation before distortion becomes excessive. It should not be overlooked that there will be some distortion present even before the limiting percentage of modulation is reached. The evaluation of this distortion is discussed below.

(C) Quantitative design data

Design formulae will be set out below so that the performance of the diode detector circuit can be assessed. These expressions are used in conjunction with the diode curves of Fig. 27.6. The design procedures are necessarily a series of compromises but the results form a useful practical guide. For a more detailed discussion the reader is referred particularly to Ref. 1 (p. 339), Ref. 2 (p. 413) and Ref. 5 (p. 553).

(a) Diode detection efficiency

This can be found from curves such as those shown in Fig. 27.6. The efficiency (assuming a sine wave input) is

$$\eta = \frac{E_{dc}}{\sqrt{2}E_{rms}} \quad (1)$$

Suppose the d.c. load is 0.5 megohm and the signal input (E_{rms}) is 15 volts (r.m.s.). Then from the curves $E_{dc} = 16.8$ volts.

$$\eta = \frac{16.8}{\sqrt{2} \times 15} = 0.793 \text{ or } 79.3\%.$$

Actually the a.c. load should be determined and used for all calculations. The a.c. load is, from Fig. 27.2,

$$R_{ac} = R_1 + \frac{R_2 R_3}{R_2 + R_3} \quad (2)$$

The d.c. load for the diode detector is

$$R_{dc} = R_1 + R_2. \quad (3)$$

If simple a.v.c. is used the effect of additional a.c. shunting due to this circuit should be taken into account. In this case the effects of additional capacitive reactance are usually neglected for simplicity.

(b) Critical modulation ratio

The highest percentage of modulation which can be handled by the detector, before serious distortion of the modulation envelope occurs, is given by

$$m = 1 - \eta F \frac{R_{dc}}{R_{dc} + R_3/F} \quad (4)$$

where F = fraction of R_{dc} across which R_3 is tapped

$$= \frac{R_2}{R_1 + R_2} = \frac{R_2}{R_{dc}}.$$

If $R_{dc} = 0.5 \text{ M}\Omega$, made up from $R_1 = 50\,000 \Omega$ and $R_2 = 0.45 \text{ M}\Omega$, then

$F = 0.45/0.5 = 0.9$. Taking $\eta = 0.793$ as before, and $R_3 = 1 \text{ M}\Omega$ we have,

$$m = 1 - 0.793 \times 0.9 \frac{0.5}{0.5 + 1/0.9} = 0.78 \text{ or } 78\%.$$

It should be noted that the smaller F is made, the higher the critical modulation ratio. If F is fixed, then R_3 is made as large as possible but is usually limited to about 1 or 2 megohms unless special circuit arrangements, such as those discussed previously, are made.

The critical modulation ratio can also be increased by applying a positive d.c.

FIG. 27.6

RECTIFIED MICROAMPERES

bias voltage to the diode plate. This arrangement is only satisfactory if the bias can be changed for each i-f input voltage (E_{rms}) see Ref. 1 (page 348).

For this case

$$m = \left(\frac{\sqrt{2E_{rms}} + E_{bias}}{\sqrt{2E_{rms}}} \right) \left(1 - \eta F \frac{R_{dc}}{R_{dc} + R_s/F} \right) \quad (5)$$

The circuit of Fig. 27.4 shows a practical arrangement for increasing the critical modulation ratio by applying positive bias to the diode plate, as mentioned previously in Sect. (A) above.

(c) **Equivalent damping across i-f transformer**

The secondary circuit damping is found approximately from

$$R_E = \frac{R_{ac}(\sqrt{1 - \eta^2} - \eta \cos^{-1} \eta)}{\eta(\cos^{-1} \eta - \eta \sqrt{1 - \eta^2})} \quad (6)$$

R_E/R_{ac} can be read directly from Fig. 27.7 for various values of η .

Suppose $R_{ac} = 0.36 \text{ M}\Omega$ and $\eta = 0.793$ then, since $R_E/R_{ac} = 0.7$, the equivalent damping resistance is $R_E = 0.7 \times 0.36 = 0.25 \text{ M}\Omega$.

It is often taken in practice (as a "rule of thumb") that the equivalent damping resistance is half the d.c. diode load resistance. This gives an equivalent damping resistance of $R_{dc}/2 = 0.5/2 = 0.25 \text{ M}\Omega$ in this case. However, it should be realized that if the diode efficiency is taken as unity, the equivalent damping resistance which appears across the tuned circuit is half the a.c. load resistance; this is indicated by Fig. 27.7.

Damping of the i-f transformer primary is serious when the a.v.c. voltage is derived from a diode detector connected to this voltage source. The usual arrangement is a capacitor ($100 \mu\text{F}$ or less) taken from the plate connection of the transformer primary to the diode plate. The additional primary damping from this source is approximately one third of the d.c. load resistance for the a.v.c. diode. This also follows fairly readily if it is considered that R_{dc} shunts the primary of the transformer, and in addition the diode conduction current also adds damping equivalent to a parallel resistance of approximately $R_{dc}/2$. From this

$$R_E = \frac{R_{dc}(R_{dc}/2)}{R_{dc} + R_{dc}/2} = \frac{R_{dc}}{3}$$

For a typical case, the a.v.c. resistance would be 1 megohm, and so the equivalent damping resistance would be approximately 0.33 megohm. If the i-f amplifier valve

has a plate resistance of 0.8 megohm the primary damping resistance would be 0.23 megohm.

This means that, with detector and a.v.c. diodes conducting, both the secondary and primary circuits of the i-f transformer are heavily damped and this damping must be taken into account when the i-f transformer, connected between the last i-f voltage amplifier valve and the diode detector, is being designed. Delayed a.v.c. will, of course, affect the primary circuit damping and three conditions arise: the diode not conducting, the diode just starting to conduct, and the diode conducting when the applied voltage is reasonably large. When conduction just starts the damping depends very largely on the diode detection efficiency and will vary quite appreciably for a small range of input voltages. It is usually sufficient, however, to know the tuned circuit damping for the two conditions, diode not conducting, and diode conducting with a reasonably large input voltage. For the diode not conducting the added damping is approximately R_{ac} ; R_{ac} should not be used here. With the diode conducting the added damping can be taken as $R_{ac}/3$ with sufficient accuracy in some cases since in this case the fact that the diode detection efficiency is not unity offsets to some extent the increase in damping which is obtained when R_{ac} is used in place of R_{dc} .

Damping of the transformer tuned circuits as determined above assumes linear diode plate-voltage—plate-current characteristics. For parabolic diode detection the damping differs by only a small amount from that given by the linear characteristics and so, in practice, it is seldom necessary to treat the two cases separately. In any case the order of accuracy to be expected in the final results from the procedures set out, would hardly justify any additional refinements in the design calculations.

(d) The actual degree of modulation

The degree of modulation applied to the detector is always less than the modulation of the incoming carrier. The actual value of m which the detector will be required to handle is given approximately by

$$m = m' \frac{R_3(R_{dc} + 2Z_L)}{R_{dc}R_3 + 2Z_L(R_{dc} + R_3)} \quad (7)$$

where m' = original modulation percentage

$R_{dc} = R_1 + R_2$ (see Fig. 27.2)

R_3 = grid resistor of following stage (see Fig. 27.2)

and Z_L = load impedance presented to the i-f voltage amplifier preceding the detector stage; including the effects of all damping on the primary and secondary of the i-f transformer.

In addition, at higher audio frequencies the reduction of side band amplitude by the selectivity of the earlier stages in the receiver results in a further decrease in depth of modulation.

(e) Audio frequency output voltage and response (frequency distortion)

The approximate r.m.s. audio frequency output voltage can be determined for a particular arrangement by using the equivalent circuit of Fig. 27.8. It is often assumed that all capacitive reactances are negligible, for simplicity in carrying out gain calculations. However, the circuit is readily modified to include C_1 , C_2 and C_3 as

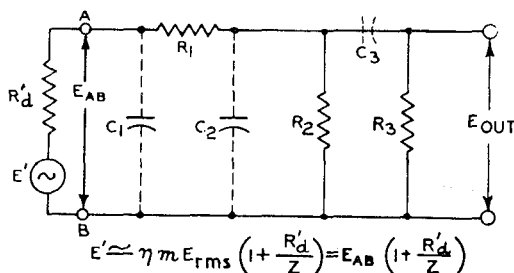

FIG. 27.8 EQUIVALENT DIODE CIRCUIT AT AUDIO FREQUENCIES.

shown by the dotted lines, and any additional capacitances in the circuit can be included if necessary. For this diagram

m = modulation factor

E_{rms} = i-f input voltage

η = detection efficiency determined from curves of Fig. 27.6

Z = total load impedance connected between the terminals AB. (This is equal to R_{ac} over the middle audio frequency range)

$$R_{ac} = R_1 + \frac{R_2 R_3}{R_2 + R_3}$$

and R'_d = internal equivalent resistance of diode at audio frequencies. This is given by the inverse slope of the curves of Fig. 27.6.

R_1 , R_2 and R_3 are as shown in Fig. 27.2.

It should be noted that R_d is not the diode conduction resistance (R_d) but is related to it by

$$R'_d = \frac{\pi R_d}{\cos^{-1} \eta} \quad (8)$$

Also R'_d and R_d are not constant for all operating conditions. For our previous example we see from the 15 volt (r.m.s.) curve of Fig. 27.6, and taking the diode load as being

$$R_1 + R_2 = 0.5 \text{ M}\Omega, \text{ for simplicity,}$$

$$R'_d = \frac{(17 - 16.5) \times 10^6}{(42 - 26)} = 31\,200 \, \Omega.$$

It will be seen that R'_d is determined in a rather similar manner to that used for finding the plate resistance of multi-element valves. The diode conduction resistance in this case is (approximately) 6500 ohms.

It is sometimes required to find the audio frequency response and this can readily be determined from the complete circuit of Fig. 27.8. A suitable procedure would be as for r.c. amplifiers in which the capacitances are ignored over the middle frequency range (say around 400 to 3000 c/s), and the audio voltage output is calculated for the resistance network only. At low frequencies the effects of C_1 and C_2 can be ignored since they are usually about 50 to 100 $\mu\mu\text{F}$ each, and only the effect of C_3 would be considered. At high frequencies C_3 would be neglected and the effects of C_1 and C_2 considered. Often only the maximum output voltage is required plus the total output variation from say 50 c/s to 10 Kc/s, and this simplifies the calculations. If Fig. 27.8 is inspected it will be seen that it is a simple matter to apply the generalized low frequency response curves given in Chapter 12. The high frequency curves can also be applied directly if R_1 can be neglected (this is usually permissible) and C_1 and C_2 are considered as being in parallel.

When using the circuit of Fig. 27.8 it is more convenient to determine the voltage E_{AB} since this is given directly by

$$E_{AB} = \eta m E_{rms}$$

It follows that, over the middle frequency range,

$$E_{out} = E_{AB} \left(\frac{R_{ac} - R_1}{R_{ac}} \right)$$

$$\text{and } \frac{E_{out}}{E'} = \frac{E_{out}}{E_{AB}} \times \frac{E_{AB}}{E'} = \frac{R_{ac} - R_1}{R_{ac} + R_d}.$$

If R_1 can be neglected in comparison with R_2 and R_3 in parallel, then $E_{out} = E_{AB}$ over the middle frequency range.

It is more accurate to determine E_{AB} from the curves of Fig. 27.6, since η is not constant for a modulated carrier voltage and the effects of contact potential are included in the measured data. The procedure is to draw the a.c. loadline on the graph and note the d.c. voltages E_{dc_1} and E_{dc_2} given by the maximum and minimum values of E_{rms} during modulation. From this

$$E_{AB} = \frac{1}{2\sqrt{2}} (E_{dc_1} - E_{dc_2}).$$

The simplified graphical procedure is only suitable when the amplitudes of harmonics higher than the second are negligible [see also (h) below]. More accurate graphical methods are required if this is not true.

To compare the results obtained by the two methods, assume $E_{rms} = 15$ volts and the percentage modulation is 50% (i.e. $m = 0.5$). As determined previously $\eta = 0.793$, and it will be taken that $R_{ac} = R_{dc} = 0.5$ megohm. Then

$$E_{AB} = \eta m E_{rms} = 0.793 \times 0.5 \times 15 = 5.95 \text{ volts (r.m.s.)}.$$

From Fig. 27.6, $E_{dc1} = 26.5$ volts and $E_{dc2} = 7.5$ volts so that

$$E_{AB} = \frac{1}{2\sqrt{2}} (26.5 - 7.5) = 6.7 \text{ volts.}$$

The discrepancy between these two results is easily explained, as an examination of typical diode circuits giving the d.c. voltage developed by the diode in the absence of signal input shows that there is about -0.5 to -1 volt developed across a diode load of 0.5 megohm. This difference is also illustrated by the curve of Fig. 27.5, which shows that -1 volt is developed for the conditions being considered. It is also seen that the variation in detection efficiency (η) over the range of voltage used does not have a large effect on the final result. The presence of d.c. voltage across the load resistor, in the absence of signal input voltage, is due to contact potential in the diode.

(f) Effect of shunt capacitance on detection efficiency

Too low a value for C_1 and C_2 will affect the detection efficiency. Provided the total shunt capacitance across the diode load is not less than $\frac{12.72}{fR_{ac}} \mu\mu\text{F}$ the effect can be neglected where

$$f = \text{frequency (expressed in Mc/s)}$$

$$R_{ac} = R_1 + \frac{R_2 R_3}{R_2 + R_3} \text{ (expressed in } M\Omega \text{)}.$$

For our previous example of $R_{ac} = 0.36 M\Omega$, and i-f of 455 Kc/s , the capacitance due to C_1 and C_2 should not be less than about $78 \mu\mu\text{F}$; this includes all stray capacitances. In the circuit of Fig. 27.2 typical values of C_1 and C_2 are $100 \mu\mu\text{F}$ each and if R_1 is neglected it is seen that the total capacitance is more than twice the value required even when strays are neglected. It would be feasible to reduce C_1 and C_2 to $50 \mu\mu\text{F}$ respectively with a reduction in attenuation at the higher audio frequencies.

(g) Non-linear distortion

If the value of total capacitance across the diode load resistance is too large, the discharge time constant will be too long and the voltage across the diode load will not follow the modulation envelope. This will give rise to non-linear distortion and suggests that the rate of discharge of the load circuit should not be less than the maximum rate of change of the modulation envelope. It can be shown that non-linear a-f distortion due to this cause can be almost completely avoided provided that

$$\frac{1}{\omega C_1 R_{dc}} \gg m. \quad (9)$$

Suppose we neglect the decoupling resistance (R_1) in Fig. 27.2, as this unnecessarily complicates calculations when its value is about $1/10$ of R_2 (the usual case).

What is required, is to determine a value for $C_1 R_{dc}$ which will allow $m = 1$, i.e. the incoming signal to be 100% modulated. However, it should be clear from previous discussion that the modulation percentage is generally a good deal lower than this figure, and it seldom happens that very high modulation percentages occur at high audio frequencies.

Take R_{dc} as 0.5 megohm, then $1/\omega C_1 = m R_{dc} = 1 \times 0.5 \times 10^6$.

Assume that the highest audio frequency is 10 Kc/s , then $\omega = 2\pi \times 10^4$ and so

$$C_1 = \frac{10^{12}}{2\pi \times 10^2 \times 0.5 \times 10^2} = 31.8 \mu\mu\text{F}.$$

This is the largest value C_1 should have if the detector is to be capable of handling audio frequencies of 10 Kc/s and 100% amplitude modulation.

It will be noticed from (e) above that the detector efficiency will be reduced if C_1 is

given the value determined. A suitable practical compromise would be to make $C_1 = C_2 = 50 \mu\text{F}$ and retain the values of R_1 , R_2 and R_3 given in the example. If improved decoupling is required then R_1 could be increased to say 0.1 megohm. This also permits a higher critical modulation ratio at the expense of some reduction in available audio output. The difficulty with non-linear distortion is not encountered when C_i is charging, since the diode is conducting and the charging time constant is approximately $C_i R'_a$ which in our example is, taking $C_i = 100 \mu\text{F}$, $100 \times 10^{-12} \times 3.12 \times 10^4 = 3.12 \mu\text{secs}$. The discharge time constant is approximately $100 \times 10^{-12} \times 0.5 \times 10^6 = 50 \mu\text{secs}$.

(h) Estimate of magnitude of non-linear distortion

The distortion can be found from the curves of Fig. 27.6 in the same way as for power amplifiers (Ref. 3, p. 100). The operating point corresponding to a given signal input is marked on the a.c. loadline. The maximum and minimum excursions of the modulation envelope are now marked on this same line. If only second harmonic distortion is required (and higher order harmonic distortion is very small) these points are sufficient. For distortion calculations which involve harmonics higher than the second the methods detailed in Chapter 13 should be used. The expression to be used here is

$$\text{2nd harmonic percentage} = \frac{1}{2} \left(\frac{A - 1}{A + 1} \right) \times 100\%, \quad (10)$$

$$\text{where } A = \frac{\text{positive current swing}}{\text{negative current swing}}.$$

Voltage swing would give the same results, since the load is taken as being a pure resistance.

Suppose we take $R_{ac} = R_{dc}$ and use the 0.5 M Ω loadline. The carrier input voltage is 15 volts (r.m.s.) and is modulated 50%. The voltage swing is thus ± 7.5 volts (r.m.s.) about 15 volts.

From Fig. 27.6 this gives (approximately)

$$A = \frac{53 - 33.5}{33.5 - 16} = 1.11$$

$$\text{2nd harmonic percentage} = \frac{1}{2} \left(\frac{0.11}{2.11} \right) \times 100 = 2.6.$$

The true a.c. loadline would indicate somewhat more distortion than is given by this simple example.

(D) Miscellaneous data

(a) With radio receivers using diode-triode or diode-pentode valves as combined detectors and a-f or i-f amplifiers several effects require consideration. Where the combined valve is used in the a-f application, difficulty is often experienced with **residual volume effect** ("play-through"). This effect is quite distinct from the minimum volume effect experienced with receivers using a reflexed amplifier. The residual volume is heard in the receiver output when the audio volume control is turned to zero (the grid may also be earthed as a further check). The cause of the effect is capacitive and electronic coupling between the detector diode and the plate of the a-f voltage amplifier.

In some cases there may be direct coupling at audio frequencies, but usually the important factor is coupling of modulated i-f currents which are detected in the audio amplifier.

A complete cure for the trouble is to combine the detector diode with the i-f voltage amplifier. However, this can sometimes lead to difficulties with regeneration or degeneration at i-f due to coupling between the detector diode and signal grid. When the valve is retained as an a-f amplifier it is necessary to keep all stray coupling to a minimum by careful layout and wiring. Diode pentodes are often helpful, particularly when series screen feed is used, as adequate screen by-passing gives a marked improvement. Adequate cathode circuit by-passing is essential in all cases. Neutralization to reduce the effect is almost useless unless rather elaborate circuits are used. In some cases different types of sockets offer an improvement. If simple a.v.c. is used,

shown (as is usual with the diode) or at the point X is immaterial from the viewpoint of operation. The diode is directly coupled to the triode and therefore the audio frequency voltages developed in the diode detector are passed on to the triode grid, but at the same time this grid is given a d.c. bias through the d.c. voltage developed in a similar way to that by which a.v.c. is obtained. Consequently the operating point of the triode varies along the e_p-i_p curve from zero towards more negative grid bias voltages as the carrier voltage is increased. This is the same effect as that obtained when the diode is omitted (Fig. 27.10) since the grid and cathode of the triode act as a diode and produce the same results. The illustration given was purely to demonstrate the derivation of the one from the other and not to be a practical form of detector since no advantage is gained by retaining the diode in the circuit.

FIG.27.10 GRID LEAK DETECTOR WITH TRANSFORMER COUPLING.

It will be seen that the operating point varies along the e_p-i_p characteristic curve between zero bias and the cut-off point (Fig. 27.11). There will be a certain strength of carrier at which the detection will be most satisfactory, and at lower or higher levels detection will not be so satisfactory on account of improper operating conditions. If with a certain carrier input voltage the d.c. bias on the grid is OA , then the point corresponding to peak modulation is B where OB equals twice OA . If the point B is on the curved part of the characteristic, or in the extreme case actually beyond the cut-off, the distortion will be severe. A valve having low μ and low g_m is capable of operating with a higher carrier voltage than a valve with improved characteristics, but the gain in the detector stage will be less. There is a further difficulty in that the plate current at no signal, or at very weak signal, may be excessively high. If transformer coupling is used this may, in extreme cases, damage the valve, or pass too much direct-current through the transformer, unless the plate supply voltage is reduced. If resistance coupling or parallel-feed is used the efficiency of the detector is decreased. As with diode detection there is distortion at low levels due to the

FIG.27.11 TYPICAL E_g-I_p CHARACTERISTIC.

"diode characteristics" but as distinct from the diode, the overload point occurs at quite a low carrier voltage. This method of detection is therefore very much limited in application.

With battery type valves used as cumulative grid detectors it is often advantageous to connect R_1 (Fig. 27.10) to filament positive; C_1 remains as before. The advantage obtained is that larger modulation percentages can be handled and detection will start with smaller input voltages. The arrangement is equivalent to supplying the grid, which is acting as the plate of a diode, with a positive bias voltage (see Ref. 1, p. 357) and moving the position of the start of grid current.

A typical circuit for a grid leak detector as used in radio receivers is shown in Fig. 27.12.

Damping of the input circuit occurs in the same manner as for a diode but additional damping occurs because of grid-plate coupling. The arrangement shown in Fig. 27.12 for the grid resistor further increases the loading on the input circuit. Detailed discussions of this type of circuit can be found in Refs. 2 (p. 414), 1 (p. 377) and 10.

FIG. 27.12: TYPICAL GRID LEAK DETECTOR WITH R-C COUPLING.

(B) Power grid detection

Power grid detection is a modification of leaky grid or cumulative detection and the circuit is identical in form, but the operating conditions are so chosen that the valve will operate on higher carrier voltages without overloading. In order to obtain a short time constant from the grid capacitor and resistor combination the capacitance and resistance are reduced, thereby improving the high audio frequency response. Under optimum conditions the distortion is at least as high as that of a diode together with increased distortion due to the curvature of the $e_g - i_p$ characteristic. The overload point, even though higher than that of ordinary leaky grid detection is at a much lower level than that with diode detection.

All forms of grid detection, particularly "power grid detection," involve damping of the grid circuit due to grid current, and this damping causes loss of sensitivity and selectivity. Grid detection is thus similar to diode detection in that it damps the input circuit. It has the advantage over diode detection in that gain is obtained in the detector which can be still further increased if transformer coupling is used between it and the following stage. Transformer coupling can, of course, only be used when the valve has a low plate resistance.

The foregoing comparison between a diode and a grid detector is on the basis of the detector alone. In modern practice the diode detector is frequently in the same envelope with a voltage amplifier and the total gain is quite high.

(C) Plate detection

Plate detection or "anode bend detection" involves operation towards the point of plate current cut-off so that non-linearity occurs, thereby giving rectification. Owing to the slow rate of curvature the detection efficiency is small, but there is an advantage in that the amplification which is obtained makes up, to a certain extent, for the poor detection efficiency. Due to the gradual curvature the distortion is very great with low input voltages, and even with the maximum input before overload occurs the distortion is rather high with high percentages of modulation. An important advantage of plate detection is, however, that the grid input circuit is not damped to any great extent, and the detector is therefore sometimes spoken of as being of infinite impedance, although this term is not strictly correct.

With pentode valves it is possible to use either "Bottom Bend Rectification" as with triodes or "Top Bend Rectification" peculiar to pentodes. This "top bend" in resistance coupled pentode characteristics can be seen on valve data sheets e.g. type 6J7 dynamic $e_g - i_p$ characteristics provide a good illustration (Fig. 12.14A).

A similar effect occurs with triodes, but only in the positive grid region, and for this reason it is incapable of being used for plate rectification. For top bend rectification with a pentode valve it is desirable to operate the valve with a plate current in the region

of $0.95 (E_b/R_L)$. The exact operating point for optimum conditions depends upon the input voltage.

Pentode valves are particularly valuable as plate detectors since the gain is of such a high order. If resistance coupling is used the gain is reduced very considerably, and in order to eliminate this loss it is usual to adopt choke coupling using a very high inductance choke in the plate circuit, shunted by a resistor to give a more uniform frequency response. If the shunt resistor were omitted the high frequencies would be much greater than the low frequencies in relative level.

With all forms of plate detectors the bias is critical and since different valves of the same type require slightly different values of bias the use of fixed bias is not recommended. A very high value of cathode resistance is usually adopted to bias the valve very nearly to cut-off, and in such a way that if valves are changed, or vary during life, the operating point maintains itself near optimum (Fig. 27.13).

FIG. 27.13 PLATE DETECTOR. B +

Screen grid and pentode valves with self-bias have been used as plate detectors very satisfactorily for a number of years, although the distortion with the usual arrangement is too high for them to be used in any but the cheapest radio receivers at the present time. Such a detector is, however, permissible for some types of short-wave reception and for amateur communication work where its high grid input impedance results in higher sensitivity and selectivity.

With the usual plate detector the cathode bypass capacitor (C_2 , Fig. 27.13) has customarily been made sufficiently large to by-pass both audio and radio frequencies. Often C_2 is a $25 \mu\text{F}$ electrolytic in parallel with a $500 \mu\text{F}$ mica capacitor. This arrangement, although widely used in the past, is not a correct one and leads to distortion when the modulation factor is at all high. The effect is similar to that described in connection with diode detectors having the a.c. loadline appreciably different in slope from the d.c. loadline. The correct procedure calls for the resistor R_2 to be by-passed for radio frequencies only, and although this results in a very considerable loss in gain because of negative feedback, the results obtainable are excellent. In a typical case R_2 might be taken as 10 000 to 100 000 ohms and C_2 as 500 to $100 \mu\text{F}$ respectively, the plate load resistor would be about 0.25 megohm; additional r-f decoupling is usual in the plate circuit, although this is not shown in Fig. 27.13. This circuit is often called a reflex detector, although this term is sometimes reserved for cases where 100% negative feedback is used with a plate detector, and the audio output is then taken from the resistor in the cathode circuit; the plate is earthed for a.c. in this case. The results obtainable from the modified plate detector are excellent, and are comparable with those given by the diode arrangement. The reflex detector is further discussed below.

(D) Reflex detector

The reflex detector is essentially a plate detector with negative feedback. Any amount of feedback may be applied from zero to 100%, and as the feedback increases, so the distortion decreases and the stage gain decreases until in the final condition with 100% feedback the gain is less than unity. The reflex detector has an even higher input impedance than the usual type of plate detector, and is therefore valuable in certain applications. Under certain conditions the input resistance is negative and can lead to instability troubles. The increased selectivity can also result in side-

band cutting. The degree of feedback may be adjusted to give any required gain (within reasonable limits) by altering the size of cathode by-pass capacitor and the relationship between the plate and cathode load resistance, but the distortion increases with gain and if low distortion is required the maximum gain is limited to about three or four times even with a pentode valve. With maximum degeneration and stable operating conditions, the distortion (see Ref. 11) is about the same as for a diode operating under similar input voltage conditions, while the reflex detector has the distinct advantage of high input impedance. One application which appears to be of importance is in high fidelity t.r.f. receivers, but even here the reflex detector has not shown any very marked improvement over the diode from a consideration of distortion alone. Input voltages in the order of 10 volts (r.m.s.) are usually most satisfactory when low distortion is desired and in a typical case using 100% feedback about 3% total harmonic distortion can be expected when the modulation depth approaches 100%. This assumes that the a.c. shunting is high (say 10 : 1 or so) compared with the d.c. load. Some useful discussion is given in Refs. 14 (pages 51-55) and 15. These performance figures can be compared with those stated previously for the diode detector under similar operating conditions. Reflex detectors do not provide a.v.c. and so are not used in normal broadcast receivers. They could be used in combination with amplified a.v.c. to provide a receiver with good characteristics.

Typical circuit component values have been discussed in (C) above in connection with modified plate detectors. For the case of 100% negative feedback (i.e. the load resistance is in the cathode circuit and the plate is earthed for a.c.) the cathode resistance is made large compared with $1/g_m$ and a typical value is 25 000 ohms. The by-pass capacitance across this resistance can be about 500 $\mu\mu\text{F}$. There is seldom any difficulty with a.c./d.c. ratios as the grid resistance of the following a-f stage is generally about 0.5 megohm. Additional components required are a blocking capacitor, to prevent the d.c. cathode voltage from being applied to the grid of the a-f amplifier, and a series resistor and shunt capacitor to provide additional r-f decoupling between the two circuits.

A limitation of the reflex detector is that there is a definite maximum for the input signal voltage for freedom from grid current. A further increase of input causes rectification at the grid, with added damping of the grid input circuit, and a steady increase in distortion. An increase in the supply voltage raises the threshold point for grid current. Further data are available in Refs. 11, 12, 13, 14 and 15.

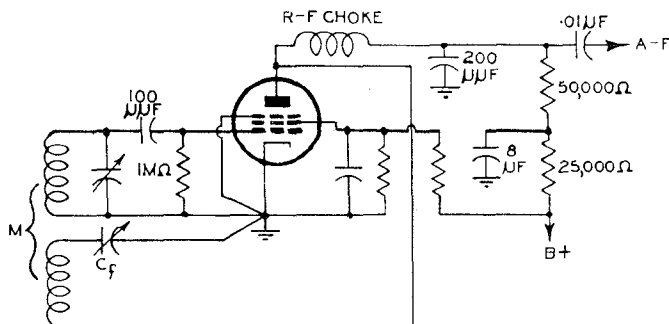

FIG. 27.14 REGENERATIVE DETECTOR.

(E) Regenerative detectors

A common arrangement for this type of detector is shown in Fig. 27.14. The amount of positive feedback is adjustable, by means of C_f , to allow increased sensitivity with various signal input voltages. Oscillation will occur when the degree of feedback is sufficiently large, and the circuit can then be used for the detection of CW telegraph signals. For battery operated valves it is usual to return the grid resistor to filament positive.

Best results are generally obtained using pentode valves and resistance-capacitance coupling to the following audio stage. This arrangement minimizes "threshold howl."

Feedback control is possible with a variety of circuits but least difficulty is usually experienced with the variable capacitor arrangement, or the use of a variable resistor in the **screen circuit**. The latter arrangement is advantageous as regards the reduction of detuning effects.

Further details of this type of detector can be found in Refs. 1, 5, 16, 17, 18, 19 and 20.

(F) **Superregenerative detectors**

The superregenerative detector is a regenerative circuit in which the detector is automatically switched in and out of oscillation at a very low radio frequency rate (usually about 15 to 100 Kc/s). This switching frequency is called the "quenching" frequency. In general the quenching frequency is increased as the carrier frequency becomes greater, but sensitivity and selectivity are improved by using the lowest permissible value of quenching frequency. For many cases it is usual to make the quench frequency about twice the highest audio frequency contained in the modulation envelope, and it is not considered good practice for the quench frequency to be lower than this value. The amplitude of the quench voltage is also important and it will have a very appreciable effect on the selectivity characteristic. In general if the quench voltage amplitude is increased in a separately quenched circuit, the selectivity is reduced.

The advantage of this circuit is the extremely high sensitivity which is possible using a single valve. The disadvantages are the high noise level in the absence of a signal, the poor selectivity, and the high distortion.

The circuit of Fig. 27.14 can be made to operate as a superregenerative detector by increasing the time constant of the grid resistance and capacitance combination, and making the amount of regeneration very large. The quenching frequency can be simply adjusted by altering the value of the grid resistance.

A separate quenching oscillator is often used with the regenerative detector arrangement, but as this requires additional circuit components and sometimes an additional valve, it is not so popular as the simple arrangement previously mentioned. The development of suitable types of double triode and converter valves largely overcomes this objection, however, and many modern circuits use separate quenching.

Several other points of interest arise with this detector. Amplitude limiting occurs, so there is less interference from car ignition and similar noises than when other detectors are used; the output on strong signals is not much greater than for weak signals. Noise quieting and limiting are improved however, by using low quench frequencies. A r-f stage should be incorporated in receivers using this type of detector to reduce radiation. This additional stage will not materially alter the signal-to-noise ratio obtainable with the detector alone. Circuits incorporating the principle of superregeneration have been used in cheap F-M receivers; this point will receive some further consideration in the section on F-M receivers in Chapter 36.

The method to be adopted for measuring the selectivity of a superregenerative receiver requires some consideration. Conventional methods are usually inadequate since in most cases the problem is similar to that of taking the selectivity curve of a receiver having a.v.c., but in this case the a.v.c. cannot be disconnected. A suitable procedure (Ref. 26) is as follows.

With no input signal applied the audio noise output is measured. A signal is applied at the resonance frequency and its amplitude adjusted until the noise is suppressed by about 10 to 20 db (or any convenient amount). The selectivity is then found by tuning the signal generator to various frequencies around resonance, in the usual manner, and the input voltage is adjusted until the same degree of quieting is obtained as at resonance. The difference between the two signal inputs off and at resonance for the same degree of quieting, gives the attenuation at the particular frequency being considered.

Further details of this detection system are available in page 622 of Ref. 5, page 148 of Ref. 20, Refs. 21, 22, 23, 24, 25, and 26.

SECTION 2 : F-M DETECTORS

(i) *Types of detectors in general use* (ii) *General principles* (iii) *Phase discriminators* (A) *General* (B) *Design data* (C) *Design example* (iv) *Ratio detectors* (A) *General* (B) *Operation* (C) *Types of circuit* (D) *Design considerations* (E) *Practical circuits* (F) *Measurements on ratio detectors*.

(i) Types of detectors in general use

Although many ingenious methods have been suggested for the detection of frequency modulated signals, only a few circuits have found general acceptance by receiver manufacturers. Of these detectors a form of locked oscillator (the Bradley detector) has been used by one large manufacturer, but does not appear to have been employed to any extent outside of this organization. Amplitude discriminators have been used to a very limited extent with duo-diode triode valves having a separate cathode for the two diodes. However, the generally accepted method of F-M detection has been the **phase discriminator**. A modification of the basic phase discriminator circuit has been used for the **ratio detector**, and this arrangement has achieved wide popularity because it allows a satisfactory F-M receiver to be constructed without the use of an additional amplitude limiting stage. Simple detuning of the signal circuits has been employed in one type of receiver (the **Fremodyne**) to give frequency to amplitude conversion, but this is only satisfactory in a very cheap receiver where cost is more important than quality.

In what follows attention will be confined, mainly, to the design procedures to be adopted for phase discriminators and ratio detectors. References are listed at the end of this chapter, and can be consulted for details of a number of the alternative detection systems available. The amplitude and phase discriminators used in connection with Automatic Frequency Control Systems are further considered in Chapter 29.

(ii) General principles

The circuits which will be considered here utilize tuned circuits to convert frequency changes to amplitude changes. The amplitude modulated carrier is then applied to detectors (usually diodes) to recover the intelligence contained in the received signals.

Although the amplitude modulated carrier applied to the detectors is also frequency modulated, the detectors are only sensitive to amplitude changes, and so it is only the resultant amplitude variations which appear at the output of the detector stage. It is because the detectors are sensitive to amplitude changes, that some method of limiting is required to overcome undesired amplitude variations.

The tuned circuits to be described are called discriminators, although this name is often taken to include the diode detectors as well. If distortion is not to be introduced by the discriminator it is essential that the amplitude variations produced be directly proportional to the frequency variations i.e. the circuit must be linear over the full range of applied frequency deviation. The usual precautions for reducing distortion in the detector circuits must also be applied, just as for any other A-M detector. These precautions have been discussed previously, and those given for diode detectors should be carefully observed here. One big advantage does appear, however, the percentage amplitude modulation is likely to be quite small, depending on the frequency-amplitude conversion efficiency of the discriminator circuit, and so the possibility of non-linear distortion is considerably reduced.

(iii) Phase discriminators

(A) General

The basic circuit arrangement, together with the voltage distribution at the resonant frequency, for a phase discriminator is shown in Fig. 27.15. The name arises because the operation is dependent on the 90° phase shift which occurs at resonance between the primary and secondary voltages of a tuned transformer. When the frequency of the applied primary voltage E_1 (the magnitude of this voltage will be

FIG. 27-15 BASIC PHASE DISCRIMINATOR CIRCUIT.

assumed constant for the moment) alters, the phase angle between E_1 and E_2 changes from that at resonance. This leads to a change in the relative magnitudes of E_A and E_B .

The vector relationship between the primary and half secondary voltages, for the phase discriminator, are shown in Fig. 27.16. This assumes constant primary voltage E_1 .

FIG. 27-16 VOLTAGE RELATIONSHIPS IN PHASE DISCRIMINATOR WITH CONSTANT PRIMARY VOLTAGE.

If the primary voltage E_1 has its amplitude varied in a suitable manner (e.g. by setting the coupling between the transformer windings, for given primary and secondary Q 's, so that two primary voltage humps of the required amplitude appear as the frequency is varied) the linearity and sensitivity of the discriminator can be very appreciably improved.

This statement, regarding linearity and sensitivity, refers, of course, to the relationship between voltage output and frequency-deviation from the central reference frequency (i.e. the nominal intermediate frequency).

Analysis of the phase discriminator for F-M applications has been made by K. R. Sturley (Refs. 27 and 28), and the results of this analysis will be used below. It might be mentioned that a number

of discriminator circuits for a wide variety of applications have been designed using the data derived by Sturley and very satisfactory results have been obtained in practice. Before proceeding to set out the design data, the circuit of Fig. 27.17 will be briefly discussed.

The voltages applied to the plates of the double diode valve V_2 will be E'_A and E'_B respectively. The output voltages from the diodes are developed across R_3 and R_4 , and the circuit is arranged so that the available output voltage is equal to the **difference** between the two separate voltages. This means that when the frequency of the carrier voltage is exactly equal to the intermediate frequency, no output will be obtained from the detector. Reference to Fig. 27.16 should help to make this point quite clear, since the rectified voltages across R_3 and R_4 in Fig. 27.17 are given by the peak voltages applied to the diode plates multiplied by the detection efficiency of the diodes. As the signal deviates from the central reference frequency (i.e. the intermediate frequency), a voltage (E_{out}) will appear between the points P and N (Fig. 27.17), and its polarity will depend on the relative magnitudes of the voltages across R_3 and R_4 ; e.g. point P will be negative with respect to point N when the voltage across R_3 is less than that across R_4 . It follows that it should be possible to calculate

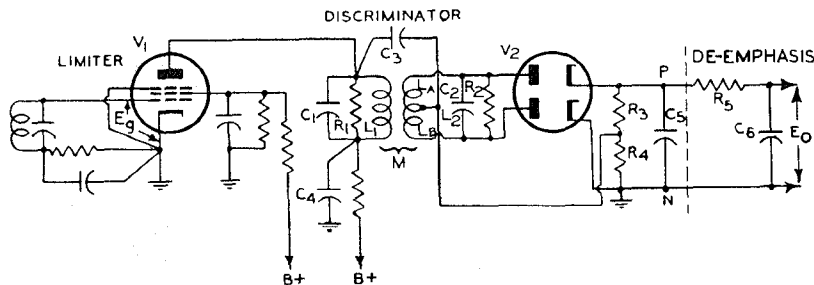

FIG. 27.17. TYPICAL PHASE DISCRIMINATOR ARRANGEMENT FOR F-M DETECTION.

the relationship between output voltage and frequency change from

$$E_{out} = \eta(E'_A - E'_B) \quad (11)$$

where η = the diode detection efficiency, and is assumed to be the same for both diodes of V_2 .

(B) Design data

For most designs it is usual to take the total secondary voltage E_2 as being twice the primary voltage E_1 i.e.

$$E_2/E_1 = 2. \quad (12)$$

Primary and secondary Q 's are made equal, so that

$$Q = Q_1 = Q_2. \quad (13)$$

The value for Q is determined from

$$Q = f_r/(2\Delta f) \quad (14)$$

where f_r = intermediate frequency

and $2\Delta f$ = total frequency range for which substantially linear operation is required.

The coefficient of coupling for the transformer is found from

$$Qk = 1.5 \quad (15)$$

when a good compromise between sensitivity and linearity is required (the usual case).

For special cases where linearity is the main requirement it is suggested that

$$Qk = 2 \quad (16)$$

be used. The loss in sensitivity in this case is about 1.54 times as can be seen by comparing eqns. (20) and (21).

From the principles of coupled circuits it is possible to show that

$$\frac{E_2}{E_1} = Q_2 k \sqrt{\frac{L_2}{L_1}} \quad (17)$$

and for our particular cases with $E_2/E_1 = 2$ and $Qk = 1.5$ or 2 , the relationship between L_2 and L_1 is

$$L_2/L_1 = 1.77 \text{ (for } Qk = 1.5) \quad (18)$$

$$\text{and } L_2/L_1 = 1 \text{ (for } Qk = 2). \quad (19)$$

The discriminator sensitivity at f_r is given by

$$S_{(Qk = 1.5)} = 5.465 \times 10^3 g_m Q^2 L_1 \eta E_o \text{ volts per kilocycle deviation,} \quad (20)$$

$$S_{(Qk = 2)} = 3.554 \times 10^3 g_m Q^2 L_1 \eta E_o \text{ volts per kilocycle deviation,} \quad (21)$$

where

g_m = mutual conductance of V_1

Q = magnification factor determined from eqn. (14)

L_1 = primary inductance of transformer

η = diode detection efficiency

and

E_o = peak voltage between grid and cathode of V_1 .

It should be apparent that the sensitivity, given by eqns. (20) and (21), is directly proportional to E_o and so the output from the discriminator is dependent on the input voltage. To overcome this difficulty the valve V_1 is arranged as a limiter in such a way that the product $g_m E_o$ is kept almost constant, and thus the output voltage is no longer directly dependent on the magnitude of the signal input voltage.

Curves of discriminator output voltage versus frequency deviation can be found from vector diagrams similar to that of Fig. 27.16, and then introducing suitable cor-

rection factors to allow for variations in E_1 deliberately introduced by the transformer design. However, it is possible to determine two generalised curves for the design conditions previously imposed, one curve for $Qk = 1.5$ and the other for $Qk = 2$. The curves are shown in Fig. 27.18A, and relate the quantity X (which is a function of bandwidth) to the relative output voltage E_{rel} . Only the positive halves of the curves are shown since the negative halves have substantially the same shape. To determine the output voltage E_{out} against frequency, it is only necessary to multiply the horizontal scale by a factor determined by eqn. (14), and the vertical scale by a factor determined by eqn. (20) or eqn. (21) (depending on whether $Qk = 1.5$ or 2 is used).

FIG. 27.18(A) GENERALISED PHASE DISCRIMINATOR CURVES OF RELATIVE VOLTAGE OUTPUT (E_{rel}) VERSUS X WITH $E_2/E_1 = 2$; $Qk = 1.5$ AND 2.

The two curves shown in Fig. 27.18(A) are calculated from the following equations. For $Qk = 1.5$, the relative voltage output is

$$E_{rel} = \frac{3.25A}{\sqrt{(3.25 - X^2)^2 + 4X^2}} \quad (22)$$

and for $Qk = 2$,

$$E_{rel} = \frac{5A}{\sqrt{(5 - X^2)^2 + 4X^2}} \quad (23)$$

$$\text{where } A = \sqrt{1 + X^2} \left[\sqrt{\left(1 + \frac{X}{1 + X^2}\right)^2 + \left(\frac{1}{1 + X^2}\right)^2} - \sqrt{\left(1 - \frac{X}{1 + X^2}\right)^2 + \left(\frac{1}{1 + X^2}\right)^2} \right]$$

$$X = Q \frac{2\Delta f}{f_r}$$

Q = magnification factor determined from eqn. (14). Equation (14) is the condition for $X = 1$

$4f$ = frequency deviation from f_r

and f_r = intermediate frequency.

To illustrate the design procedure, and to bring out additional points, a worked example is appended.

(C) Design example

A phase discriminator is required for use with a 10.7 Mc/s F-M i-f channel. The maximum frequency deviation of the carrier is ± 75 Kc/s. To make the problem

complete it will be taken that the highest audio frequency is 15 Kc/s and the de-emphasis time constant is 75 micro-seconds.

(a) The majority of applications call for reasonable discriminator sensitivity and so the condition $Qk = 1.5$ (see eqn. 15) is practically always used. Also, high primary dynamic impedance will increase the sensitivity of the discriminator. However, since Q is fixed by other considerations (see eqn. 14) L_1 should be large, but L_1 is limited by L_2 which in turn is limited by the permissible minimum secondary capacitance C_2 . A value is selected for C_2 and the design can then proceed.

(b) A suitable value for C_2 , including all strays, is $50 \mu\mu\text{F}$. Then

$$L_2 = \frac{25\,330}{10.7^2 \times 50} = 4.41 \mu\text{H}.$$

From eqn. (18),

$$L_1 = \frac{L_2}{1.77} = \frac{4.41}{1.77} = 2.5 \mu\text{H}.$$

From this

$$C_1 = \frac{25\,330}{10.7^2 \times 2.5} = 88.5 \mu\mu\text{F} \text{ (including all strays).}$$

(c) If the discriminator frequency—voltage characteristic were exactly linear then it would be sufficient to make the total frequency range $2\Delta f = 2 \times 75 = 150 \text{ Kc/s}$. To this would be added an allowance for frequency drift due to the oscillator and the discriminator tuned circuits. Since the discriminator characteristic is not exactly linear (it is linear for about 80% of the total curve using the data given as can be seen from Fig. 27.18) and the frequency drift is not always small it has become common practice in broadcast F-M circuits (of the type being considered) to make $2\Delta f$ from 200 to 400 Kc/s.

As a practical compromise we will take the total bandwidth ($2\Delta f$) as 250 Kc/s, but the design procedure is the same irrespective of what bandwidth is selected.

With $2\Delta f = 250 \text{ Kc/s}$ we have from eqn. (14)

$$Q = 10.7/0.25 = 42.8.$$

From eqn. (15), $Qk = 1.5$

and so $k = 1.5/42.8 = 0.035$.

(d) Summarizing, for the discriminator transformer (see also Fig. 27.17)

$L_1 = 2.5 \mu\text{H}$; $L_2 = 4.41 \mu\text{H}$; $C_1 = 88.5 \mu\mu\text{F}$; $C_2 = 50 \mu\mu\text{F}$; $Q = Q_1 = Q_2 = 42.8$; $k = 0.035$; $M = 0.116 \mu\text{H}$. Secondary winding to be centre-tapped. The capacitance values include all strays.

FIG. 27.18(B) Discriminator Characteristic Obtained From Design Example

(e) The discriminator sensitivity at f_r is given by eqn. (20). Assume $E_g = 1$ volt (peak), $g_m = 5$ mA/volt and $\eta = 0.7$. Then

$$S_{(Qk=1.5)} = 5.465 \times 10^3 \times 5 \times 10^{-3} \times 42.8^2 \times 2.5 \times 10^{-6} \times 0.7 \times 1 \\ = 0.0875 \text{ volts per kilocycle deviation.}$$

This also allows the vertical scale factor to be determined for the complete discriminator curve as shown on Fig. 27.18(B). The horizontal scale factor is found from

$$X = Q \frac{2\Delta f}{f_r} = 1 \text{ [i.e. eqn. (14)].}$$

$$\text{Therefore } \Delta f = \frac{Xf_r}{2Q} = \frac{10.7 \times 10^3}{2 \times 42.8} = 125 \text{ Kc/s.}$$

The procedure for finding the plotted points on the curve of Fig. 27.18(B) is as follows. Draw up a table, as shown below, with values of X corresponding to values of E_{rel} read from the curve of Fig. 27.18(A). Since it has just been determined that $\Delta f = 125$ Kc/s when $X = 1$, the column for Δf can be filled in (e.g. when $X = 0.8$ then $\Delta f = 125 \times 0.8 = 100$ Kc/s, and so on). The sensitivity has been determined as 0.0875 volts per kilocycle deviation, and so for 25 Kc/s deviation $E_{out} = 0.0875 \times 25 = 2.19$ volts (the lowest deviation frequency in the table should be used to find E_{out} in this case). It is now seen that the value of $E_{out} = 2.19$ volts corresponds to $E_{rel} = 0.28$, and so the scale factor is $2.19/0.28 = 7.82$. If 7.82 is now multiplied by E_{rel} in each case, the column for E_{out} can be filled in. The complete curve for E_{out} versus Δf can now be plotted.

X	Δf	E_{rel}	E_{out}
0.2	25	0.28	2.19
0.4	50	0.56	4.38
0.6	75	0.84	6.56
0.8	100	1.12	8.76
1.0	125	1.36	10.61
1.2	150	1.52	11.9
1.4	175	1.6	12.5
1.5	187.5	1.62	12.7
1.6	200	1.6	12.5
1.8	225	1.52	11.9
2.0	250	1.31	10.5

(f) It now remains to determine suitable values for the other components in the circuit of Fig. 27.17.

C_3 is for the purpose of connecting the transformer primary to the secondary centre-tap, and providing isolation of the secondary from the h.t. on the plate of V_1 . A suitable value is $100 \mu\mu\text{F}$. The capacitor should have high insulation resistance.

C_4 is a by-pass capacitor; a value of about $0.01 \mu\text{F}$ is usual.

R_3 and R_4 are made equal, and are generally about 100 000 ohms each.

C_5 acts as a by-pass for i-f but must not appreciably affect the audio frequency response. The usual value is about $100 \mu\mu\text{F}$.

The de-emphasis network consists of R_5 and C_6 . For 75 microsecond de-emphasis the nominal values would be 75 000 ohms and $0.001 \mu\text{F}$ respectively. If an improved a.c./d.c. ratio is thought to be necessary then suitable values would be say, $0.25 \text{ M}\Omega$ and $300 \mu\mu\text{F}$. The grid resistor in the following a-f stage should not be less than $1 \text{ M}\Omega$ if excessive loss in gain is to be avoided. However, the actual values used in a receiver will generally deviate from these nominal figures if the overall audio frequency response of the receiver is made to follow the 75 microsecond de-emphasis curve to 15 Kc/s, because of the presence of stray capacitances etc. and in some cases to help compensate for the overall a-f response.

To determine R_1 :—the transformer primary damping due to a single diode circuit, connected as shown, is $R_{dc}/3$. For this circuit $R_{dc} = R_3 = R_4 = 100$ 000 ohms.

Also, because of the circuit arrangement, R_3 and R_4 are in parallel. The total damping, due to diode conduction currents in addition to R_3 and R_4 , is then

$$\frac{1}{2} \left(\frac{R_{dc}}{3} \right) = \frac{100\,000}{6} = 16\,600\ \Omega.$$

If R_3 is not equal to R_4 , the damping resistance is given by $R_3/3$ and $R_4/3$ in parallel i.e.

$$R_3 R_4 / 3(R_3 + R_4). \quad (\text{When } R_3 = R_4 = R_{dc} \text{ the value } R_{dc}/6 \text{ is obtained as above}).$$

Take the undamped primary Q (written as Q_u) as being 100, and neglect the additional damping due to the plate resistance of V_1 . Then the total damping resistance (R) required to obtain a primary Q of 42.8 is

$$R = \frac{Q_u Q \omega L_1}{Q_u - Q} = \frac{100 \times 42.8 \times 2\pi \times 10.7 \times 2.5}{100 - 42.8} = 12,500\ \Omega.$$

From this

$$R_1 = \frac{12\,500 \times 16\,600}{(16\,600 - 12\,500)} = 50\,600\ \Omega.$$

To determine R_2 : The transformer secondary damping is given by

$$R_3 = R_4 = R_{dc} = 100\,000\ \Omega.$$

(This follows because the damping across each half of the secondary is $R_3/2$ and $R_4/2$ respectively, and in each case there is a step up, due to the transformer being centre tapped, of 4 times. From this, across the whole of the transformer secondary there are two resistances $4R_3/2$ and $4R_4/2$ in parallel, and since $R_3 = R_4 = R_{dc}$ the above result is obtained immediately).

The total damping resistance (R') required to make $Q_2 = Q_1 = 42.8$ is

$$R' = 12\,500 \times 1.77 = 22\,100\ \Omega.$$

From this

$$R_2 = \frac{22\,100 \times 100\,000}{(100\,000 - 22\,100)} = 28\,400\ \Omega.$$

The design of the limiter stage will be discussed in Chapter 29.

(g) Some causes of discriminator unbalance will be mentioned, before leaving this section, and it is helpful to consider the circuit as a bridge in which unbalance has to be eliminated. Even when the transformer secondary is centre-tapped accurately, unbalance can occur because the capacitive coupling between the two halves of the secondary winding and the primary winding is not necessarily equal. This calls for care in the method of arranging the windings. Two methods are in common use. The first uses a bifilar method with the two halves of the secondary wound side by side. The second method arranges the secondary into two halves, placed on either side of the primary winding, and the coupling of both sections, including that due to stray capacitances, is made equal.

Capacitive unbalance will also occur when the input capacitances of the diodes are not equal. Suitable arrangement of stray capacitances can often be used to help in offsetting this effect.

The use of a small capacitance connected across one of the diodes is helpful in reducing capacitive unbalance effects.

Balancing of the conduction resistances of the two diode units is largely outside the control of the receiver designer, but variation in the value of R_3 and R_4 can be made to assist in cases where a very high degree of balance is thought to be necessary. Additional precautions of this nature are seldom carried out in commercial receivers.

It should be noted in Fig. 27.17 that, if the resistors R_3 and R_4 are shunted by two separate capacitors, an additional series resistor or r-f choke will be required between the junction of R_3 and R_4 and the centre tap on L_2 . Connecting the junction of R_3 and R_4 through a by-pass capacitor to ground would also effectively short-circuit the i-f primary voltage to ground, if the additional component is not used. For most circuits the arrangement shown is applicable, since it requires a minimum of components consistent with satisfactory performance. The alternative arrangement

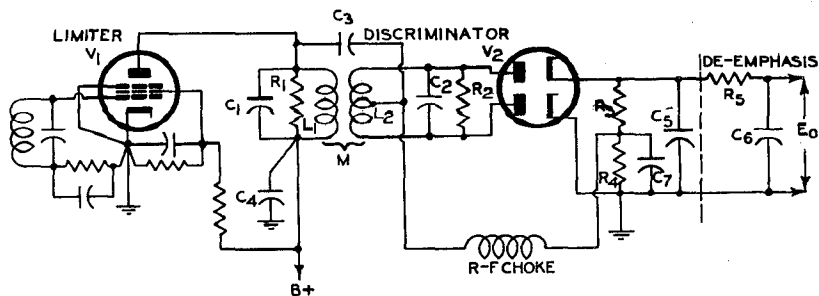

FIG. 27.19 ALTERNATIVE ARRANGEMENT FOR PHASE DISCRIMINATOR.

is shown in Fig. 27.19. The design procedure to be used is exactly as before, except that the primary circuit damping due to the diode circuits (the damping is actually across the r-f choke) will be approximately $R_{de}/4$ instead of $R_{de}/6$; the secondary circuit damping is R_{de} as previously, where $R_{de} = R_3 = R_4$. If a resistor is substituted for the r-f choke then the circuit damping is again modified depending on the value of resistance used in the circuit. Considerations leading to the choice of a suitable value for the inductance of the r-f choke will be given in detail in Chapter 29 Sect. 2, in connection with the discussion on a.f.c. discriminators.

It is perhaps worth mentioning that hum due to heater-cathode leakage is sometimes troublesome in discriminator circuits, particularly with miniature diodes, and a simple and effective cure for this trouble is to make the cathode positive with respect to the heater. This can be readily effected, for example in Fig. 27.19, by connecting a $10\,000\ \Omega$ resistor by-passed by, say, a $0.01\ \mu\text{F}$ mica capacitor between the earthy end of R_4 and ground; the junction of R_4 and the $10\,000\ \Omega$ resistor is then connected to B+ via a series resistor whose value is selected so that about 10 to 15 volts appears across the $10\,000\ \Omega$ resistor (which now forms one arm of a voltage divider). In a typical case the series resistor would be about $0.16\ \text{M}\Omega$ for a B+ of 250 volts.

(iv) Ratio detectors

(A) General

Many of the details given below, regarding ratio detectors, have been taken from Refs. 34, 35 and 36. Practical experience with several of the arrangements shown has confirmed much of the data given in the design sections. However, a number of additional factors will warrant discussion.

The principle underlying many circuits for F-M detection is the peak rectification of two i-f voltages, the relative amplitudes of which are a function of frequency, together with means for combining the rectified voltages in reversed polarity. The output is then equal to the difference between the two rectified voltages. This statement is directly applicable to the phase discriminator circuits of Figs. 27.17 and 27.19, the two i-f voltages being those applied to the diode plates, and the rectified voltages combined in reversed polarity being those which appear across the load resistors R_3 and R_4 . The way in which the two i-f voltages, applied to the diode plates, are dependent on the instantaneous intermediate frequency has been discussed in connection with Figs. 27.15 and 27.16. It was mentioned previously that, with the phase discriminator, changes in the magnitude of the input signal will give rise to amplitude changes in the resultant output voltage, and the need for some form of amplitude limiting was emphasized.

In an attempt to eliminate the necessity for a limiter, a ratio type of detector has been developed from the basic phase discriminator circuit. In this modified circuit the rectified voltages are split into two parts in such a way that their ratio is proportional to the ratio of the instantaneous i-f voltages applied to the detector diodes, and the sum of the two rectified voltages is kept constant. It has been found in this type of circuit that the useful output voltage, which is proportional to the difference between the two rectified voltages developed by the diode detectors, tends to be independent

of amplitude variations superimposed on a frequency modulated voltage applied to the discriminator circuit input terminals.

A basic ratio detector circuit is shown in Fig. 27.20(A). It can be seen that this is similar to the conventional phase discriminator but one of the diodes is reversed, and so the total voltage between the points P and N is equal to the **sum** of E_1 and E_2 . The **sum** of E_1 and E_2 is held constant by means of a battery or a large capacitance. This point will be further discussed as we proceed. The audio output voltage is taken from the junction of R_3 , R_4 and C_5 , C_7 and is equal to $(E_1 - E_2)/2$. The voltage output with frequency change is seen from Fig. 27.20(B) to be similar to that for a conventional discriminator circuit.

The sum voltage ($E_1 + E_2$) can be stabilized by using either a battery or by shunting a large capacitance across the load resistors R_3 and R_4 . A battery would limit the operation in such a way that the input signal would need to be at least strong enough to overcome the fixed bias due to the battery voltage. A better solution is to use a capacitor, since the voltage across it will vary in proportion to the average signal amplitude and thus automatically adjust itself to the optimum operating level. This allows amplitude rejection to be secured for a wide range of input signal voltages, the lowest useful signal being determined by the ability of the diode rectifiers to conduct with small input voltages.

When a capacitor is used to stabilize the rectified output voltage its capacitance must be sufficiently large so that the sum of $E_1 + E_2$ cannot vary at an audio frequency rate. This calls for a time constant in the circuit made up from R_3 , R_4 and the additional capacitance C of about 0.2 seconds. The effects of C_5 and C_7 on the time constant can be neglected, since the value of the capacitance C will be of the order of microfarads (usually about $8\mu\text{F}$).

FIG.27-20

(A) BASIC CIRCUIT OF RATIO DETECTOR.
(B) TYPICAL OUTPUT CURVE.

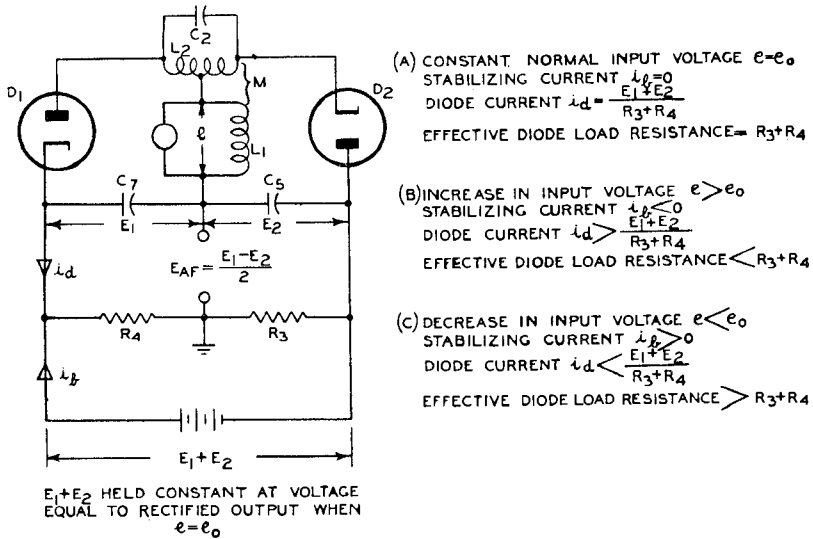

FIG. 27.21 RATIO DETECTOR CIRCUIT SHOWING CONDITIONS FOR DIFFERENT SIGNAL INPUT VOLTAGES.

It is worth noting that the a.v.c. voltages available from ratio detector circuits have values which are not always directly suitable for application to controlled stages. Some form of voltage divider arrangement is often necessary to obtain suitable voltages for securing the desired a.v.c. characteristic.

(B) Operation

A brief qualitative description of the operation of the ratio detector will be given here. A complete quantitative analysis has not been made, although many of the significant factors have been investigated (see Refs. 34, 35 and 36).

Fig. 27.21 shows the same basic circuit as Fig. 27.20(A), rearranged in a more convenient form for discussion. The main details of operation are also indicated, and show what happens in the circuit when the amplitude of the signal input voltage changes. For the case (A) where the amplitude of the signal input voltage is constant, the stabilizing current is zero and the circuit has essentially the same output characteristic as a phase discriminator. When the signal amplitude increases (B), the average diode current also increases, and resultant direct current flows into the stabilizing voltage source (i.e. the battery is being charged). From this since $E_1 + E_2$ remains constant, it is seen that the **effective** diode load resistance must decrease and so the primary and secondary circuits are more heavily damped than for the case (A) where the input voltage has a fixed value. The increased damping on the transformer circuits will tend to offset the increase in the amplitude of the input voltage, and so the output voltage will also tend to be constant.

Similarly, when the signal amplitude decreases—case (C)—the stabilizing voltage source supplies additional current (i.e. the battery is being discharged) to offset the reduction in diode current, so as to maintain $E_1 + E_2$ constant; the effective diode load resistance is now increased, and so the circuit damping is reduced.

From this it is seen that stabilizing the rectified voltage results in the equivalent load resistance varying in such a way as to offset changes in the amplitude of the signal input voltage. It also follows that there must be optimum circuit conditions which will allow the undesired amplitude variations to be offset most effectively (although these conditions are not necessarily the same for all input voltages). The conditions for obtaining the most satisfactory operation will be summarized below when discussing the design of the ratio detector.

(C) Types of circuit

There are two types of ratio detector circuit in common use. The first of these is the so called balanced circuit and is illustrated by Fig. 27.22. At first glance this does not seem to be the same as the basic circuit previously discussed. However, if the tertiary winding is considered as L_1 for the moment (its presence will be explained presently), and it is taken that C_8 has a high reactance at audio frequencies and negligible reactance at i-f, then a simple re-arrangement of the circuit will show that it is the same as that of Figs. 27.20 and 27.21. Whether the junction of C_5 and C_7 is connected to ground, as shown in Fig. 27.22, or C_8 is connected from the junction of C_5 and C_7 to the junction of R_3 and R_4 as would be expected (since C_8 is part of the audio load circuit) is unimportant, as can be seen by redrawing the circuit. C is the stabilizing capacitor.

FIG.27-22 BALANCED TYPE OF RATIO DETECTOR CIRCUIT.

The second type of circuit in common use is the unbalanced arrangement of Fig. 27.23. The operation is similar to the balanced arrangement but it obviously cannot be redrawn directly into a balanced arrangement. The A-M rejection is the same whether the centre-tap of R_3 and R_4 or any point along the load is grounded, provided that the stabilizing capacitor can hold the voltage across its terminals constant. This condition is not easily met, however, at very low audio frequencies because very long time constants for the diode load circuit have undesirable effects when the receiver is being tuned.

In general the balanced circuit will give better amplitude rejection at low frequencies than the unbalanced arrangement, when the time constants of the two circuits are the same.

Additional advantages of the balanced ratio detector are that the ratio of a.v.c. voltage to audio voltage is comparable with that obtained in conventional A-M detector circuits, and also a voltage is available which is zero at the centre frequency and can be used for a.f.c. purposes if so desired.

The presence of the tertiary winding in the discriminator transformer is readily understood when it is considered that it provides a simple method of tapping down on the transformer primary without the use of blocking capacitors and a choke, and at the same time allows the overall sensitivity of the detector to be increased by permitting a high primary circuit dynamic impedance. This is particularly helpful since the value of the total diode load resistance is generally small (usually less than 50 000 ohms total).

Because of the low value of load resistance it should be clear that high detection efficiencies are not easy to obtain, and so high perveance diodes are of considerable assistance in this regard because their internal impedance will be comparatively small. However, it is often found that high perveance diodes are more susceptible to hum pick-up than the medium perveance types and so are not necessarily the best choice in all circuits.

Before leaving this section an additional point of interest will be discussed. In Fig. 27.24 are shown typical curves of output voltage against signal input voltage for a ratio detector. It can be seen from these curves that the output is not constant with input voltage for a given frequency deviation. This effect can be offset to a large extent by using the valve preceding the ratio detector as a partial limiter. For weak signals the driver valve can be used as a straight voltage amplifier, but if a grid resistor and capacitor are included which have a fairly short time constant (say 10

microseconds or so) they can be used to derive a bias voltage for the grid of the valve when the signal exceeds some pre-determined level, and the valve can then be used to provide a degree of limiting. In this way the use of an additional valve is still avoided, since most ratio detectors operate satisfactorily with as little as 10 millivolts (or less) applied to the grid of the driver valve, but the advantages of additional amplitude limiting can be obtained on strong signals. Of course, satisfactory results are obtainable with a ratio detector alone and the application of a.v.c. bias to the earlier stages is helpful but improvement is possible with the arrangement suggested, and with very little additional trouble. With the partial limiter arrangement a.v.c. is sometimes applied to the first i-f voltage amplifier, the a.v.c. bias being derived from the ratio detector circuit as indicated in Figs. 27.22 and 27.23. Some receiver manufacturers do not use a.v.c. at all, but use suitable grid resistor-capacitor arrangements with both i-f valves to provide additional bias when the signal is sufficiently large. Some care is necessary with the limiter arrangements, since detuning of the i-f transformer can have adverse effects particularly with some types of noise interference. This point received consideration in Chapter 26 when the design of the F-M i-f transformers was being discussed.

FIG. 27.23
Unbalanced Type of Ratio Detector

FIG. 27.24 Typical Input-Output Voltage Curves for Ratio Detector

(D) Design considerations

The data given below are quite general, but the circuit constants suggested are based on a centre frequency of about 10.7 Mc/s and a peak separation of approximately 350 Kc/s. Most of the information which follows (with certain modifications) is taken from Ref. 34, where a more detailed explanation is available.

Diode characteristics

Good ratio detector performance can be obtained with either high perveance diodes such as type 6AL5, or medium-perveance diodes such as type 6H6.

The circuits used will differ with high and medium perveance diodes in the extent to which the rectified output voltage is held constant. They will also differ with respect to the compensation used to minimize the residual unbalanced component of amplitude modulation in the output. The unbalance is brought about by secondary transformer detuning effects caused by input reactance variations due to the diodes. The magnitude of the effect is generally less for diodes having lower perveance.

Because the diode rectification efficiency, and hence the diode circuit loading, varies with signal level, optimum A-M rejection is obtained for a particular input voltage. The level at which optimum A-M rejection is obtained can be altered by varying the circuit constants, particularly the fraction of the total rectified voltage which is stabilized, or the ratio of secondary and tertiary voltages.

Secondary inductance

The secondary L/C ratio should be as high as possible consistent with circuit stability. This suggests capacitance values from 25-70 μF . Also, the secondary Q should be as high as possible, depending on the required peak separation. Suitable Q values are 75 to 150, with the higher values giving improved sensitivity, for a given A-M rejection, but less peak separation.

Load resistors

The value R of the diode load resistors is generally selected to reduce the operating secondary circuit Q to a value of approximately one-fourth or less of its unloaded

value. Smaller values for R will increase the downward modulation handling capabilities of the detector, but will also reduce its sensitivity.

Primary L/C ratio and Q

The primary L/C ratio should be as large as possible to increase the sensitivity. The limiting factor is the maximum stable gain between the grid and plate of the ratio detector driver valve (i.e. the last i-f valve preceding the detector). When determining the maximum gain it should be remembered that the gain may increase during downward amplitude modulation, particularly on either side of the centre frequency.

If the primary Q is high enough so that the operating Q is determined mainly by the diode loading, the grid-plate gain will rise during the A-M cycle. This is advantageous since it increases the ability of the detector to reject downward modulation. The primary Q is made as high as possible consistent with peak separation and stable gain requirements.

Coupling

The value of coupling used, together with the number of turns in the tertiary winding, is the principal factor in determining the ratio of the tertiary voltage to the half secondary voltage. This ratio should always be close to unity. The coupling is generally adjusted to half critical in the actual circuit, since the degree of coupling is dependent on the other circuit component values and these are selected before the coupling is finally set to the desired amount.

Tertiary inductance

The number of turns on the tertiary winding is adjusted so that the required ratio of tertiary voltage to half secondary voltage is obtained (see under Coupling).

Reducing unbalanced A-M component

There will always be some residual amplitude modulation in the detector output because of the variation in the effective diode input capacitance during the A-M cycle, and because of the unbalance introduced by the transformer and other circuit components. Several methods are useful in overcoming this effect. One is to vary the effective centre-tap on the secondary winding (this method is shown in Fig. 27.26) and another is to make the resistors R_3 and R_4 shown in Fig. 27.25 unequal. In addition a resistor R_5 is used in series with the tertiary winding (see Fig. 27.25) to modify the peak diode currents, which has the effect of appreciably reducing the unbalanced A-M component particularly at high input voltages. The methods using resistors to reduce unbalance also reduce the detector sensitivity.

The reduction of unbalance effects is carried out by observing the condition for minimum A-M output when a signal which is simultaneously amplitude and frequency modulated is applied to the detector.

Time constant of stabilizing voltage

The discharge time constant of the stabilizing capacitance and the load resistance should be about 0.2 second. Larger time constants will give better amplitude rejection when the undesired modulating frequency is low, but have undesirable effects on the tuning. The tuning effect is similar to that given by an ordinary A-M receiver when the a.v.c. time constant is too long.

Experiments with the time constant of this circuit give some interesting effects. If the stabilizing capacitance is made very large, say 100 μF or so, and the receiver is tuned rapidly across a signal, it will be found that the point of maximum output is very easily determined, and there is no effect from the usual side responses. When the receiver is detuned the noise level rises, as the capacitor discharges, and the side responses again become evident until the receiver has been tuned once through the point of maximum output.

Additional details

It is not particularly easy to achieve a good balance with the ratio detector circuit, and usually more care is required in this respect than with the conventional phase discriminator. However, the better the balance obtained the better will be the rejection of undesired amplitude modulation.

Although the side responses are normally well down on the response at the main tuning point, with this type of circuit, considerable improvement has been noticed

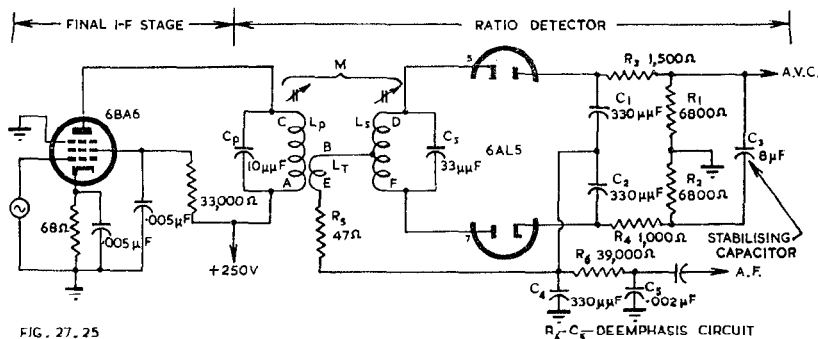

FIG. 27.25

R₁-C₅ DEEMPHASIS CIRCUIT

when the bandwidth of the discriminator is fairly large (say 300 to 400 Kc/s) and the i-f response is such as to give steep sides to the overall selectivity curve. With receivers using two i-f transformers (each critically-coupled and both having primary and secondary Q 's of about 75) the side responses are still sufficiently large to be noticeable, although they are 12-15 db down on the main tuning position. Receivers using three transformers (each critically-coupled and having Q 's of about 70) give a very marked improvement, and the two undesired side responses can only be found after careful searching. If the transformers are made more selective the side responses are reduced, but the additional non-linear distortion introduced by the tuned circuits may no longer be negligible, as can be determined from the data given in Chapter 26. Further, the amount of amplitude modulation on a carrier goes up as the selectivity of the transformers is increased, and this undesired A-M has to be removed by the ratio detector thereby reducing its effectiveness to other undesired external noise. Even in the case of the receiver with only two i-f transformers, the undesired side responses are very much less noticeable than with receivers using the usual limiter and discriminator combination

(E) Practical circuits

Two circuits which have been constructed and tested under working conditions are shown in Figs. 27.25 and 27.26. The intermediate frequency is 10.7 Mc/s. Constructional details and performance data can be found in Refs. 34 and 37.

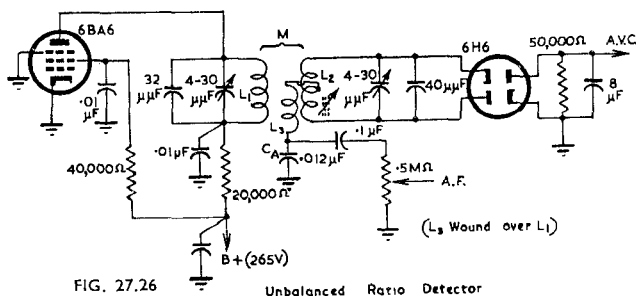

FIG. 27.26

Unbalanced Ratio Detector

De-emphasis is obtained in the circuit of Fig. 27.26 by adjusting the value of the capacitor marked C_4 . The time constant (0.4 second) of the diode load circuit is about twice as long as that previously recommended for typical cases, but the performance is quite good, and, as suggested in Ref. 37, the individual designer can set the constants to suit his own requirements.

The secondary winding for the circuit of Fig. 27.25 is a bifilar arrangement, while that of Fig. 27.26 has the secondary split into two sections placed on either side of the primary. In the latter case slug tuning is used for one half of the secondary so that the effective centre tap can be set to any desired position.

(F) Measurements on ratio detectors

Primary and secondary Q 's

To measure the unloaded primary Q , the double diode valve is removed from its socket and the secondary is detuned. The primary Q is then determined by the selectivity of the primary tuned circuit. The loaded primary Q is measured in the same way but with the double-diode valve in the circuit.

To measure the secondary Q the primary is heavily loaded by a shunt resistor. The secondary Q is then determined from the selectivity of the secondary winding as indicated by the rectified voltage variation with frequency. When measuring the unloaded secondary Q , the diode load resistance should be replaced by a resistance of about one megohm. When measuring the loaded secondary Q , the normal load resistors should be used. For these measurements the centre-tap of the secondary winding should be disconnected from the tertiary winding, to prevent the tertiary voltage from contributing to the rectified voltage.

Coupling

The percentage of critical-coupling can be measured by noting the change in primary voltage as the secondary is varied from a tuned to a detuned condition. With all circuit conditions normal, and the signal input voltage set to the intermediate frequency, the primary voltage (E_1) is noted. With the same input signal level, the secondary is detuned so that the primary voltage rises to E_2 . The percentage of critical-coupling can then be expressed in terms of the ratio between the primary voltage with the secondary detuned and tuned using the relationship

$$\frac{k}{k_{crit}} = \sqrt{\frac{E_2}{E_1} - 1}.$$

For example, if the signal voltage at the plate rises 25 per cent. (i.e. $E_2 = 1.25 E_1$) when the secondary is detuned, the coupling is 50 per cent of critical.

The ratio between the secondary and tertiary voltages can be measured indirectly in terms of the rectified output voltage which is obtained (a) with the secondary tuned and (b) with the secondary detuned. In both cases the input signal is adjusted so that the primary voltage remains constant. If the ratio between the voltages read in (a) and (b) is r , that is if

$$r = \frac{\text{Rectified voltage (tuned secondary)}}{\text{Rectified voltage (detuned secondary)}}$$

$$\text{then } \frac{S}{P} = \sqrt{r^2 - 1}$$

where S = half secondary voltage at centre frequency

P = "primary" (i.e. tertiary) voltage effective in the diode circuit at the centre frequency.

The ratio S/P is usually made equal to unity.

Signal generator

It is convenient to have available a signal generator of good quality capable of being simultaneously frequency and amplitude modulated. Undesired amplitude and frequency modulation should not be present in the generator output.

Alignment procedure

The ratio detector may be aligned by using either an unmodulated signal set to the centre frequency and a d.c. vacuum-tube voltmeter, or by using a F-M signal generator and an oscillograph.

If an unmodulated signal generator is used, the procedure is to set the signal to the intermediate frequency, and with the d.c. vacuum-tube voltmeter connected to measure the rectified output voltage (this is usually the a.v.c. take-off point), the primary tuning being adjusted for maximum voltage output.

The procedure used for adjusting the secondary tuning depends upon whether the centre-tap of the stabilizing voltage is earthed or whether one end is earthed. If the centre-tap is earthed, the secondary tuning is adjusted so that the d.c. voltage at the audio take-off point is equal to zero; the d.c. vacuum-tube voltmeter is shifted to the audio take-off point for this measurement. If the detector is of the unbalanced

type the secondary tuning is adjusted so that the d.c. voltage at the audio take-off point is equal to half the total rectified voltage. As an alternative an amplitude modulated signal can be used, the primary trimmer is adjusted for maximum d.c. output voltage and the secondary trimmer adjusted to give minimum audio output ; the residual output is measured in the conventional manner. Circuit unbalance is indicated if the two methods do not give the same secondary trimmer setting.

If sweep alignment is used, the primary can be accurately aligned by using a comparatively low deviation, and adjusting the primary trimmer for the maximum amplitude of output voltage. The secondary may be adjusted by using a deviation such that the total frequency swing (twice the deviation) is equal to the peak separation. This procedure makes it possible to adjust the secondary tuning so that a symmetrical detector characteristic is obtained.

Peak separation

The separation between the peaks on the F-M output characteristic of a ratio detector may be measured by applying a frequency modulated signal and increasing the deviation until the response is just observed to flatten at the peaks. When this is done, the peak separation is equal to twice the deviation.

If an attempt is made to measure the peak separation by plotting the output characteristic point by point, the peak separation obtained will usually be considerably less than that obtained under dynamic conditions with the output voltage stabilized. The F-M detector characteristic may be plotted point by point provided a battery of the proper voltage is connected across the stabilizing capacitor. The voltage of this battery must be equal to the rectified voltage which exists at the centre frequency. In practice it is convenient to use a 7.5 volt "C" battery and to adjust the signal input so that the capacitor-stabilized voltage at the centre frequency is equal to the battery voltage.

It is worth noting that the peak separation is not constant for all values of input voltage, and measurements should be made for several representative voltages of the magnitude likely to be encountered under practical conditions of reception. The peak separation is wider for larger input voltages, as a result of the increased diode loading on the tuned circuits. Similarly the peak separation is less for smaller input voltages because of reduced circuit damping.

Measurement of A-M rejection

The measurement of A-M rejection can be carried out using a signal generator which can be simultaneously frequency and amplitude modulated.

Ref. 34 shows a number of the typical wedge-shaped patterns which are obtained when visual methods are used for determining the amplitude modulation present in the audio output. A pattern of the type to be expected is shown in Fig. 27.27.

FIG. 27.27

The measurement of the A-M rejection of a ratio detector can be described in terms of the pattern obtained for a given frequency deviation and a given percentage of amplitude modulation.

The measurements should be made for several different values of input voltage. Ideally the pattern obtained should be a diagonal line regardless of the presence of amplitude modulation. The amount by which the pattern departs from a straight line indicates the extent to which the detector fails to reject amplitude modulation.

To measure A-M rejection with a generator which can only be frequency modulated the procedure is as follows. A frequency modulated signal fully deviated (± 75 Kc/s

in the usual case) is applied, and a battery of which the voltage is equal to the rectified output is shunted across the stabilizing capacitor. The magnitude of the input signal is now reduced until the output becomes distorted as a result of the diodes being biased by the stabilizing voltage, and finally the F-M output drops to zero. The ratio between the initial input signal and the minimum input signal for which the F-M output becomes distorted is then a measure of the amount of downward modulation that the detector can reject. For example if the voltage ratio is r , then the percentage of downward amplitude modulation which can be handled is $100(r - 1)/r$. To determine the rejection of the detector for upward amplitude modulation the same set-up is used and the change in output is noted as the input signal is increased. Since the amplitude of the input signal is not varied dynamically, this method will not indicate any unbalanced component which may be present in the output. The latter is more conveniently measured using simultaneous F-M and A-M as discussed previously.

Another method which can be applied to measure the amplitude rejection properties of any type of detector for different signal input voltages may be worth discussing. The input signal is simultaneously frequency and amplitude modulated. Any audio modulating frequencies can be selected which are not harmonically related, and suitable values are say 400 c/s for F-M and 30 c/s for A-M. The percentage A-M can be taken as 30% (or any value desired) and the deviation as ± 22.5 Kc/s (or any other value). The ratio of the desired and undesired audio outputs can then be measured on a frequency selective voltmeter such as a wave analyser. Measurements can be made at the centre frequency to indicate residual A-M, and for various frequencies off the centre frequency to determine the rejection capabilities of the detection system under operating conditions; e.g. those which occur when oscillator and other frequency drift occurs. Low audio frequencies are preferable for this test (and also for the previous methods), particularly with ratio detectors, since the amplitude rejection is least for this condition. Tests on a number of ratio detectors have indicated similar performance when high audio modulating frequencies are used, but considerable variation occurs in the amount of amplitude rejection obtained for the lower audio frequencies using balanced and unbalanced circuits. This is readily understood when the function of the stabilizing capacitor is considered.

Standard test procedures have been devised for F-M receivers, and standard methods for evaluating the degree of A-M rejection, downward modulation handling capability, and the effects of mistuning are described in Chapter 37.

Non-linear distortion

Distortion measurements are usually quite difficult to carry out with any degree of accuracy because of the inherent non-linear distortion present in the signal source and test equipment. Tests on typical F-M receivers using limiter-discriminator combinations and ratio detectors have been made, using the low power stages of a F-M broadcast transmitter as the signal source. The non-linear distortion in the transmitter signal was less than 0.5% for frequencies from 100 c/s to 15 Kc/s, and less than 1% from 30 to 100 c/s; the frequency deviation was set to ± 75 Kc/s in all cases.

Both types of receiver indicated a measured overall distortion of the order of 2 to 2.5% in the frequency range 100 c/s to 7.5 Kc/s, 3 to 5% at 50 c/s and 5% at 15 Kc/s although this latter case was a visual check only. Above 10 Kc/s the non-linear distortion with ratio detector receivers is generally somewhat higher than with limiter-discriminator receivers. The input in all cases was approximately 100 μ V and the output was adjusted to 0.5 watt. The test frequency was 97.2 Mc/s and the i-f of all receivers was 10.7 Mc/s. The measured distortion for the a-f amplifier alone was 0.5% for the range 100 c/s to 7.5 Kc/s and 2% at 50 c/s; above 7.5 Kc/s, observation was made using an oscillograph and as there was no visible distortion it was assumed that distortion was less than 3%.

The non-linear distortion is increased with ratio detector receivers when the magnitude of the input voltage is made very large. With the other type of receiver the input signal must be sufficiently large to ensure satisfactory limiter operation. Receivers

using a combination of partial limiting and a ratio detector give excellent results for a wide range of signal input voltages, and do not require extra valves.

The test conditions used are very severe, as it is unlikely that a 15 Kc/s audio signal will cause 75 Kc/s deviation; although it should not be overlooked that pre-emphasis in the transmitter will cause a 15 Kc/s modulating signal to be increased in magnitude by about 17 db. Listening tests indicate that excellent results are obtainable with any of the receiver arrangements. It will be appreciated that the possibility of errors in the distortion measurements are very large, and the results are given to serve as an indication of the magnitude of the distortion to be expected with typical F-M receivers which do not include elaborate design features, but conform to good engineering practice.

SECTION 3 : AUTOMATIC VOLUME CONTROL

(i) Introduction (ii) Simple a.v.c. (iii) Delayed a.v.c. (iv) Methods of feed (a) Series feed (b) Parallel feed (v) Typical circuits (vi) A.V.C. application (vii) Amplified a.v.c. (viii) Audio a.v.c. (ix) Modulation rise (x) A.V.C. with battery valves (xi) Special case with simple a.v.c. (xii) The a.v.c. filter and its time constants (xiii) A.V.C. characteristics (xiv) An improved form of a.v.c. characteristic (xv) Design methods.

(i) Introduction

Automatic volume control is a device which automatically varies the total amplification of the signal in a radio receiver with changing strength of the received signal carrier wave. In practice the usual arrangement is to employ valves having "remote cut-off" or "variable-mu" grids and to apply to them a bias which is a function of the strength of the carrier.

From the definition given, it would be correctly inferred that a more exact term to describe the system would be automatic gain control (a.g.c.). The older term a.v.c. has been retained here as the name is not likely to lead to any confusion, and is widely used throughout the radio industry.

(ii) Simple a.v.c.

In order to obtain simple a.v.c. it is only necessary to add resistor R_4 and capacitor C_4 to the ordinary diode detector circuit shown in Fig. 27.28. In any diode detector there is developed across the load resistor (R_1 and R_2 in series) a voltage which is proportional to the strength of the carrier voltage at the diode. The diode plate end of the load resistor is negative with respect to earth (Fig. 27.28) and therefore a negative a.v.c. voltage is applied to the controlled grids. R_4 and C_4 form a filter to remove the a-f component and any residual i-f and leave only the direct component of voltage.

FIG. 27.28

Since a capacitor in series with a resistor takes a finite time to charge or discharge, the a.v.c. filter circuit has a "time constant." The time constant of R_4 and C_4 is equal to $R_4 C_4$. For example, if R_4 is 1 megohm and C_4 is 0.25 microfarad the time constant will be 0.25 second. In this circuit the time constant is also influenced by R_1 during charge and by R_2 during discharge, but since R_1 is small compared with R_4 it will be sufficiently close for practical purposes to regard $R_1 C_4$ as giving the time

constant during charge, and $C_4(R_4 + R_2)$ as the time constant during discharge. It is seen that the charge time constant is shorter than the discharge time constant. Time constants in a.v.c. circuits will be discussed in detail in (xii) below.

For 100% rectification efficiency the a.v.c. voltage would equal the peak i-f voltage applied to the diode. Because of losses the a.v.c. voltage is always somewhat less than the peak carrier voltage (this is readily seen from Figs. 27.5 and 27.6), and since, in general, a higher voltage is required for the a.v.c. than for detection, this will be a limitation to the use of simple a.v.c.

The design of the i-f transformer to couple the i-f voltage into the diode circuit is quite straightforward. The damping to be expected across the windings due to the diode circuits has already been discussed in Sect. 1(i)Cc of this chapter. Methods of i-f transformer design are detailed in Chapter 26.

In the circuit of Fig. 27.28 the d.c. diode load consists of R_1 and R_2 in series, R_1 being used in conjunction with capacitors C_1 and C_2 to form a filter to prevent the major part of the undesired i-f voltages from appearing across R_2 . The volume control is R_2 in this circuit, and the advantages and disadvantages of using the control in this position were discussed in Sect. 1(i)Dc above. At audio frequencies R_2 is shunted by R_4 and by R_3 when the setting for R_2 is at the maximum. It follows that the diode load for a.c. is considerably different from that for d.c., and, as previously discussed in Sect. 1(i), considerable non-linear distortion of the a-f output will result when the modulation percentage is high. R_4 and C_4 will substantially remove all audio frequency variations from the a.v.c. bias applied to the controlled stages, as well as any residual i-f voltages which may be present across R_2 .

Fig. 27.28 shows R_4 connected to the junction of R_1 and R_2 , but in some cases R_4 is connected to the top of R_1 . This latter arrangement will give a slightly higher a.v.c. voltage, the amount depending on the size of R_1 , but the amount of i-f filtering for the controlled stages is reduced. With the usual component values it is not very important which arrangement is used.

Owing to the effects of contact potential in the diode, together with rectification due to unavoidable noise voltages, there is a voltage developed across R_2 even with no carrier input. Even with a weak carrier input this voltage is increased. Consequently it will be seen that with the weakest carrier likely to be received there is an appreciable negative voltage applied to the controlled grids. If no means were taken to compensate for this, the overall sensitivity of the receiver would be decreased. Compensation for the initial standing bias, before a carrier is received, can be carried out by applying a lower minimum negative bias to the controlled stages. However, a very real disadvantage of simple a.v.c. is now apparent in that the sensitivity of the receiver may decrease as soon as a carrier is received. To overcome the loss in sensitivity on weak signals a delayed a.v.c. system is used and this gives very much improved control.

A special case of the effects of contact potential with zero bias valves is worth noting before leaving this section. Suppose a negative bias voltage exists between the grids and cathodes of the controlled valves due to positive grid current. This current can be sufficiently large to cause an appreciable negative bias voltage to appear across the resistance common to the controlled stages and the detector, and so give rise to a negative bias voltage between plate and cathode of the diode. Under this condition, if simple a.v.c. is being used, there will be no output from the receiver until the signal is sufficiently large to overcome this delay bias on the detector. If a separate diode is used for a.v.c. the effect will be to increase the delay bias. Typical examples of the effect have occurred in practice with type 1P5-GT voltage amplifiers used in conjunction with the diode section of a type 1H5-GT. An obvious remedy is to apply a small positive bias voltage to the diode plate, but the grid current can often be appreciably reduced by increasing the screen voltage.

(iii) Delayed a.v.c.

The "delay" in delayed a.v.c. refers to voltage delay, not time delay. A delayed a.v.c. system is one which does not come into operation (i.e. it is delayed) until the

carrier strength reaches a pre-determined level. The result is that no a.v.c. voltage is applied to the grids of the controlled stages until a certain carrier strength is reached, and the receiver will have its maximum sensitivity for signals with an amplitude below this pre-determined level.

The circuit used for delayed a.v.c. also makes possible improved rectification efficiency in the a.v.c. circuit, thus producing slightly greater a.v.c. voltage for the same peak diode voltage. This is due to the higher value of a.v.c. diode load resistance (R_7 in Fig. 27.29) permissible in this circuit. With the a.v.c. arrangement shown the a.c. loading on the detector circuit is reduced when compared with the arrangement of Fig. 27.28 and this reduces the distortion of the audio output voltage. Some non-linear distortion of the modulation envelope does occur at the primary of the transformer but this is considerably less than that introduced when the a.v.c. voltage is obtained from the secondary circuit. In addition, the overall selectivity up to the primary of the i-f transformer is less than that at the secondary, and the a.v.c. will start to operate further from the carrier frequency than if fed from the secondary. The advantage here is that the tendency to give shrill reproduction is reduced as the receiver is detuned from a carrier.

FIG. 27.29

Differential distortion, caused by variable damping of the a.v.c. diode input circuit, is frequently mentioned as an inherent disadvantage of delayed a.v.c. because of the distortion which is introduced when the diode bias line cuts the modulation envelope. Careful measurements have shown that the additional distortion occurring just as the a.v.c. diode starts to conduct is quite small provided that the delay voltage is small and the average depth of modulation is not large (say 50% or so). With a delay voltage (E_D , Fig. 27.29) of 3 volts the total harmonic distortion was found to increase from an average level of about 2.5% to a peak of 4%. Not only is the amount of distortion fairly small, with the usual depth of modulation, but it only occurs over a limited range of input signals, which, with a small delay voltage such as 3 volts or less, occurs at such weak signal strengths as to be relatively unimportant. However with 100% modulation this type of distortion will always occur. Of course, when the input voltage is too small for the a.v.c. diode to conduct there is no distortion. From the evidence available, it appears that the effect of differential distortion is a comparatively minor one when the circuit is correctly designed, and a small delay voltage is used. Detailed discussion of the distortion produced by delayed a.v.c. can be found in Refs. 44 (p. 189) and 46.

If it is desired to apply full a.v.c. voltage to certain controlled stages and a fractional part only to another stage, this may be done by tapping R_7 at a suitable point and by adding a filter circuit similar to that made up from R_4 and C_4 .

Staggering* of the a.v.c. is sometimes advantageous, as a considerable improvement in signal-to-noise ratio is often possible by controlling mainly the i-f amplifier valves.

*By staggering of the a.v.c. is meant the application of different values of a.v.c. voltage to various stages

However, in some cases this leads to difficulties with cross modulation. When cross modulation is a serious problem it is preferable to control the r-f amplifier valves fully. Often no great care is taken with broadcast receivers in the method of applying a.v.c. With high quality communications receivers precautions are necessary, and it is helpful if the r-f and i-f valves to be controlled by a.v.c. can be selected by the operator. In this way optimum performance can be obtained under all conditions. The usual arrangement, however, is to design an a.v.c. system with compromise characteristics and fit manual switching for the selection of suitable time constants. The signal-to-noise ratio of the receiver should be measured when the a.v.c. characteristic is being determined, to ensure that the performance of the receiver is not seriously impaired when the signal input voltage is increased. Cross modulation tests are also necessary when the receiver performance is being determined. Further discussion of these problems can be found in Ref. 43 (pages 169 and 179). A dual a.v.c. system which has interesting possibilities is described in Ref. 50. Further discussion on a.v.c. and noise is given in Chapter 35 Sect. 3(i).

When a duo-diode triode (or pentode) valve is used with cathode bias, the value of the bias is usually between 2 and 3 volts. Such a voltage is suitable for use as a.v.c. delay bias; a very simple arrangement is possible by returning R_7 to earth as shown in Fig. 27.34. Alteration of the delay bias because of the presence of contact potentials must be considered, and this effect has already been discussed in (ii) above.

A circuit which eliminates differential distortion, even with large delay voltages and high modulation levels, is shown in Fig. 27.38B. Signal detection and a.v.c. detection are carried out as before, but a diode, D_3 , and the three resistors R_9 , R_8 and R_{10} are also used. R_9 and R_{10} form a voltage divider from B+ to ground, the junction of these resistors and R_8 having a potential of, say, +50 volts. Typical values for R_4 and R_8 could be 1 megohm and 5 megohms respectively, and it will be seen that R_4 and R_8 form a voltage divider between +50 volts and the source of a.v.c. potential.

The operation of the circuit can be explained most simply if the diode D_3 is ignored initially. Under these conditions, with no signal input to the receiver, point X will be practically at ground potential since there will be no i-f input to the diode D_2 and the voltage at Y will be approximately

$$+ 50 \times \frac{R_4}{R_4 + R_8} = + 8\text{-}1/3 \text{ volts.}$$

Now as an increasing signal is applied to the input of the receiver, the available a.v.c. voltage at X will increase, and when this voltage reaches -10 volts, the potential across the voltage divider R_4R_8 will be $50 - (-10)$ volts, and the potential at Y will be

$$-10 + (50 + 10) \frac{R_4}{R_4 + R_8} = 0 \text{ volts.}$$

A still larger voltage of -40 volts at X will give at Y

$$-40 + (50 + 40) \frac{R_4}{R_4 + R_8} = -25 \text{ volts}$$

Thus in the absence of the diode D_3 , point Y would have a potential with respect to ground which was positive in the absence of a signal and became less positive, zero and then more negative progressively as the signal input increased.

However the diode D_3 modifies this voltage variation by conducting whenever point Y tends to become positive. The result is that under no signal and small signal conditions point Y, from which a.v.c. is applied, is substantially at ground potential but as the signal input increases above some critical value, Y becomes progressively more negative. Thus the requirements of delayed a.v.c. have been met, although the loading of the diode D_2 on the primary tuned circuit is near enough to being constant whether a.v.c. is being applied or not.

After the delay has been overcome, the increase in negative potential at Y is not so rapid as the increase at X, the ratio being the same as that of the voltage divider formed

by R_4 and R_8 . However by using a large value of resistance for R_8 and a high positive voltage the ratio can be made as close to unity as required by any practical considerations.

The cost of the resistors R_9 and R_{10} can often be avoided by using a source such as the screen of a valve which has no a.v.c. applied, or a voltage divider used for some other purpose, for the positive potential. To save the cost of a valve having an additional diode for D_3 it is quite possible to use the signal diode D_1 as the source of a.v.c. voltages, and D_2 as the "sinking" diode. Alternatively D_1 and D_2 can be used as in Fig. 27.38B and the suppressor grid of say the i-f amplifier can be used as D_3 , although in this case with no signal applied the a.v.c. line will take up the potential of the cathode of the i-f valve.

This method of providing delay either to the first stages or to all controlled stages of a receiver is of course equally applicable whether manual or automatic volume control is used

(iv) Methods of feed

The a.v.c. voltage may be fed through the secondary of the r.f. transformer to the grid of the valve (sometimes called "Series Feed") or directly to the grid (sometimes called "Shunt or Parallel Feed"). In the latter case it is necessary to use a blocking capacitor between the top of the tuned circuit and the grid to avoid short-circuiting the a.v.c. voltage to ground through the comparatively low resistance of the tuned-circuit inductor. Actually the second term is a misnomer, since either circuit arrangement leads to the r-f and d.c. bias voltages being applied, effectively, in series with one another between grid and cathode of the controlled valve. This may not be immediately obvious in the case of so called "parallel feed," but can be readily seen by drawing an equivalent circuit consisting of a r-f voltage generator in series with a capacitor and in parallel with these a resistor in series with a battery. The capacitor charges to some value q because of the battery, and the r-f voltage due to the generator then acts in series with the resultant voltage across the capacitor, varying the total charge and consequently the voltage across the output terminals of the circuit.

It should be noted that the terms "Series Feed" and "Parallel Feed" have no bearing on the type of a.v.c. filter circuit, which may be series, parallel or a combination of both. The two types of a.v.c. feed circuits will now be considered in greater detail.

FIG. 27.30

(a) Series feed

One arrangement of series feed is shown in Fig. 27.30. It will be seen that in each r-f tuned circuit a blocking capacitor (C_8 , C_6) is used so that the rotor of the ganged tuning capacitors may be earthed and the a.v.c. voltage fed to the lower ends of the coils. In the r-f stages the use of this blocking capacitor will reduce the frequency coverage, and may also affect the tracking of the tuned circuits. To reduce these effects the same capacitance value should be used in each of the i-f stages, and the value selected should be fairly large consistent with other considerations. Also, if the capacitors are not to affect the Q of the tuned circuits adversely, they must be of a low loss type. A disadvantage of a high capacitance is that it increases the time constant of the a.v.c. circuit.

For typical cases C_5 and C_6 would be about $0.05 \mu\text{F}$ if the maximum capacitance of the tuning capacitor is about $400 \mu\mu\text{F}$. The effect on the tuning range is easily

determined by considering the reduction in total capacitance due to the capacitors being connected in series. Resistors R_5 and R_6 are used in conjunction with the capacitors to provide decoupling between the various stages; typical resistance values are 100 000 ohms.

Since the tuning capacitors in i-f transformers need not be connected directly to earth, blocking capacitors are not necessary. In these circuits the capacitor C_4 (Fig. 27.29) serves to by-pass all high-frequency components of current from the earthy sides of the secondaries of the tuned circuits of the i-f stages to earth, as well as being part of the a.v.c. filter.

FIG. 27.31

With the r.f. stages an alternative arrangement is to insulate the rotor of the ganged capacitors, and to by-pass it to earth by a single capacitor (C_6 , Fig. 27.31). This enables the a.v.c. voltage to be applied without using any blocking capacitors in the r-f tuned circuits, and has the further advantage that the time constant of the a.v.c. circuit may be made small. The arrangement also has obvious disadvantages and is little used.

(b) Parallel feed

The "parallel (or shunt) feed" circuit is shown in Fig. 27.32. In this arrangement a blocking capacitor is necessary to prevent a low resistance d.c. path being formed from grid to earth by the tuning inductor. The resistors R_8 , R_9 and R_{10} provide part of the d.c. path from the valve grids back to the cathodes. Since the individual resistors are shunted across their corresponding tuned circuits, the values selected must not be too low as otherwise appreciable damping occurs. A 0.5 megohm resistance in parallel with a typical r-f tuned circuit generally is not serious, but could appreciably reduce the dynamic resistance of an i-f circuit. For these reasons "parallel feed" is sometimes used with r-f stages, but it is seldom applied to i-f stages, and receivers are often designed to use both systems of a.v.c. feed.

FIG. 27.32

"Parallel feed" for the r-f stages is sometimes more convenient than "series feed," and appears to be satisfactory in most respects, although it has been found that grid blocking is more likely to occur with "parallel feed" than with "series feed."

With any method of feed it is important that the total resistance in the grid circuit should not exceed the maximum for which the valves are rated. Depending on the characteristics of the particular valve type and the effects on electrode dissipations and total cathode current, as determined by equation (6) on page 82, the following maximum values of grid resistor may be used as a general guide.

For one controlled stage	3 megohms
For two controlled stages	2.5 megohms
For three controlled stages	2 megohms

These resistances are to be measured between the grid of any valve and its cathode.

The values above assume that the receiver is normally tuned to a station and that the controlled valve or valves are operating at reduced cathode currents and trans-conductance, as determined by the a.v.c. bias.

(v) Typical circuits

A typical circuit of a simple a.v.c. system, with three controlled stages, is shown in Fig. 27.33. In order to provide the simplest arrangement the cathode of the duo-diode valve is earthed and grid bias is obtained for the triode section by the grid leak method using a resistor of 10 megohms. This method of biasing reduces the a.c. shunting across the diode load resistor. The cathodes of the controlled stages are normally returned to a point of positive voltage to ensure that the recommended negative grid bias is obtained for conditions where the input signal is very small; cathode bias is the usual arrangement.

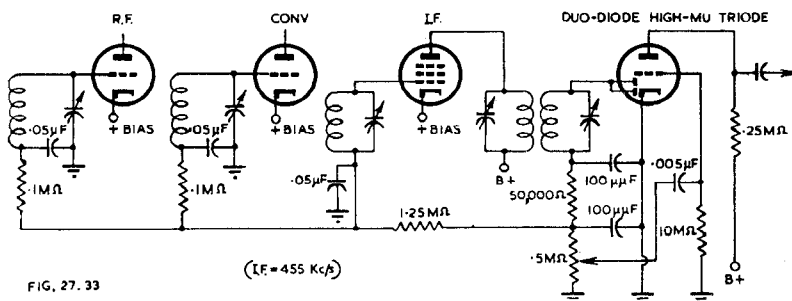

FIG. 27.33

The circuit values shown are typical for an intermediate frequency of 455 Kc/s. An a.v.c. resistor of 1.25 megohms is used so that the total resistance to earth from any grid does not exceed 2 megohms. If there were only two controlled stages this could be increased to about 1.75 megohms with a consequent decrease in the a.c. shunting.

A typical delayed a.v.c. circuit is shown in Figs. 27.34. Cathode biasing is used for the pentode section of the duo-diode pentode valve, and since the bias will usually be about two or three volts this also provides a suitable a.v.c. delay voltage without any further complication. With circuits using delay voltages on the a.v.c. diode the bias due to automatic volume control on the controlled valves is zero until the peak voltage on the diode exceeds the delay voltage. The controlled stages are arranged to have a self-bias voltage equal to the recommended minimum grid-bias voltage.

(vi) A.V.C. application

Automatic volume control is normally applied to the converter on the A-M broadcast band, irrespective of valve type. On the short-wave band some types of converters give very satisfactory operation with an a.v.c. bias voltage applied to the signal grid, while others introduce difficulties because of the appreciable shift in oscillator frequency caused by the changing signal grid bias. When no r-f stage is used it is often necessary to apply a.v.c. to the converter, but when a r-f stage is incorporated

FIG. 27.34

it is frequently advantageous to operate valve types 1A7-GT, 1C7-G, 6A8, 6D8-G on fixed bias. Valve types 6J8-G, 6K8, 6BE6, 6SA7 and all triode hexodes may be used with a.v.c. on A-M broadcast and short wave bands*. For receivers operating in the 88-108 Mc/s F-M broadcast band, a.v.c. bias is not applied to the signal grid of the converter valve; very often on this band fixed bias is used for the r-f stage, and a.v.c. is applied to the i-f stages only. Whether a.v.c. is used at all with these receivers often depends largely on the type of detector, but it is advisable to avoid overloading of the early stages so as to reduce the possibility of the generation of undesired spurious responses; this often calls for a.v.c. bias to be applied to the r-f stage.

Some oscillator frequency shift occurs with all types of converters when the signal grid bias is altered. With valve types such as the 6A8 operating on the short wave band the reception of a fading signal is difficult since the variations caused by a.v.c. bias may cause the signal to swing in and out of the pass band of the receiver. An even greater difficulty occurs when the receiver is being tuned to a strong signal, since the magnitude of the output will be different when tuning in from either the high frequency or the low frequency side of the signal. Very careful adjustment is required to obtain the best tuning position. A rather similar effect has been noticed on both the broadcast and short-wave bands, but in this case the effect is generally due to faulty gang wipers. When this is the cause it can occur with any type of receiver (t.r.f. or superheterodyne), but with superheterodynes the oscillator section of the ganged capacitor should be checked first, as this is generally the one causing most of the difficulty.

With ordinary broadcast receivers having a r-f stage, converter, and a single i-f stage, automatic volume control is normally applied to all three stages. If decreased modulation rise is required it is preferable to operate the i-f stage with about one-half of the full a.v.c. bias or, alternatively, to supply the screen voltage by means of a series resistor; the latter arrangement is the more usual one in practice. Negligible modulation rise is possible, with effective a.v.c. action, if all control is omitted from the i-f stage, but difficulties such as those due to decreased signal-to-noise ratio must not be overlooked when this system of a.v.c. is used on a number of tuning ranges (see (iii) above).

In a receiver without a r-f stage it is difficult to avoid overloading with large input signals, and a.v.c. is applied to both stages even though modulation rise may be objectionable with very high inputs. In order to obtain maximum control the screen voltage for the i-f valve should be obtained from a voltage divider. The degree of control must, however, be weighed against the possibility of non-linear distortion; this factor has already been discussed in Chapter 26 in connection with distortion in i-f amplifiers.

For a receiver having two i-f stages the second stage should preferably be operated at fixed bias in order to prevent modulation rise. It is possible that better overall performance at high input signal levels will be obtained when the second i-f stage is operated at a negative bias somewhat greater than the minimum bias. Removal of control from the last i-f valve will often reduce the possibility of overloading this stage, although this is not always a good solution as will be discussed in (xv) below.

(vii) Amplified a.v.c.

There are a number of methods available whereby the a.v.c. voltage to be applied to the controlled stages can be amplified, either before or after rectification.

(a) One or more stages of amplification may be used to form an a.v.c. amplifier channel operating in parallel with the signal channel, and having a separate diode rectifier. If the total gain of the a.v.c. amplifier channel is greater than the total gain of the equivalent section of the signal channel, there is effectively a system of amplified a.v.c. This is more effective than the usual arrangement with a single channel, since it retains the full amplification of the a.v.c. channel under all conditions. It also has advantages in flexibility due to the isolation of the two channels, and the a.v.c. channel may be designed to have any desired selectivity characteristics.

*See also Chapter 25 Sect. 2 pages 990-1001.

(b) If a common i-f channel is used, it is possible to add a further i-f stage with fixed bias for a.v.c. only, followed by a separate a.v.c. rectifier. By this means it is possible to avoid the distortion due to shunting of the diode load resistor, or to "differential loading" at a point where the a.v.c. delay is just being overcome.

(c) A d.c. amplifier may be used to amplify the voltages developed at the rectifier. A typical circuit arrangement giving d.c. amplified a.v.c. is shown in Fig. 27.35. Design methods are given in Refs. 44 and 45.

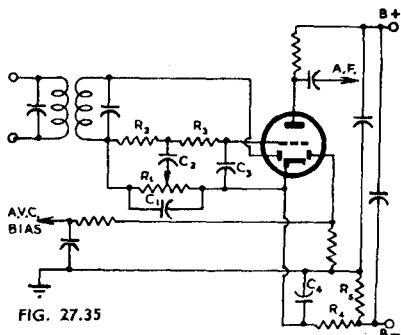

FIG. 27.35

Circuit Arrangement for Obtaining D.C. Amplified A.V.C.

See also Fig. 27.43 and the description given in Sect. 4(ii) later in this chapter.

(viii) Audio a.v.c.

Audio a.v.c. is sometimes used in radio receivers in conjunction with a.v.c. applied to the r-f and i-f stages to flatten out the overall a.v.c. characteristic. Whole or part of the a.v.c. bias voltage is applied to an audio frequency voltage amplifier valve having a grid with a variable-mu characteristic.

It should be clear that conventional a.v.c. systems cannot give a perfectly constant a-f output with a varying input voltage, because conventional a.v.c. is a "back-acting" device in which the effect on the controlled stages must follow the change occurring at a later stage in the receiver. Audio a.v.c. is "forward-acting" and so a constant or even a drooping characteristic is possible for increasing signal input voltages. Simple audio a.v.c. systems tend to introduce a considerable amount of non-linear distortion into the audio output voltage when the signal input voltage is large. This is due to the curvature of the $g_m - e_g$ characteristic of the controlled valve.

The amount of distortion can be reduced to negligible proportions by the use of elaborate circuits, but as these systems generally require an additional a-f amplifier valve they are not used to any extent in commercial radio receivers.

If it is decided that audio a.v.c. is desirable, the usual procedure is to obtain the best possible a.v.c. characteristic, apart from the a-f amplifier, and then to add just

FIG. 27.36

FIG. 27.37

enough a.v.c. bias voltage to the a-f amplifier to give the required overall results. The improvement in the overall a.v.c. characteristics, when audio a.v.c. is used, can be seen from Figs. 27.36 and 27.37.

An example of combined a.v.c. occurs in receivers using a reflexed voltage amplifier stage (see Chapter 28). In this case the a.v.c. bias voltage applied to the valve control grid is effective in controlling both the i-f and a-f gain, and if properly used the system can be made to assist very materially in obtaining good a.v.c. characteristics from a receiver having only one other controlled stage, namely the converter stage in the usual receiver. Another example of a circuit using audio a.v.c. is shown in Fig. 27.45.

(ix) Modulation rise

When a modulated carrier voltage is applied to a voltage amplifier stage in which the valve has a curved $g_m - e_p$ characteristic, the modulation percentage will increase. This modulation rise is noted in the output as audio frequency harmonic distortion (non-linear distortion), mainly second harmonic. Practically all of the modulation rise occurs in the final i-f stage. 20% modulation rise is equivalent approximately to 5% second harmonic. Modulation rise with fixed bias is extremely small even with remote cut-off valves, but there is a slight advantage in using a valve having a sharp cut-off characteristic. Modulation rise may be decreased by operating the i-f stage on a fraction of the a.v.c. voltage, but this adds to the expense of the receiver. Alternatively, a noticeable improvement may be made by supplying the screen from a series dropping resistor connected to B+. This is recommended for circuits having one r-f and one i-f stage. Modulation rise can sometimes be reduced by increasing the gain from the grid of the final i-f valve to the a.v.c. diode. Improving the amount of control on the earlier stages by reducing the screen voltage (this provides cut-off with lower grid voltages) will help in reducing modulation rise, but is likely to lead to difficulties with cross modulation when the receiver is used in close proximity to a powerful transmitter.

(x) A.V.C. with battery valves

When battery valves operating at zero bias are used, it is possible to obtain delayed a.v.c. by incorporating a duo-diode-triode or duo-diode-pentode valve having a diode plate situated at each end of the filament. A delay of between 1 and 2 volts (depending on the filament voltage) is obtainable by this means, and makes a very simple and satisfactory arrangement. The diode at the positive end of the filament is used for

a.v.c. and its return is taken to filament negative. The diode at the negative end of the filament is used for detection and its return is taken to filament positive.

It sometimes happens that the filaments of battery valves are operated in series or series-parallel arrangements. Under these conditions it becomes more difficult to design an efficient a.v.c. system than when parallel filament operation is used. In the usual type of a.v.c. circuit the grid returns from the several controlled stages are brought to a common point, and the zero signal grid voltage on these stages is the same. With series or series-parallel operation, however, the filament voltages differ with the result that the zero signal bias on one or more stages may differ from zero by a multiple of the filament voltage. Circuit arrangements which allow the bias on the grids to be zero for no signal input generally allow only a reduced proportion of the a.v.c. voltage developed by the diode to be applied to some of the controlled stages; full a.v.c. bias can only be applied to one or two stages in most cases. Fig. 27.38A shows a typical circuit arrangement for the case where the filaments are connected in series and operated from the H.T. supply. The a.v.c. voltage divider is made up from the resistors R_8 , R_9 , R_{10} and R_{11} . A value of about 2 megohms is usual for R_{10} while R_{11} is made about 2 megohms per 1.3 volt drop, in the case of 1.4 volt valves (which are operated with 1.3 volts as a recommended value for the series filament connection). In the circuit shown a higher proportion of the a.v.c. control voltage is applied to valve V_2 than to valve V_3 . The purpose of the resistors R_7 , R_2 , R_3 , R_4 and R_5 is to allow the correct filament voltage to be applied to each of the valves, since it should be obvious that the valve V_1 , at the negative end of the chain, carries the total cathode current for all the valves, and each of the other valves carries the cathode currents for all the other valves which are nearer to the positive end of the chain than the valve being considered. This statement is modified when R_6 is used, because this provides an alternative path for the cathode currents. From this it follows that no shunting resistor is required for V_6 .

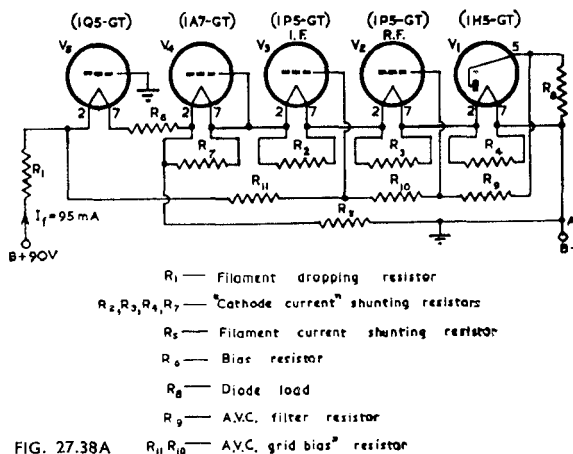

FIG. 27.38A

(xi) Special case with simple a.v.c.

If a simple a.v.c. circuit, such as that shown in Fig. 27.28, is used in conjunction with a diode-pentode (or triode) operating with cathode bias, the diode load return will be two or three volts above earth. It is necessary, in this case, to provide additional negative bias voltage on the controlled stages if the correct minimum bias voltage is to appear between grid and cathode in each case.

(xii) The a.v.c. filter and its time constants

There are several reasons why filter circuits, such as those shown in Fig. 27.33, are required. One important reason is to prevent r-f and a-f voltages which appear

across the a.v.c. diode load from being applied back to the grids of the controlled stages. If r-f or i-f voltages are applied back to the grids then instability troubles are certain to arise. A-F applied to the grids can lead to a reduction in the percentage of modulation present on the carrier. Inter-stage filtering is also necessary because undesired coupling can lead to instability and spurious whistle responses. From this it can be seen that the prime function of the filter circuits is to allow only the d.c. voltage developed across the diode load to be applied as additional bias on the controlled valves. The components making up the filter also serve the necessary function of completing the r-f and i-f circuits through low impedance paths and, furthermore, the resistors serve to complete the d.c. return path between grid and cathode of each controlled valve so that the correct negative bias voltage can be applied.

It is not permissible to choose values of resistance and capacitance at random if satisfactory circuit operation is to be obtained. Several conflicting factors must be considered when the component values are being selected. The time constant (defined below) of the filter network, must be low enough so that the a.v.c. bias voltage can follow the changes in signal input voltage with sufficient rapidity to offset the effects of fading. Limiting values for the total circuit resistance have been stated in (iv) above, and the choice of suitable values for R and C will be discussed as we proceed, but first the expression "time constant" will be defined.

The "time constant" of a resistance-capacitance network is the time in seconds required for the capacitor to acquire sufficient charge for the voltage between its plates to be equal to 63.2% of the total voltage applied to the circuit. Alternatively, it is the time taken for a charged capacitor to lose sufficient charge for the voltage across its plates to fall to 36.8% of the initial voltage existing between the plates in the fully charged condition. It is a simple matter to show that, for the conditions stated, the time constant (T) is given by

$$T = RC \text{ seconds}$$

where R = circuit resistance in ohms

and C = circuit capacitance in farads.

(It is usually more convenient to write

$$T = \text{resistance in megohms} \times \text{capacitance in microfarads} = \text{seconds}.)$$

If the total resistance in the circuit is altered in any way from its value during the charging operation to a different value during the discharge of the capacitor, then it is helpful to use the terms "charge time constant" and "discharge time constant." In a.v.c. circuits there is always a difference between the charge and discharge time constants, because during charge the diode is conducting and its conduction resistance effectively short-circuits the d.c. diode load resistor. This also means that the "charge time constant" is always more rapid than the "discharge time constant" in these circuits.

Suitable values for "charge time constants" are

Broadcast good fidelity receivers	0.25 to 0.5 second
Broadcast receivers	0.1 to 0.3 second
Dual wave or multi-band receivers	0.1 to 0.2 second

For the reception of telegraphy longer time constants are often required to ensure silence between signals, and a value of about 1 second is often used. In any good quality communications receiver it is usual to provide facilities for selecting any one of a number of a.v.c. time constants. This enables the operator to select the most suitable condition to offset the particular type of fading being encountered. Too rapid a time constant is not selected for high quality broadcast reception as rapid fading would cause bass-frequency anti-modulation and so reduce the audio frequency bass response. See also Chapter 35 Sect. 3(i)B2, page 1233.

In broadcast receivers the charge and discharge time constants are often very nearly equal. However, for some types of reception it may be preferable for the charge time constant to be rapid to prevent the beginning of a signal from being unduly loud, but the discharge time constant is made comparatively slow to prevent a rapid rise in noise output during intervals between signals (see also Ref. 43, p. 181).

The procedure for calculating charge and discharge time constants is as follows. Consider Fig. 27.30 in conjunction with Fig. 27.28, then

For 2 stages

Charge time constant =

$$R_1(C_2 + C_4 + C_5) + R_4(C_4 + C_5) + R_5C_5$$

Discharge time constant =

$$C_5(R_5 + R_4 + R_2) + C_4(R_4 + R_2) + C_1(R_1 + R_2) + C_2R_2.$$

These follow readily when it is considered that the diode is conducting during charge, and $R_1 \ll R_2$; the diode is non-conducting during discharge.

For 3 stages

Charge time constant =

$$R_1(C_2 + C_4 + C_6 + C_8) + R_4(C_4 + C_5 + C_6) + R_5C_5 + R_6C_6.$$

Discharge time constant =

$$C_6(R_6 + R_4 + R_2) + C_5(R_5 + R_4 + R_2) + C_4(R_4 + R_2) + C_1(R_1 + R_2) + C_2R_2.$$

If the circuit of Fig. 27.28 were considered alone the charge time constant would be $R_1(C_2 + C_4) + R_4C_4$ (assuming $R_5 \gg R_1$), and the discharge time constant $C_1(R_1 + R_2) + C_2R_2 + C_4(R_4 + R_2)$. The way in which the total time constant is built up for the more complicated cases will be readily seen, and the addition of extra controlled stages should offer little difficulty when the new time constants are to be determined.

For a more detailed discussion of time constants in a.v.c. circuits the reader is referred particularly to Ref. 47.

Fig. 27.38B. Circuit for "sinking diode" arrangement which reduces differential distortion.

FIG. 27.38B

(xiii) A.V.C. characteristics

A.V.C. Characteristic Curves may be plotted on 6 cycle log-linear graph paper as shown in Fig. 27.36. The input is usually taken from 1 μ V to 1 volt. The output is usually shown in decibels, with an arbitrary zero reference level. The complete curves are useful not only for demonstrating the effectiveness of the a.v.c., but also to indicate modulation rise.

To facilitate the developmental work on the complete receiver it is helpful to draw on the same graph

- A curve of distortion against input voltage for 30% modulation at 400 c/s.
- A curve of the developed a.v.c. voltage against input voltage.
- Curves of the total bias voltages on the controlled stages against input voltage.
- A curve of noise output against signal input voltage*. This allows the signal-to-noise ratio, for any input voltage to be determined.

If fixed minimum bias is used, curves (b) and (c) will differ only by the bias voltage. If self-bias is used they will differ by the minimum bias voltage present with no input voltage, and will tend to run together at high input voltages. For methods of conducting the experimental measurements see Chapter 37.

*See also Chapter 35 Sect. 3(i) pages 1229-1234.

Fig. 27.36 shows several a.v.c. curves, each corresponding to a particular condition. In taking these curves two separate diodes were used to maintain constant transformer loading and other conditions. Contact potential in the diode results in a slight increase in the standing bias voltage on the controlled stages; this effect has been discussed in (ii) above.

Curve A is the "no control" characteristic and is the curve which would be followed, with the a.v.c. removed from the receiver, up to the point at which overloading commences. This characteristic is a straight line and the slope is such that an increase of ten times in the input voltage gives a 20 db increase in output.

Curve B is the a.v.c. characteristic for a delay of -9 volts. For inputs of 3 to 18 μV the experimental curve follows the no control line exactly, and then deviates sharply for inputs above 18 μV . From 18 to 500 000 μV the slope of the curve is fairly constant, the output increasing by about 3.25 db for each 10 times increase in the input voltage. Above 500 000 μV (i.e. 0.5 V) input the curve tends sharply upward, indicating severe modulation rise.

Curve C is the a.v.c. characteristic for a delay of -3 volts. The a.v.c. comes into operation at a lower input voltage, as would be expected, and the average slope is steeper than for the higher delay voltage. In both cases, however, the "knee" of the curve as it leaves the no control line is very clearly defined.

Curve D is the a.v.c. characteristic for a delay of zero voltage, with due compensation for the effect of contact potential on the standing bias of the controlled valves.

Curve E is typical of the characteristics obtained when audio a.v.c. is added to a receiver. Over the range of inputs from 100 to 500 000 μV the total rise in output is only 3 db.

Curve B has been drawn according to the conventional method whereby the output is adjusted to half the maximum undistorted output of the receiver for an input signal of 1 volt. Curves C and D were then taken directly, without any further adjustment to the volume control. Owing to a slight effect on the gain of the receiver when the delay voltage is varied, Curves C and D fall slightly below the datum line at an input of 1 volt. Curve E has been drawn to correspond to Curve C, since both have the same delay voltage. The volume control, however, was advanced considerably for Curve E. It should be noted that no conclusions should be drawn from the relative vertical positions of a.v.c. characteristics drawn according to the conventional method since the volume control settings are unknown.

(xiv) An improved form of a.v.c. characteristic

The conventional method of obtaining a.v.c. characteristics does not give all the information which is available, and an improved method yielding additional data has been suggested by M. G. Scroggie (see Ref. 51). This method will now be described.

Instead of commencing at an input of 1 volt and adjusting the volume control to give one-quarter or one-half of the maximum undistorted power output at 30% modulation, Scroggie's method is to commence at a low input voltage with the volume control set at maximum. The input is increased until the output is approximately one-quarter of maximum, and the volume control is then set back to reduce the power output to one-tenth of the reading. This process is repeated until an input of 1 volt (or whatever is the maximum available from the signal generator if this is less than 1 volt) is reached.

This method is illustrated by the curves shown in Fig. 27.37. The scale of power output represents the output (at 400 c/s) which would be obtained with the volume control at maximum and 30% modulation, provided that no overloading occurred in the audio amplifier. A number of interesting facts may be obtained from an examination of these curves.

1. The residual noise level of the receiver may be shown.
2. The sensitivity of the receiver in microvolts input for any selected output level (e.g. 50 mW or 0.5 W) may be read directly from the curves. It should be noted that the output includes noise.

3. The power output corresponding to any selected input voltage and any position of the volume control may be obtained. For example, with a delay of -3 volts (curve B1) the delay voltage is overcome at an output level of slightly less than 2 watts with the volume control set at maximum. As a further example (again assuming 400 c/s and 30% modulation) take the same curve at an input of $1000 \mu\text{V}$, where the output is shown as approximately 10 watts with the volume control at maximum. The setting of the volume control to give 4 watts output and using 100% modulation instead of 30% is

$$\sqrt{(30/100)^2 \times (4/10)} = 0.11$$

of the maximum resistance of the control. The actual amount of rotation will depend on whether the volume control resistance is related to rotation by a linear or a logarithmic law.

4. The voltage at the detector may be calculated from a knowledge of the a-f gain and the detection efficiency. The a.v.c. bias voltage can also be determined indirectly by calculation from the data obtained.

5. The slope of the initial part of the curve can show up an under-biased valve in the receiver. Cheap receivers frequently use a common source of bias for two or more valves, and under these conditions it can happen that one of the valves has too little bias and gives less than its maximum gain when there is no signal input to the receiver. As the input is increased, a.v.c. is applied to each controlled valve and this gives a comparatively rapid increase in gain from the under-biased valve. Such an increase shows up as an early section of the a.v.c. curve with a slope more vertical than it would otherwise be—usually with a slope in excess of 6 db per octave—and with a noticeable bend towards the horizontal at the point at which the valve receives the bias required for maximum sensitivity.

To operate a valve under these conditions is of course undesirable, and in use the receiver will emphasize the fading of any signals which fade through the range of signal inputs over which the effect operates.

6. The signal-to-noise ratio for any input can be read directly from the graph, as mentioned previously. In addition, the increments of signal-to-noise ratio with increasing input can be checked. An ideal receiver would give a 20 db improvement of signal-to-noise ratio for each 20 db increase in input, and it is possible for a normal receiver to approach this value, at least over the first decades of the a.v.c. graph. Any significant departure from the ideal can usually be traced to the application of a.v.c. to the first valve in the receiver [see Chapter 35 Sect. 3(i)] and care should be taken to keep the signal-to-noise ratio improving as rapidly as possible until it has reached a value of at least 45 db.

Scroggie's method makes possible the measurement of ratios as great as this, or much greater, because although one reading, the power output, may be beyond the range of the output meter used, the volume control of the receiver is in effect used as a multiplier.

7. The noise curve of the receiver might be expected to decrease indefinitely with increasing a.v.c. voltage, but there are two reasons why it may not do so. The first is that although the object of the test is to measure the signal-to-noise ratio of the receiver, in practice the signal-to-noise ratio of both the signal generator and the receiver are being measured. A 50 db ratio between 30% modulation and residual noise with no modulation is a representative figure for a signal generator of reasonable quality, and it is generator noise which causes the noise curve in Fig. 27.37 to become approximately horizontal shortly after $1000 \mu\text{V}$ input.

The second reason for the noise curve not decreasing indefinitely is that in most receivers in which power supply filtering has been kept to a minimum, for reasons of economy, there is some modulation hum with high inputs. This hum shows up as an increase in the level of the noise curve, and by plotting the curve over the full range of inputs expected to be applied to the receiver the designer can assure himself that the level of modulation hum does not become objectionable. An increase in modulation hum can be seen in Fig. 27.37 as the input approaches 1 volt.

The a.v.c. characteristics in Fig. 27.37 can be taken as typical of curves taken by this method. B_1 and B_2 show the signal and noise curves respectively for a 5 valve receiver without audio a.v.c. and C_1 and C_2 show the results for the same receiver with audio a.v.c. It will be seen that the delay is overcome at about 15 μ V input and that at say 0.1 volt input there is 8½ db of audio control by the a.v.c. The noise ratio ($B_1 - B_2$) should be identical with the ratio ($C_1 - C_2$) since the only difference between the B curve and the C curves is that due to modified audio gain. Thus the curve C_2 would become approximately horizontal at 2000 μ V input and at -25 db.

This method enables greater accuracy to be obtained for very small input signals since the power output reading will be well up on the scale of a typical output meter. With the conventional method the output is too small to measure accurately with a standard type of output meter.

At extremely low input voltage levels the noise fluctuations make accurate output measurements very difficult to carry out.

(xv) Design methods

One of the difficulties faced by a receiver designer in making a preliminary calculation of the a.v.c. performance of a receiver is often the lack of complete data on some of the valve types he is expected to use. If a completely satisfactory preliminary design is to be made it is necessary to have available, firstly, data on the manner in which mutual or conversion conductance varies with grid bias voltage; this data must be for conditions of fixed screen voltage, and also for the case where the screen voltage is applied by means of a series dropping resistor. The second requirement is to know for a given percentage of non-linear distortion the signal handling capabilities (input and output) for various grid bias voltages, of the valves to be used in the controlled stages; this knowledge is required particularly in the case of the last (and sometimes an earlier stage, as will be discussed below) i-f voltage amplifier valve when a large delay bias is used on the a.v.c. diode. Diode characteristics are also required, but these are usually available. The requirements of valve data are partly fulfilled in some cases, and for later valve types some additional information is available.

Because of the time required to carry out measurements to obtain the additional data, receiver designers, in the majority of cases, make only a few preliminary calculations to determine the desired time constants etc., and then proceed to achieve suitable a.v.c. characteristics by experimental procedures. As an example, with broadcast receivers it is usual to take the cathode bias voltage used for control grid bias on the multi-element valve containing the a.v.c. diode as providing sufficient a.v.c. delay bias (this bias is generally about -3 volts) and with the usual series of valves (e.g. 6SK7, 6J8-G etc.) and transformers a reasonably satisfactory a.v.c. characteristic is obtained; this assumes that component values are used which are of the order of those discussed in previous sections in connection with Figs. 27.33, 27.34 etc. For the type of receiver where improved a.v.c. characteristics are called for, a fairly large delay bias may be used on the diode. In general, the higher the delay voltage the flatter will be the a.v.c. characteristic (over the range of a.v.c. operation) and this is illustrated by Fig. 27.36. The limitation on the allowable amount of delay bias is set, however, by the magnitude of the signal voltage appearing at the grid and plate of the last i-f amplifier valve, and it is for this reason that, when large delay bias voltage is used, the i-f valve is sometimes operated with reduced or zero a.v.c. bias. However, as this reduces the number of controlled stages it is not necessarily a satisfactory solution, and a better arrangement is to use an additional stage to obtain the necessary control.

Design examples

Attention will be confined mainly to simple delayed a.v.c. systems of the more common types. For additional design information and discussion the reader is referred to Refs. 45, 44, 43 and 53. A good practical approach to the problem is given in Ref. 43.

(1) A receiver is to have one r-f and two i-f stages controlled by a.v.c.; the converter operates with fixed bias. It is required to estimate, roughly, the diode delay

bias required if the detector output voltage is not to change by more than 6 db for a change in signal input to the aerial stage of 50 db.

Assume first that the a.v.c. and signal detectors are linear, that equal signal voltages are applied to the detector and a.v.c. diodes, and that the detection efficiency (η) is unity. Since stage gain varies with change in mutual conductance (g_m) it can be taken, with typical voltage amplifier valves, that the gain alters by about 1.5 db for each additional volt of negative grid bias (this can be determined with greater accuracy from similar methods to those given later). Since there are three controlled stages using similar valves, the total gain decrease is 4.5 db per volt of bias. (Suppose similar valves are not used, one valve giving a gain change of 2 db per volt of bias and two others giving 1.5 db per volt, then obviously 1 volt of a.v.c. bias change alters the receiver gain by 5 db).

The total decrease in receiver gain which is required equals $50 - 6 = 44$ db. To achieve this the additional a.v.c. bias needed is $44/4.5 = 9.8$ volts. That this is also equal to the delay bias required for the stated conditions, can be appreciated because, at the threshold of a.v.c. operation, the voltage on the detector diode will be 9.8 volts peak, and for a further 9.8 volts (peak) increase in signal input the total voltage applied to the detector is 19.6 volts giving an increase in a-f output voltage of 6 db. The effect of 19.6 volts (peak) signal applied to the a.v.c. diode is to produce the required 9.8 volts d.c. bias since half the peak input voltage is required to overcome the delay voltage.

To illustrate a further point, suppose it had been taken that an 80 db input change should only give 6 db output voltage change. Then the delay bias required would be $(80 - 6)/4.5 = 16.4$ volts. This also means that the stage preceding the detector must deliver 32.8 volts peak when the carrier is constant. During modulation of the carrier the peak voltage delivered by the last i-f stage can reach 65.6 volts, and if distortion is to be avoided the valve preceding the detector must be capable of delivering this amount of output voltage when the total bias is 16.4 volts plus the standing bias. Whether this is possible can be determined from curves of the signal handling capability of the valve in question, or by direct measurements using a modulated carrier. It will be found, usually, that the maximum output voltage which can be handled without severe distortion is very much reduced when the grid bias voltage is large. This then suggests that reducing the a.v.c. bias on the last i-f amplifier valve will allow the permissible plate voltage swing to be increased. Reducing the bias voltage also results in the stage gain being increased, and so the same a.v.c. bias voltage is produced with a smaller signal input voltage. However, the amount of total control is reduced, and so partial or zero a.v.c. bias on the last i-f valve is not necessarily a satisfactory solution in every case.

It should be observed that the last i-f stage is not necessarily the one in which overloading will occur first. In Chapter 26, when discussing the crystal filter stage, it was pointed out that the grid to plate gain of the valve preceding the filter was very high with the arrangement shown. Suppose the grid to plate gain of the first valve is 400 times, but the gain from the grid of the first to the grid of the second valve (into which the filter feeds) is 5 times, then if the grid to plate gain of the second valve is less than 80 times it becomes immediately apparent that the first i-f valve will be overloaded before the second one. Extreme cases of this type are not likely to occur, but they present possibilities which should not be overlooked.

(2) A detailed design for a single controlled stage is to be carried out from valve data. Simple a.v.c. is to be used.

The valve type selected for this example is the 6SK7 remote cut-off pentode. The average characteristics are shown in Fig. 27.39. The standing bias is -3 volts and the mutual conductance (g_m) for this condition is 2000 micromhos. For a total grid bias of -35 volts the g_m is 10 micromhos. If cathode bias were used some additional error would be introduced, although this is usually neglected.

The first step is to convert the $g_m - E_g$ curve of Fig. 27.39 to a curve showing the change in gain of the controlled stage with variation in grid bias. The actual value of stage gain is not required since it is assumed to be directly proportional to g_m .

The change in g_m is expressed in decibels, taking as the reference level (0 db) the value of g_m for maximum gain, i.e. the g_m with only the standing bias (-3 V) applied to the grid. In this case the g_m used for zero reference level is 2000 micromhos. Then using

Change in gain (db) = $-20 \log_{10} \frac{g_m(E_{c1} = -3 \text{ V})}{g_m} = -20 \log_{10} \frac{2000}{g_m}$

the following values are obtained (the values for g_m are taken from Fig. 27.39).

FIG. 27.39 6SK7 Mutual Characteristics

d.c. voltages are tabulated in column (2) below against r.m.s. signal (E_{rms}) applied to the diode.

E_{rms} (= signal input to diode)	A.V.C. Bias (volts)	Total bias (= A.V.C. + standing bias)	Diode Signal Input Change (db)
2	- 2.2	- 5.2	0
5	- 6.2	- 9.2	8
8	- 9.1	-12.1	12
10	-11.8	-14.8	14
15	-17.8	-20.8	17.5
20	-23.9	-26.9	20
30	-35.6	-38.6	23.5

* = $-(3 + \text{a.v.c. bias})$.

These results are plotted in Fig. 27.40 as curve 1. It might be noted that the average slope is 1.4 to 1.5 db per volt.

It is next required to determine the amount of a.v.c. bias voltage developed by the diode circuit, for various input voltages applied to the diode. In a typical case the d.c. diode load resistance would be 1 megohm, and the d.c. voltage developed for various signal input voltages can be taken directly from Fig. 27.6. The developed

FIG. 27.40

It is now necessary to relate the total bias (a.v.c. + standing bias) to the **change** in diode input voltage; the change is conveniently expressed in decibels. Any signal voltage applied to the diode may be taken as zero reference level (0 db), and in our case $E_{rms} = 2$ volts will be convenient. Then the change in diode input voltage is given by,

$$\begin{aligned} \text{db change in diode input} &= 20 \log_{10} \frac{E_{rms}}{E_{rms} \text{ (for total bias = } -5.2 \text{ V)}} \\ &= 20 \log_{10} \frac{E_{rms}}{2} \end{aligned}$$

The results are tabulated in column (4) of the table given above, and the total bias versus diode signal input change is plotted as curve (2) in Fig. 27.40.

Finally, it is required to find the way in which the output changes with changes in signal input to the amplifier. If we assume various values for the change in signal voltage applied to the diode, it is a simple matter to determine the total grid bias, and from this the change in stage gain, by using curves (2) and (1) Fig. 27.40. Also from the curves, it is seen that, with zero change in diode input (0 db), the amplifier stage gain is 3 db down on the maximum possible gain. (This is because we selected $E_{rms} = 2$ volts as being the zero reference level). If now we assume, say, 2 db change in diode input, the actual change in stage gain is $-4.3 - (-3) = -1.3$ db. Because voltage input applied to the diode has increased 2 db, and the amplifier stage gain has decreased 1.3 db, it follows that the signal voltage applied to the amplifier grid must have increased $2 + 1.3 = 3.3$ db.

The direct output voltage change across the detector load, for 3.3 db change in signal input, is from -2.2 volts to -2.9 (i.e. from curve (1), Fig. 27.40, the total bias voltage change is from -5.2 to -5.9 volts, which correspond respectively to -2.2 volts and -2.9 volts across the diode load, when the standing bias is -3 volts). Expressing the direct output voltage change in decibels, we have

$$\begin{aligned} \text{Output change (db)} &= 20 \log_{10} \frac{\text{a.v.c. bias}}{\text{a.v.c. bias for } E_{rms} = 2 \text{ V}} \\ &= 20 \log_{10} \frac{\text{a.v.c. bias}}{-2.2} \end{aligned}$$

From this we have for 3.3 db change in signal input voltage (2 db change in diode input) a corresponding output change of 2.4 db. The complete a.v.c. characteristic is tabulated below and plotted in Fig. 27.41.

Change in diode input (db)	A.V.C. Bias Voltage	Change in Signal Input (db)	Change in diode output (db)
0	- 2.2	0	0
2	- 2.9	3.3	2.4
4	- 3.5	6.5	4.0
6	- 4.5	10.6	6.2
8	- 6	16.8	8.7
10	- 7.5	22	10.6
12	- 9.1	27.2	12.3
14	- 11.8	33.9	14.6
16	- 15	40	16.7
18	- 18.5	46	18.5
20	- 23.9	52.8	20.7
22	- 29.5	60	22.5
22.8	- 32	65.8	23.2

It is seen that a change of 60 db in signal input gives an increase of 22.5 db in output. It should also be observed that in most cases it can be taken that the diode input is directly proportional to diode output, and the additional set of calculations need not be made—e.g. 60 db change in signal input gives 22 db change in diode input or 22.5 db change in diode output. For three similar controlled stages the output change would be reduced to 7.5 db. If the valves to be controlled are not of the same type, then individual input-output curves must be drawn and the results combined to give the complete a.v.c. characteristic.

Fig. 27.41. Calculated a.v.c. characteristic for a single controlled stage using type 6SK7.

The a.v.c. characteristic for diode input voltages smaller than $E_{rms} = 2$ volts can be readily plotted, but as the useful range of signal input voltages, where control is mainly required, is usually greater than this value in a reasonably sensitive receiver (and because of the limitations of the diode curves) this value has been taken as affording a satisfactory example.

The variation in gain given by simple a.v.c. is limited, and for very strong signals a local-distance switch or some other method to prevent overloading of the receiver is required.

(3) The voltage amplifier and diode detector used for the previous example are to be used in a delayed a.v.c. circuit, in which the delay bias applied to the diode is -10 volts.

If they are not available, the diode characteristics relating r.m.s. input voltage to d.c. output voltage, for various delay bias voltages, can be measured directly. The rectified voltage, used for a.v.c. bias, is not completely independent of modulation when a delay bias is used, and there is an increase in the available d.c. when the percentage modulation is increased. Usually the a.v.c. comes into operation for lower carrier input voltages than would normally be expected, particularly when the percentage of modulation approaches 100%.

The complete design procedure now follows that given previously for simple a.v.c. using the data derived by the method given in the last paragraph. It should be clear that curve (1) in Fig. 27.40 remains unchanged, but curve (2) must be replotted. The resultant data are then available for plotting the a.v.c. characteristic. For signal input voltages of which the peak value does not exceed the diode delay bias, the receiver operation is the same as for one which does not incorporate a.v.c. (this is clearly shown in Fig. 27.36).

The slope of the no control line is readily determined since it is taken that the output is directly proportional to the input.

SECTION 4 : MUTING (Q.A.V.C.)

(i) *General operation* (ii) *Typical circuits* (iii) *Circuits used with F-M receivers*

(i) General operation

When a sensitive receiver which incorporates automatic volume control is being tuned from one signal to another there is an objectionable increase in noise output. This effect can be overcome by using a circuit arrangement which will make the receiver silent in the absence of a signal. Arrangements of this nature are known by various names such as muting, interstation-noise suppression, quiet automatic volume control (Q.A.V.C.), or squelch systems.

It is desirable, with these circuits, for the receiver to come into operation with the weakest possible useful signal voltage. Since the useful signal voltage may be variable for different conditions of reception, communications receivers are usually fitted with a variable threshold control which can be adjusted to give the best results. For broadcast receivers variable external controls are not used, the muting range being pre-set by the manufacturer.

Most systems of muting depend for their operation on the application of a large bias voltage to an i-f amplifier valve, the detector or an a-f amplifier valve. A wide variety of circuits has been used by receiver designers, but attention will be confined here to a few typical arrangements, since the general principles are much the same in all cases.

(ii) Typical circuits

(a) Biased diode detector

A simple type of biased detector muting system is shown in Fig. 27.42. It is seen that the circuit arrangement for the detector is quite conventional except that the diode load is returned to a tap on the cathode resistor. This makes the diode plate negative with respect to cathode, by the voltage developed between the cathode and the tapping point on the bias resistor R_k and so detection cannot occur until the peak signal input voltage exceeds this negative bias voltage. The components are marked to correspond to those in Sect. 1 of this Chapter.

It should be apparent that there will be a range of signal input voltages around the threshold point over which the audio distortion will be severe.

FIG. 27.42 Biased Detector Muting System

A more elaborate muting system, giving improved results over the simple system of Fig. 27.42 has been described by K. R. Sturley (Ref. 44). This uses a negatively biased diode and at the same time the circuit is arranged to provide d.c. amplified delayed a.v.c. The operation of this circuit can be readily understood from Fig. 27.43. The diode marked D_3 acts as the automatic volume control detector, and the d.c. voltage developed across the load resistor R_2 is applied to the grid of the triode section of V_3 and amplified. The diode D_4 will only come into operation when the cathode of V_3 becomes negative with respect to the diode plate, and the a.v.c. bias is delayed until this condition occurs. Considering now the double diode V_2 , it is seen that D_1 acts as the detection diode, but it can only detect when the signal input voltage exceeds the negative bias voltage developed across the cathode circuit R_k, C_k . This negative

grid 1 has a remote cut-off and grid 3 a sharp cut-off characteristic. Some systems use two valves in place of V_2 to effect muting and audio frequency amplification. Improved systems are also available (Ref. 54) which use a duo-diode pentode to eliminate the separate double diode valve, the pentode section being used as the intermediate frequency voltage amplifier. Audio a.v.c. is readily applied in this latter case.

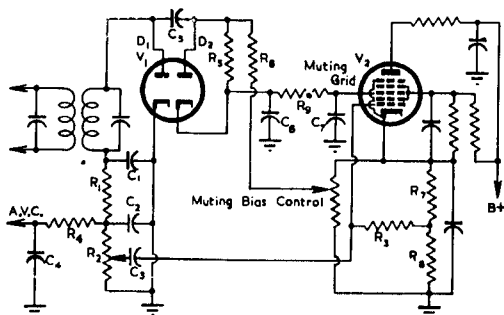

FIG. 27.44 Inoperative Audio Amplifier Muting System

From Fig. 27.44 it is readily seen that the diode detector and simple a.v.c. arrangements are quite conventional. The audio output from the detector is applied to grid 1 of the valve V_2 . Only part of the cathode bias is applied to grid 1 by using a tap on the cathode resistor. In the absence of conduction through the diode D_2 there is a large negative bias applied to grid 3 due to the total cathode bias voltage developed across R_7 and R_8 in series. The d.c. path to grid 3 is via R_6 , R_5 and R_9 . R_6 has a high value of resistance to prevent the plate of D_2 from being connected to ground through the comparatively low impedance of the cathode circuit of V_2 (which includes the muting control as shown). The circuit made up from R_9 , C_6 and C_7 is merely a filter to allow the application of direct bias voltage only to the muting grid (3) of V_2 ; however, R_9 also performs the useful function of stabilizing the voltage applied to grid 3 in the event of the anti-muting bias being sufficiently large to cause grid current. R_5 is the diode load resistor for D_2 , and C_5 allows the application of i-f voltage to the plate of the diode D_2 . When a signal is received the voltage developed across R_5 is sufficiently large, and of the correct polarity, to reduce the total negative bias on grid 3 and so allow the valve V_2 to perform the function of voltage amplifier for a-f voltages applied to grid 1.

An interesting arrangement (Ref. 54) is shown in Fig. 27.45, in which a duplex-diode pentode and its associated circuit combine the functions of muting, detection, conventional and audio a.v.c., and audio frequency amplification. The valve V_1 is a duo-diode pentode in which grid 1 has a remote cut-off characteristic (the circuit was developed around the Australian-made type 6G8-G). The operation of this circuit is somewhat different from those previously discussed. The maximum gain obtainable from a resistance-capacitance coupled audio frequency amplifier occurs when the negative grid bias has a particular value. For a negative bias less than the optimum value (and for a particular screen voltage, which is generally made fairly low), g_m will drop and the stage will effectively be muted. When the negative bias is made larger than the optimum value the gain of the stage will decrease at a comparatively slow rate. This principle is used in the circuit of Fig. 27.45 and the signal, muting, and audio a.v.c. voltages are all applied simultaneously to the control grid. The cathode resistors R_{10} and R_{11} are used to set the bias voltage to give the optimum value for maximum gain. R_{11} is then adjusted to a lower value to reduce the total bias voltage, and to cause the gain to drop to such a low value that muting has effectively occurred. It is necessary to select the values of bias and screen voltage so that the maximum screen dissipation is not exceeded. When a signal voltage is applied to the a.v.c. diode, the rectified voltage developed across R_7 increases the grid bias

in a negative direction which increases g_m (and so the stage gain) and the valve unmutes. For further increases in signal voltage the a.v.c. comes into operation, and the gain of the audio stage (and also the other controlled stages) begins to fall off in the usual manner. It is seen that only part of the total a.v.c. bias is applied to the grid of V_1 .

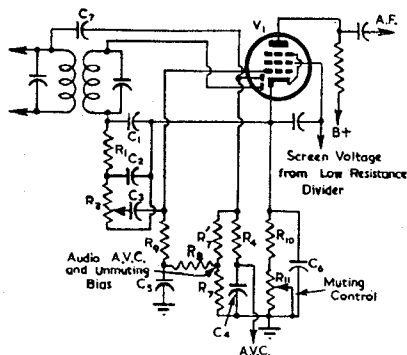

FIG. 27.45 Single Valve Arrangement to Provide Muting, Audio A.V.C., Detection and A.F. Amplification

(iii) Circuits used with F-M receivers

The general principles for muting circuits used in F-M receivers are much the same as for the circuits previously discussed. However, many of the circuits are novel and a few typical arrangements will be discussed.

One typical arrangement (Ref. 59) is shown in Fig. 27.46(A). Valve types V_1, V_2 and V_3 are those normally employed for limiting and detection. Valve V_4 is a double triode with separate cathodes such as the type 6SN7-GT. Section (1) is used as a d.c. amplifier for the muting control bias voltage which is applied to the grid of Section (2). The triode of Section (2) is used as an audio frequency voltage amplifier in the usual manner.

The operation of the circuit is as follows. In the absence of a signal the limiter valve V_2 draws full plate current, and the positive voltage applied to the cathode of triode (1) of V_4 (from the voltage divider R_1, R_2, R_3) is a minimum. At the same time there is a positive voltage on the grid of (1) which is sufficiently large to ensure that there is a resultant positive voltage on the grid with respect to cathode. This allows the plate of (1) to draw full current and makes point A negative with respect to point B across the resistor R_6 , and so a negative bias is applied between grid and cathode of triode (2). This bias is made sufficiently large to cut off the plate current of (2) and so prevents any a-f output from being obtained.

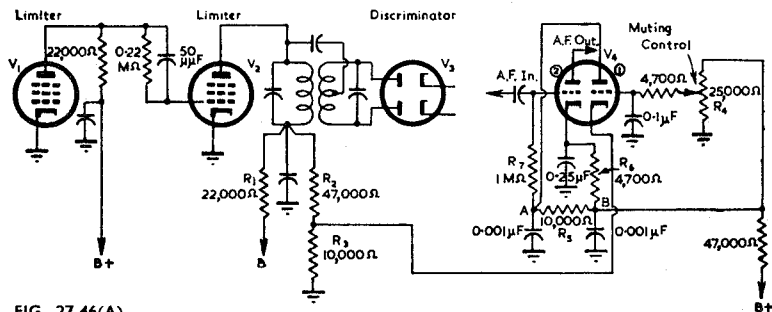

FIG. 27.46(A)

Muting System for F-M Receiver

When a signal voltage is impressed on the limiter V_2 the plate current is reduced, and so the positive voltage applied to the cathode of triode (1) (V_4) is increased. When the signal input is sufficiently large the positive cathode voltage will exceed the positive voltage on grid (1) by an amount which is sufficient to cut off the plate current. This puts the points A and B at the same potential and so removes the negative bias from the grid (2). Triode (2) of V_4 then acts as an ordinary a-f voltage amplifier, and its normal bias is obtained from the voltage drop across the cathode resistor R_6 .

FIG. 27.46(B)

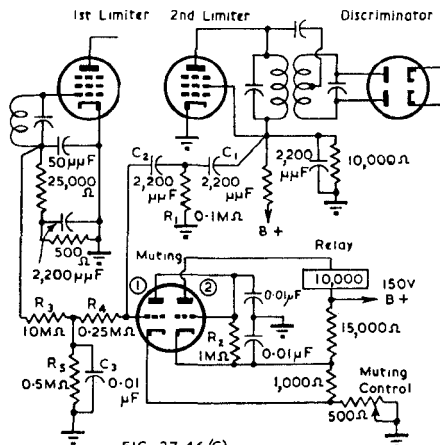

FIG. 27.46(C)

Fig. 27.46(B) shows a simple but effective arrangement for muting. Noise voltages, in the absence of a signal, which appear in the screen circuit of the second limiter valve, are applied to the control grid of the triode section of the muting valve (e.g. type 6AV6) and the amplified noise voltage is applied to the diode detector circuit. The d.c. voltage across the diode load is applied as additional negative bias to the grid of the a-f voltage amplifier valve and cuts off this stage. When a signal is received the noise voltages are reduced and so the additional bias on the a-f valve falls and the stage begins to function in the normal manner.

Another useful arrangement is shown in Fig. 27.46(C). In this circuit noise voltages from the screen circuit of the second limiter are applied to the grid of the muting valve (which could be a type 12AT7) via the high pass filter $C_1 C_2 R_1$. Triode section (1) operates as an anode bend detector and the direct voltage developed across R_2 cuts off triode section (2); the relay is then in the unoperated condition. When a signal is received the noise voltages are reduced due to the receiver quieting, and at the same time additional bias is applied to triode (1) by the rectified voltage appearing at the first limiter grid. The voltage across R_2 is now insufficient to cut off triode (2) and the relay is operated by the plate current. The relay can operate a contact to short the grid of the output valve to earth: additional contacts can also be utilized should the receiver be used for special purposes. The circuit can readily be re-arranged so that the relay is not required, and an additional control bias is made available to cut off the a-f voltage amplifier by increasing the voltage in the cathode circuit in the absence of a signal. The coupling network $R_3 R_4 R_5 C_3$ has a suitably selected time constant, and the circuit arrangement is such as to prevent amplitude modulation or over deviation of the frequency modulated signal from muting the receiver.

Both of the circuits of Fig. 27.46(B) and (C), or variations of them, have been widely used in f-m mobile and V.H.F. link receivers. In some cases additional negative bias is applied to both the a-f voltage amplifier valve and the a-f output valve; this has the advantage in the case of mobile receivers that the battery drain is reduced very appreciably during stand-by periods since a large proportion of the battery drain is due to the H.T. current drawn by the output valve.

If muting ON-OFF is required it is usual to switch an additional resistor into the cathode circuit of the muting valve. This resistor is made sufficiently large to cut off the valve and so render the muting inoperative.

A number of other useful circuit arrangements can be obtained from Refs. 58 and 59. Many circuits have appeared in the patent literature, but have not been generally published. One of particular interest uses the two limiters (which are resistance-capacitance coupled) as a multivibrator unit, the output of the second valve being coupled back to the input of the first by means of resistance and capacitance connected in series. In the presence of signal input voltages the relatively low amplification between the valves prevents the feedback network from being effective. In the absence of a signal the grid biases are such that noise voltages will be amplified sufficiently until the circuit operates as a multivibrator. One of the two valves is then always in a non-conducting condition and there is no audio output. This system is described by J. A. Worcester in G.E. Patent Docket 68743. Another useful circuit is given by R. A. Peterson in R.C.A. Patent Docket 21,998. This incorporates d.c. amplification and also requires the use of an additional double diode with separate cathodes. The diodes rectify noise output (which contains A-M) from the limiter. The d.c. voltage developed across the diode load is amplified and applied as a muting bias on the a-f amplifier valve. Unmuting occurs in the presence of a signal by using a negative voltage from the limiter grid to oppose the rectified voltage appearing across the diode load.

Muting circuits are generally applied only to F-M receivers using the limiter and discriminator combination. The noise level between stations with receivers using ratio detectors or locked oscillator arrangements is generally fairly low, and muting is not usually considered to be so necessary in these cases. However, it is a relatively simple matter to utilize the rectified d.c. voltage available at the output of a ratio detector (or also in a conventional discriminator, see Ref. 62 p. 120) to operate a muting system, since the rectified d.c. voltage is proportional to the strength of the incoming signal.

SECTION 5 : NOISE LIMITING

(i) *General* (ii) *Typical circuit arrangements.*

(i) **General**

The purpose of a noise (or crash) limiter in a radio receiver is to assist in the reduction of noise pulses, such as those due to ignition interference and crashes of static, so that their effects may be minimized at the receiver output. The difference between muting systems and noise limiters should be carefully distinguished, as they perform quite different functions in connection with the type of noise which they are meant to eliminate.

Noise limiters in general follow two trends. One group "punches a hole" in the signal so that the receiver output is momentarily cut off. The other main group functions by limiting the maximum output to a value which is not appreciably greater than some pre-determined level.

It can be shown fairly readily (Ref. 63) that the best results for noise reduction can be obtained by placing the limiter in the receiver at a point of low selectivity. The Lamb silencer (Ref. 65) for example, is usually placed after the first i-f stage and its operation is such as to cut off the plate current in the second i-f amplifier valve, momentarily.

For many purposes elaborate noise limiting circuits (Refs. 65, 71) are not essential, and the tendency in the usual communications receiver is to use simple diode limiting to remove noise peaks. For amateur work sufficiently good results are often possible using audio output limiters (see Refs. 66, 67, 68). With the A-M receivers used in mobile communications systems a very elaborate noise limiter may be incorporated.

See also Chapter 16 Sect. 6 for speech clippers and Sect. 7 for noise peak and output limiters.

The threshold of operation for noise limiters can be arranged for either automatic or manual setting for different signal input voltages. Good results are possible using automatic setting, but the more elaborate circuits practically always make some provision for manual control.

(ii) Typical circuit arrangements

The Lamb silencer can be made to give excellent results, but because it is rather elaborate it is not extensively used in commercial communications receivers. For a description of its operation, together with complete circuit data, the reader should consult Ref. 65.

Fig. 27.47 shows a typical example of the "shunt" type of diode limiter. It is seen that the circuit to the left of the dotted line AB is the usual diode detector circuit and the component values are identical with those normally selected. The negative direct bias voltage is set to prevent the diode D_2 from conducting until the peak input voltage exceeds the bias. When this occurs the diode D_2 acts as a virtual short circuit, and there is practically no output from the detector circuit.

A "series" type of diode limiter is shown in Fig. 27.48. The diode D_1 is used for detection in the usual manner. Diode D_2 is biased to be conducting with normal signal voltages applied to the detector circuit. For bursts of noise there is an instantaneous negative voltage applied to the plate of D_2 , and when this negative voltage exceeds the positive bias the diode stops conducting and so opens the audio output circuit. A large amount of audio gain is required when this type of circuit is used, because of the low audio voltage available.

These simple circuits have several disadvantages. Firstly they are both susceptible to hum because of heater-cathode leakage when the cathode of D_2 is above earth. For example this limits the size of the resistor R which can be used in the circuit of Fig. 27.48, and so results in a loss in audio output. (An increase on the value shown would be permissible however). A further disadvantage is that stray capacitances will allow some of the high frequency noise components to appear in the receiver output, even though the diodes are operating in the prescribed manner; this can be largely overcome with care in layout and wiring to minimize stray capacitances.

Automatic threshold control may be arranged with simple "series" and "shunt" limiters. Suitable methods are given in the references (particularly Refs. 62A, 64 and

FIG. 27.49 Automatic Noise Limiting Circuit

70). However, a much more satisfactory circuit (Ref. 44) is shown in Fig. 27.49. The diode D_1 is incorporated in the usual detector arrangement and this circuit provides a variable bias voltage for the noise limiting diodes D_2 and D_3 . A short burst of noise voltage having a positive polarity will cause the diode D_3 to conduct and so flatten out the audio waveform. A noise voltage having negative polarity causes D_2 to conduct which then flattens out the negative peak of the audio output. In the absence of noise the positive and negative half cycles are equally damped and so distortion is reduced.

Additional methods used for noise limiting in radio receivers are given in Chapter 16 Sect. 7; methods of noise reduction for use with reproduction from records are described in Chapter 17 Sect. 7.

SECTION 6 : TUNING INDICATORS

(i) Miscellaneous (ii) Electron ray tuning indicators (iii) Null point indicator using Electron Ray tube (iv) Indicators for F-M receivers.

(i) Miscellaneous

A tuning indicator is a device which indicates, usually by means of a maximum or minimum deflection, when a receiver is correctly tuned. These indicators have taken a number of forms, particularly before the advent of the Electron Ray tuning indicator, originally called the "Magic Eye," and a few of these will be briefly discussed before considering the Electron Ray Tube in detail.

FIG. 27.50 Saturated Reactor Tuning Indicator

One arrangement is to use a milliammeter connected in the plate circuit of a voltage amplifier valve which is controlled by a.v.c. Circuits of this type can also be arranged to indicate relative signal strength, and the meter scale may be calibrated in arbitrary "S" units. Another form is the saturated reactor or dimming lamp indicator. This uses a pilot lamp, in series with a special form of iron-cored inductance, which is excited from a suitable winding on the power transformer. A second winding on the inductance (or transformer) carries the plate current of one or more valves which are controlled by a.v.c. In this simple form the maximum plate current is sufficient to saturate the core and so reduce the impedance in series with the pilot lamp, which is then at full brilliance. When a signal is being tuned the plate current is reduced and the lamp dims. In order to make the pilot lamp reach full brilliance when the receiver is tuned to a station instead of dimming, a "bucking" current can be passed through another winding so that saturation occurs when the plate current is very small, instead of it occurring when the plate current is large. Both arrangements can be understood by studying Fig. 27.50.

A further arrangement is to use a neon tube in which the length of the illuminated column is proportional to the d.c. voltage obtained from a resistance connected in series with the plate of an amplifier valve controlled by a.v.c.

(ii) Electron Ray tuning indicators

Electron Ray tuning indicators are the most popular of all the arrangements being considered. These indicators operate from either the signal diode or the a.v.c. diode circuit. The Electron Ray tube is not limited to use in receivers with a.v.c., since it operates to indicate a change of voltage across any part of the circuit. For example it may be connected to the signal diode circuit irrespective of the presence of a.v.c., or it may be connected across the cathode bias resistor of an anode bend detector. The correct type of Electron Ray tube to be selected for any position depends on the controlling voltage available.

The most popular types of Electron Ray tube (e.g. 6U5/6G5) have a triode amplifier incorporated in the same envelope, so that the voltage necessary to obtain full control is decreased. In most types this amplifier has a remote cut-off characteristic so that the sensitivity may be high for weak signals and yet not cause "overlapping" on strong signals. Type 6E5 has a linear characteristic and is occasionally used for special applications. Type 6AF6-G has two independent Ray-Control Electrodes, one of which may be used for strong signals and the other for weak signals, but has no amplifier incorporated in the same envelope.

In a typical receiver with delayed a.v.c. the Electron Ray tube may be connected to either the signal or the a.v.c. circuit, but since it will give no indication until the diode starts to conduct, it will not operate on weak signals when connected to a delayed a.v.c. circuit. Consequently most receivers using delayed a.v.c. employ the signal diode circuit for operating the tuning indicator. The disadvantage of this latter arrangement is that it introduces additional a.c. shunting effects on the detector diode load resistance and so leads to increased distortion at high modulation levels (see Sect. 1(i) above). The a.c. shunting effects are minimized by using a high resistance in the grid circuit of the tuning indicator, a value of about four times the diode load resistance being typical. In order to prevent flicker due to modulation, adequate decoupling between the diode load and the indicator grid is necessary. A capacitance of about $0.05 \mu\text{F}$ is usually connected from grid to ground, and this, in conjunction with the grid resistor previously mentioned, should lead to satisfactory operation (see Fig. 27.51). If simple a.v.c. is used (i.e. no delay voltage) it is preferable to operate the tuning indicator from the a.v.c. line to reduce a.c. shunting (see again Fig. 27.51). From the diagram it can be seen that with the switch in the "Det." position the grid of the tuning indicator is connected through a 2 megohm resistor to the detector diode circuit. With the switch in the "a.v.c." position the indicator is connected directly to the a.v.c. line. This shows the two alternative connections just discussed. The cathode of the tuning indicator is returned to a suitable tapping point on the cathode bias resistor of the power valve as discussed below.

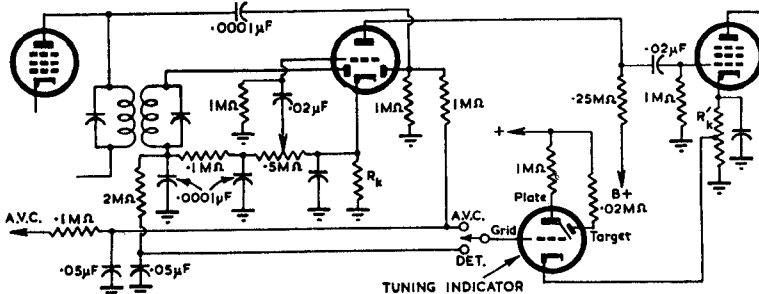

FIG. 27.51

Methods for Application of the Magic Eye Tuning Indicator

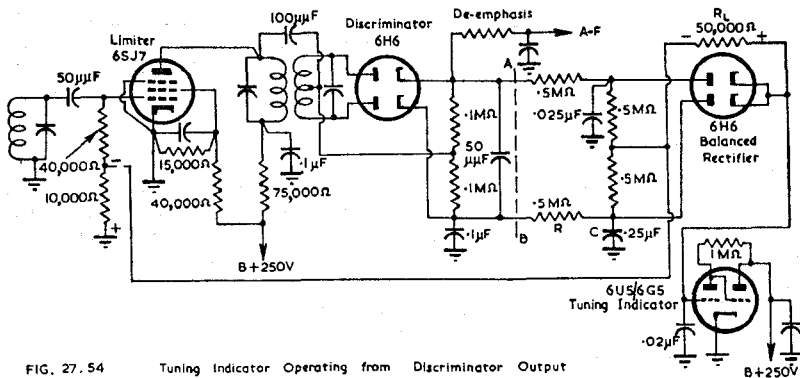

FIG. 27.54

Tuning Indicator Operating from Discriminator Output

This latter feature is not available with similar arrangements operating from the discriminator output alone.

Tuning aids are sometimes used in receivers with ratio detectors. The simplest arrangement in this case is to take the control bias voltage from the a.v.c. take-off point, or to use whatever fraction of this total voltage that is thought to be necessary for operating the tuning indicator.

SECTION 7 : CRYSTAL DETECTORS

(i) Old type crystal detectors (ii) Fixed germanium crystal detectors (iii) Fixed silicon crystal detectors (iv) Theory of crystal rectification (v) Transistors.

(i) Old type crystal detectors

Crystal detectors of the "cat's whisker" type have been used for many years, but are very touchy, require frequent adjustment, and are affected by even slight vibration. However, when correctly adjusted, they make quite efficient detectors. Crystal sets are briefly mentioned in Chapter 34 Sect. 1(ii).

(ii) Fixed germanium crystal detectors

These have the advantages of small size and of needing no heater supply, thereby avoiding the possibility of introducing hum into high impedance circuits. Their main disadvantages are that the impedance presented to negative voltages is comparatively low and dependent upon the applied voltage, and that the characteristics from unit to unit show comparatively large variations.

Reverse resistance in a typical case varies from 2 megohms with 20 volts applied to 0.2 megohm at about 100 volts. In some circuits, e.g. a F-M ratio detector, this reverse conductance affects the operation and modifications are required to obtain satisfactory performance. The forward resistance is very low e.g. 200 ohms with one volt applied, falling below 100 ohms at somewhat higher voltages for a typical unit—and this feature can be valuable in some applications.

In this type of rectifier (see Ref. 79 from which this description is taken) as distinct from silicon rectifiers, the outstanding advantage lies in an ability to handle large voltages in the reverse direction, while in the forward direction, the slope (measured at +1 volt) may be of the order of 100 ohms (10 mA at 1 volt).

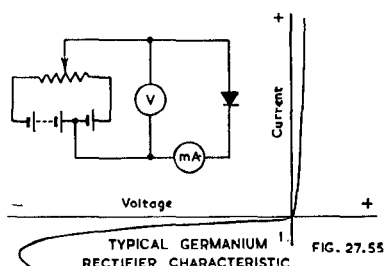

The slope in the reverse direction reaches a maximum resistance value at the order of -2 volts, beyond which the resistance falls slowly until, at a particular voltage known as the "turnover voltage," the slope resistance falls to zero and then becomes negative.

Measurements of rectification efficiency at various frequencies up to 100 Mc/s indicate that the efficiency falls with frequency by an amount which depends upon the "turnover voltage," the higher the "turnover voltage" the lower the rectification efficiency. In view of this, crystals intended for use at very high frequencies have a maximum as well as a minimum "turnover voltage" rating.

A typical current/voltage characteristic is shown in Fig. 27.55.

Rectification occurs at the junction between a metallic point and the surface of crystalline germanium. During manufacture this junction is treated to obtain optimum impedance characteristic and time stability. After assembly, the metal point is cemented to the germanium to prevent dislodgment by vibration, and the complete assembly is sealed to prevent ingress of moisture.

A characteristic of fixed germanium crystal detectors is their remarkable property of withstanding severe mechanical shock or vibration. The estimated life of the rectifier is indefinite—in excess of 10 000 hours.

There is little change in rectifier characteristics from 15°C to 50°C, but above this temperature up to 100°C, both forward and back slope resistances decrease slowly.

The characteristics of germanium crystal diodes vary considerably, depending on the application and the manufacturer, but the following data are representative of the majority of types.

Allowable direct current	20 to 60 mA.
Allowable surge current	100 to 600 mA.
Allowable reverse voltage	25 to 250 volts
Turnover voltage (reverse voltage for zero dynamic resistance)	40 to 275 volts
Minimum current with +1 volt	2.5 to 15 mA (some are less than 2.5 mA).
Reverse current with -50 volts applied (this only applies to types having an allowable reverse voltage of 50 volts)	40 to 1660 μ A
Capacitance	0.8 to 3.0 μ F.
Maximum ambient temperature	+70° to +85°C.
Minimum ambient temperature	-40° to -55°C.
Maximum frequency	up to several hundred Mc/s.

References to germanium detectors : 78, 79, 80, 81, 83, 84, 85, 85A, 85B.

(iii) Fixed silicon crystal detectors

The fixed silicon crystal detector is principally used as a frequency converter at frequencies above 100 Mc/s. Some designs go up to 1000 Mc/s, while others go as high as 5000 or 10 000 Mc/s. The silicon detector is liable to damage by transient voltage overloads in the reverse direction. The conversion loss is about 6 to 8 db.

References to silicon detectors : 82, 83.

(iv) Theory of crystal rectification

The modern theory of crystal rectification is given in Ref. 83 : See also Ref. 79.

(v) Transistors

Transistors are crystal devices with three or more electrodes, which are capable of amplifying. A good introductory article is Ref. 86. See also Refs. 87, 88, 89, 90, 91, 92, 93, 94, 95, 96.

SECTION 1 : GENERAL DESCRIPTION

(i) *Description* (ii) *Advantages and disadvantages of reflex receivers.*

(i) Description

A reflex amplifier is one which is used to amplify at two frequencies—usually intermediate and audio frequencies.

Reflex radio and audio frequency stages have also been used in very small T.R.F. receivers (see Sect. 5).

Reflex receivers were fairly common in U.S.A. and Australia in the period 1934 to 1937, but suffered from serious distortion and high play-through. These receivers usually had high a-f plate load resistors giving comparatively high a-f gain, low i-f gain and low operating plate voltages and currents. A.V.C. was not applied to the reflex stage which was frequently a sharp-cut-off valve such as the 6B7 or 6B8. A considerable advance was made in Australia by the use of the remote cut-off type 6G8-G with a.v.c., and a further advance was made in the adoption of a comparatively low a-f plate load resistor. The latter enabled nearly full i-f gain to be obtained with normal voltages on the electrodes, thus increasing the maximum plate voltage swing for a limited distortion. The most common application of a reflex amplifier in Australia* at the present time is in a 3/4 valve receiver comprising converter, reflex stage, power amplifier and rectifier. The reflex stage in such a receiver amplifies at intermediate frequency, provides detection and a.v.c. from its diode or diodes, and then amplifies at audio frequency. It may be compared with a straight receiver in which the second valve is used as i-f amplifier and detector, the output from the detector being used to excite the power stage. Using the same valves and components in both cases, the reflex receiver may have a sensitivity up to 10 times that of the straight set.

(ii) Advantages and disadvantages of reflex receivers

Advantages of the reflex receiver

1. Higher sensitivity.
2. Greater flexibility in design, permitting use of negative feedback either with or without tone compensation (bass boosting) for small cabinets.

*Reflex receivers do not appear to be in commercial use in either U.S.A. or Great Britain at the time of writing.

Disadvantages of the reflex receiver

1. Increased cost due to additional components.
2. Increased tendency to overload on strong signals.
3. More complicated design, although once a satisfactory design has been evolved there are no outstanding production difficulties.
4. Somewhat increased distortion at high modulation percentages at medium and high input levels than for a well-designed straight receiver, although both are still in the same class.
5. Play-through—that is the occurrence of a-f output with the volume control at its zero setting. This leads to a further defect known as the “minimum volume effect” whereby minimum volume from the receiver is obtained with the volume control at some setting slightly above zero setting. At the point of minimum volume the signal is very badly distorted since there is a balancing-out of the fundamentals between the normal signal and the out-of-phase play-through signal. Both play-through and the minimum volume effect may be reduced by good design so as not to be objectionable. See Sects. 2, 3 and 4. Perhaps a fairer comparison is between a 3/4* valve reflex receiver and a 4/5 valve straight set. In this case the reflex receiver will be more economical to produce, through the saving of one valve, while there will be a slight saving in space, heat dissipation and current consumption. The 4/5 receiver is capable of being designed to have negligible play-through and may have slightly greater sensitivity.

The design of reflex receivers must necessarily be a compromise, with juggling of inter-acting characteristics. However, by reflexing it is possible to achieve an acceptable performance which would not otherwise be obtainable with the same number of valves. The fact that reflex receivers form a substantial percentage of the Australian market for 3/4 valve sets indicates that their performance is acceptable.

On account of the complicated inter-action which occurs in a reflex receiver, it is impossible to design the reflex stage alone; the whole receiver must be treated as a single design unit. If any change is subsequently made in any other stage, it is usually necessary to make consequential modifications to the reflex stage for the best results.

So far as sensitivity is concerned, a straight 3/4 receiver using modern valves can give 15 μ V broadcast sensitivity†, and 30 μ V short-wave sensitivity†, which for most applications is adequate. Nevertheless the higher a-f gain of the reflex receiver removes the problem, which is experienced with straight 3/4 sets, of preventing the a.v.c. from limiting the a-f output before the output valve is fully loaded.

The advantages to be obtained at audio frequencies from reflexing a 3/4 valve receiver are considerable. A straight 3/4 valve set without an a-f stage almost invariably suffers from “bubbling” at high a-f outputs on strong signals, and to prevent this the low frequencies are reduced as much as possible without making the reproduction too thin. With the additional stage of a-f amplification provided by reflexing, the regenerative effect which causes bubbling becomes degenerative, and the bass can be boosted to any desired extent without bubbling being experienced.

In addition it is not possible in straight 3/4 valve sets to use negative feedback for any purpose other than mild frequency correction because any reduction in the mid-frequency gain of the output stage makes i-f overloading probable before the output valve is driven to full output. With reflexing an appreciable amount of the added a-f gain can be used for any desired form of negative feedback.

Reflex superhet. receivers may be divided into two principal groups, those employing plate reflexing (see Sect. 3), and those employing screen reflexing (see Sect. 4).

*A 3/4 valve receiver is one having three amplifying valves and a rectifier.

†For 50 milliwatts output.

SECTION 2 : SOME CHARACTERISTICS OF REFLEX SUPERHET. RECEIVERS

(i) *Play through (residual volume effect)* (ii) *Over-loading* (iii) *Automatic volume control* (iv) *Reduction in percentage modulation* (v) *Negative feedback* (vi) *Operating conditions of reflex stage.*

(i) Play-through (residual volume effect)

This effect has been briefly described in Sect. 1. Play-through in a reflex receiver is due to the rectification caused by the curvature of the valve dynamic characteristics. Play-through increases as the input signal is increased, and may be measured with a large signal input—preferably with a high modulation percentage and with the volume control at zero. During design it may be found that play-through increases rapidly when the signal input to the reflex stage passes some critical level. In such a case the a.v.c. system must be designed to prevent signals of this magnitude from appearing at the grid of the reflex stage. Since play-through is a function of rectification and therefore of the curvature of the characteristic, it is a variable depending on the bias. By plotting play-through for varying bias voltage on the reflex stage with a constant input signal to the reflex stage, it is possible to determine the range of a.v.c. voltages which may be applied to the stage without resulting in serious play-through. This may entail using only a small fraction of the developed a.v.c. voltage on the reflex stage.

(ii) Overloading

It is practicable to design a reflex receiver to handle input voltages up to 1 volt without serious distortion (of the order of 10% at 100% modulation).

(iii) Automatic volume control

The a.v.c. system should be designed so that high peak i-f plus a-f voltages are not built-up in the plate circuit of the reflex stage. There are three principal a.v.c. systems in use :

1. Full a.v.c. applied to both converter and reflex stages.
2. Fractional a.v.c. applied to both stages, although the two fractions may be different.
3. Full a.v.c. is applied to the converter and fractional a.v.c. to the reflex stage.

The choice of converter valve has considerable bearing on the a.v.c. design. The use of a converter with a not-too-remote cut-off (e.g. 6BE6) assists in the reduction of play-through by limiting the maximum signal voltage applied to the grid of the reflex stage.

If the fraction of the a.v.c. applied to the reflex stage is reduced too much, or omitted entirely, the reflex stage may run into grid current and cause "bubbling" with the volume control at maximum because the rectified a-f signal returned to the grid from the plate of the reflex stage may exceed the bias on the valve. If the fraction of a.v.c. applied to the reflex stage is increased too much, the a.v.c. characteristic will tend to reach a maximum output and then to fall with increasing input voltages. The worst effect of excessive control is the inability of a receiver to give full a-f output on strong stations even with the volume control at maximum. Also, in such a case the effect of tuning to a powerful signal is to produce less output when the receiver is tuned directly to the carrier than when it is tuned to one side, so that there are two adjacent tuning positions of maximum volume. A further effect of too large a fraction of a.v.c. voltage is the increase in play-through referred to above.

As a criterion of good a.v.c. design, the volume control should be approaching its maximum position for maximum undistorted a-f output at any signal level. The minimum volume effect may be reduced by using a tone control which gives severe treble attenuation.

(iv) Reduction in percentage modulation

With a large signal input and with the volume control at maximum, a reduction in the percentage of modulation occurs due to the curvature of the characteristics. Under laboratory conditions this can be quite considerable, for example 30% modulation may be reduced to 10%, but it is usually unimportant with ordinary listening because it only occurs under conditions which would also cause overloading of the power stage. However, where a Scroggie-type of a.v.c. characteristic indicates serious a-f overloading with the volume control at maximum, the actual overloading with a strong input signal may be appreciably less than that indicated, owing to the reduction in percentage modulation.

(v) Negative feedback

If full a.v.c. is applied to the reflex valve, a strong signal will then reduce the a-f gain, which in turn will reduce the a-f feedback, if any. Under these conditions feedback is available on weak signals where it is not needed, but it is very much reduced on strong signals where it is most needed. As a consequence, negative feedback is only practicable with a small fraction of the a.v.c. voltage on the reflex stage.

Negative feedback, in addition to its use for the reduction of distortion and for tone compensation, also assists very considerably in the reduction of play-through (e.g. Fig. 28.3).

(vi) Operating conditions of reflex stage

The reflex stage should be biased, with a very small signal, to give maximum gain unless this bias is insufficient to prevent the valve from drawing grid current due to a-f signals in excess of the bias voltage being applied to the control grid at input signals such that the a.v.c. has not yet become fully effective.

Adequate r-f filtering of the demodulated signal is necessary before returning it to the grid of the same valve again, to avoid regeneration or actual i-f oscillation.

SECTION 3 : DESIGN OF PLATE REFLEX SUPERHET. RECEIVERS

(i) *General considerations* (ii) *Full a.v.c. applied to both stages* (iii) *Fractional a.v.c. applied to both stages* (iv) *Full a.v.c. on converter, fractional a.v.c. on reflex stage.*

(i) General considerations

The majority of reflex receivers are in this class. Plate reflexing is less critical in relation to valve operating point and less critical so far as design is concerned. However, under some conditions, screen reflexing will give less play-through. With high i-f gain in any receiver it is difficult to eliminate regeneration entirely without some filtering, but in a plate reflex receiver i-f decoupling is an inherent feature due to the plate circuit components, and no other i-f filtering is necessary.

(ii) Full a.v.c. applied to both stages

With suitable valve types, this very simple system is capable of handling an input of 1 volt (30% modulated) with distortion as low as can be obtained from any other a.v.c. arrangement. Current designs of reflex receivers employing this a.v.c. arrangement have fairly high play-through but this may be due to factors other than the a.v.c. system.

(iii) Fractional a.v.c. applied to both stages

A typical example is Fig. 28.1 in which a large fraction of the a.v.c. voltage is applied to the converter stage and a small fraction to the reflex stage. As a result of reduced a.v.c. voltage on the reflex stage, the play-through is considerably reduced.

(iv) Full a.v.c. on converter, fractional a.v.c. on reflex stage

An example of a receiver in this class is Fig. 28.2 in which one ninth of the a.v.c. voltage is applied to the reflex stage. The receiver has a sensitivity of $40 \mu\text{V}$ (for 50 mW output), the comparatively low sensitivity being due principally to the use of low Q i-f transformers. It is capable of handling an input up to 1 volt with complete stability under all conditions, and has several interesting features. The plate load

resistor was selected to provide optimum operation together with minimum hum ; a certain amount of hum neutralization is possible between the reflex (a-f) and power amplifier stages. Feedback in the reflex stage is neutralized by the very small fixed capacitances C_{Y1} and C_{Y2} , while a small degree of negative feedback is provided on the output stage.

Considerably improved performance is obtainable by the use of type 6AR7-GT in the reflex stage, together with high Q i-f transformers. This avoids the necessity for neutralization and gives higher gain. Still higher gain is obtainable with a high-slope output valve, although the play-through is increased thereby. This circuit arrangement has considerable merits and there are prospects that, by suitable choice of valve types and a.v.c. design, the play-through may be reduced to a low level.

A possible alternative form of the circuit would be to use type 6BE6 converter, 6BA6 reflex amplifier and a duo-diode-output pentode.

SECTION 4 : DESIGN OF SCREEN REFLEX SUPERHET. RECEIVERS

(i) Screen reflex receivers (ii) Comparison between plate and screen reflexing.

(i) Screen reflex receivers

In a screen reflex receiver the screen of the reflex stage is by-passed to earth for intermediate frequencies only, and the screen is coupled to the grid of the power stage for audio frequencies. For the same number of components and the same economy, screen reflexing permits the use of separate screen dropping resistors for the converter and reflex stages, thus giving greater flexibility in design and less interaction. The play-through is less than with plate reflexing and may be made quite small with the application of negative feedback. It is necessary for the diode-screen capacitance to be low, and in this respect the Australian type 6AR7-GT is satisfactory. The screen dropping resistor and grid bias must be designed for optimum i-f gain ; in the 6AR7-GT this also provides satisfactory a-f gain. Screen reflexing requires good hum filtering.

With screen reflexing, careful design is necessary for optimum results to be obtained. An example of a well designed screen reflex receiver is Fig. 28.3. This has been designed for high sensitivity with reasonably low distortion and low play-

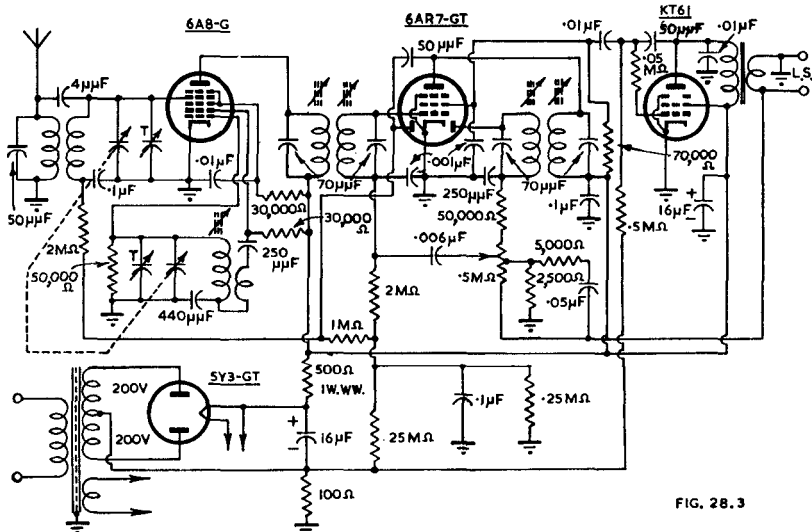

FIG. 28.3

Fig. 28.3. Reflex superhet. receiver with screen reflexing (Ref. 4).

through. The aerial sensitivity is approximately $5 \mu\text{V}$ for 50 mW output, and the signal to noise ratio is 10 to 13.5 db at $5 \mu\text{V}$ input. The distortion is 6.9% with an input of 1 volt, 30% modulated, but 12% with an input of 0.5 volt, 100% modulated. An output of 0.5 watt is obtained with $20 \mu\text{V}$ input, 30% modulated. With an input of 1 millivolt to the aerial terminal, 30% modulated at 400 c/s, an output of 2 watts is obtained with 10% overall distortion.

Feedback is applied by returning the lower end of the volume control to the voice coil. Maximum bass boosting is provided when the volume control is at the tap, which is adjusted for the lowest listening level. The high frequency peak and bass boosting are reduced as the volume control setting is increased towards maximum. The response above 5000 c/s is cut sharply by a combination of shunt capacitances together with negative feedback. The overall result is an automatic high frequency tone control which gives a "mellow" tone with weak signals and a normal radio tone on strong stations. The gain reduction due to feedback is 14 db with 1 mV signal input and with the volume control at its minimum position. The gain reduction decreases as the volume control is advanced.

The conventional i-f filter in a reflex circuit is a series resistor from the volume control slider, connected to a by-pass capacitor at the cold end of the first i-f transformer secondary. These two components give phase shift at some high frequency with the volume control at its minimum setting, additional to the phase shifts already in the circuit and may thus cause oscillation when heavy feedback is applied with the volume control at zero. However if the resistor is wired in series with the hot end of the volume control, as in Fig. 28.3, with the volume control at its zero setting there is no series resistor in the feedback path, phase shift is reduced and high frequency peaks (or oscillation) are avoided.

Resistance-capacitance filtering is used here for economy. The plate supply voltage is 185 volts. One ninth of the a.v.c. voltage is applied to the reflex stage. The play-through is as low as in some commercial receivers that do not use reflexing.

(ii) Comparison between plate and screen reflexing

Plate reflexing is capable of higher a-f gain than screen reflexing, since the latter is limited by the "triode μ " of the reflex valve. For this reason, types 6AR7-GT and 6BA6 with grid-to-screen μ factors of 18 and 20 respectively are quite suitable for use in screen reflex receivers. However, plate reflexing gives more play-through than screen reflexing for similar conditions in both cases.

Type 6AR7-GT as a screen reflex amplifier allows a higher gain in the output stage than a lower gain valve (e.g. 6G8-G) with plate reflexing, for the same play-through performance in both cases, and similar converter conditions.

SECTION 5 : DESIGN OF T.R.F. REFLEX RECEIVERS

In such a receiver the r-f amplifier is reflexed and used also as an a-f amplifier. The only application at the time of writing is to 2/3 valve receivers having a diode-pentode as a reflexed r-f, a-f amplifier and diode detector, followed by a power pentode (e.g. 6AR7, KT61). A sensitivity of the order of $1000 \mu\text{V}$ (for 50 mW output) is practicable. A limited degree of regeneration assists gain and selectivity.

SECTION 1 : LIMITERS

(i) *General* (ii) *Typical circuits for F-M receivers* (a) *Single stage limiter* (b) *Cascaded limiters.*

(i) General

In this section it is proposed to discuss only the conventional type of amplitude limiter using a pentode valve operating as a saturated amplifier. Other circuits, which combine the dual functions of detection and the removal of amplitude variations, such as the ratio detector and locked oscillator, will not be treated here. The ratio detector has been discussed in detail in Chapter 27 Sect. 2. Details of several other alternative systems can be found in Refs. 2, 5, 6, 7 and those at the end of Chapter 27.

The need for some form of amplitude limiting was stressed in Chapter 27 Sect. 2, when the phase discriminator was being discussed. It was pointed out that the diodes in a phase discriminator are amplitude modulation detectors, and if undesired amplitude variations are not to appear in the receiver output the amplitude of the voltage applied to the discriminator should be constant. This was emphasised by reference to eqns. (20) and (21), where it was seen that the product $g_m E_g$ should be held constant if the discriminator sensitivity is to remain fixed for a given frequency deviation.

Circuit arrangements for limiters in F-M broadcast receivers have become quite stereotyped. Sharp cut-off pentodes having fairly high values of g_m are the usual choice, and typical of these are types 6SJ7, 6SH7 and 6AU6. The limiting action is brought about by a combination of grid-leak bias and low values of plate and screen voltage. Grid-bias limiting is obtained by adding a resistor and capacitor, of suitable value, to the grid circuit and using zero or very small values of cathode bias. The grid circuit arrangement is the same as for a grid-leak detector, and the operation is almost identical since the average negative bias on the grid is determined by the $e_g - i_g$ characteristics of the valve in conjunction with the associated circuit. The value of the average grid bias, together with the low screen voltage, determine the condition for which plate current cut-off occurs. Any signal input voltage whose amplitude is sufficiently large will cause the average negative bias to increase and so tend to hold the output voltage constant. Because of the low values of plate and screen voltage the plate voltage swing is limited to a comparatively small value and, for an input signal of sufficient magnitude, there will be practically no corresponding increase in output voltage when the signal input voltage is increased.

The added damping on the i-f transformer secondary, which connects to the limiter grid, is given approximately by $R_g/2$ or $R_g/3$, depending on the circuit arrangement, in exactly the same way as discussed previously for a diode detector; R_g being the value of resistance selected for the grid leak. This should be taken into account (as

well as circuit detuning caused by changes in the valve input capacitance) when the i-f transformer is being designed.

The necessity for high gain in the receiver stages preceding the limiter stage will be appreciated when it is realized that a minimum of about 2 volts peak is required at the limiter grid to obtain satisfactory operation with a typical circuit arrangement; it is preferable to have voltages of the order of 10 to 20 volts peak for best results under adverse condition of reception. Since this limiter input voltage must be obtained with the smallest signal input voltage likely to be met in the field, the gain of the preceding stages in the receiver should be sufficient to give satisfactory limiter operation with signal voltages as low as 2 or 3 μV ; in F-M mobile communications applications the limiter should saturate with signals of less than 1 μV . Also, because the conversion from F-M to A-M in the discriminator usually results in a low equivalent value of percentage amplitude modulation, it is necessary for the limiter output voltage to be large if the detected audio voltage is to be sufficient to drive the audio amplifier to full output; this means that something in excess of 10 volts peak is desirable at the plate circuit of the limiter.

For completely satisfactory amplitude limitation two limiter stages are necessary. However, because of the cost factor, commercial domestic type receivers seldom use more than one limiter stage. When two stages of limiting are used, it is essential that the coupling circuit between them should not introduce any appreciable amplitude modulation due to its selectivity characteristic. The selectivity should be sufficient to attenuate harmonics of the intermediate frequency generated by the limiter, although this is also accomplished by the primary of the discriminator transformer; with single stage limiters the discriminator transformer is relied upon to give the necessary attenuation of the i-f harmonics. Transformer coupling between the two limiter valves is the most satisfactory arrangement, but single tuned circuits are often used.

The choice of the time constant for the grid resistance-capacitance combination is important. It must be sufficiently short for the grid bias to be proportional to changes in amplitude, but not so short as to prevent the bias change from being sufficiently large to control the amplification of the limiter stage, so as to offset any change in signal input voltage. For a single stage, limiter time constants of 2.5 microseconds are usual, although 10 to 20 microseconds and even higher have been used in some receivers. For two stages the first limiter grid circuit uses a time constant of 1.25 to 5 microseconds and 2.5 to 10 microseconds or longer in the second stage, in typical cases. The longer time constants of 10 to 20 microseconds are suitable for most types of noise impulses, but some forms of motor car ignition noise are more completely suppressed when the shorter time constants are used. A careful choice of the time constants is necessary if the noise is not to be heard in the receiver output because the bias on the limiter valve must be able to follow the changes in the amplitude of the input voltage.

No matter how effective the amplitude limiters may be and how carefully their time constants are chosen it will often be found that the F-M receiver will not effectively suppress bursts of noise such as those emitted by car ignition systems. To obtain the best results it is most important that the pass band of the receiver be symmetrical and that the centre frequency of the i-f amplifier coincides exactly with the centre frequency of the discriminator. A useful test is to align the receiver on an unmodulated carrier at the signal frequency and then to switch off the carrier; if the alignment is correct, and the circuits symmetrical, a d.c. vacuum tube voltmeter connected across the discriminator output will give a reading of approximately zero (of course the usual noise will be heard from the receiver output). Small inaccuracies often arise when the receiver is aligned so as to give maximum grid current at the limiter stage, or stages, even though the signal (unmodulated carrier) frequency is such that zero d.c. output voltage is obtained from the discriminator. The grid current reading is usually rather broad, and it will be found that the i-f and limiter circuits, in particular, can often be realigned to give zero d.c. output voltage at the discriminator on noise without reducing the limiter grid current on signals. As a

further check on alignment and symmetry the receiver is tuned very carefully to an unmodulated carrier so that the a.c. voltage at the output transformer is a minimum (i.e. for maximum quieting) and for this condition the reading of the d.c. voltmeter at the discriminator is noted; then it will usually be found that this latter reading is the same as that obtained from noise alone. (A casual reading of the text may not bring out the full significance of this test, but a practical trial will lead to a better appreciation of its possibilities). If minimum noise output, zero d.c. discriminator output voltage, and maximum limiter grid current do not all occur at the same carrier frequency, then in general the optimum conditions for impulse noise rejection have not been obtained.

For applications other than domestic receivers the above factors require very careful attention.

(ii) Typical circuits for F-M receivers

(a) Single stage limiter

A typical single stage limiter is shown in Fig. 29.1, and an alternative arrangement is shown for the input circuit in Fig. 29.2. The time constant for $R_g C_g$ is 2.5 microseconds in each case.

FIG. 29.1

FIG. 29.2

The operation of both circuits is identical, but the damping of the i-f transformer due to grid current is less with the arrangement of Fig. 29.1, being approximately $50\,000/2 = 25\,000$ ohms. The damping in the alternative arrangement is $50\,000/3 = 16\,600$ ohms. Whichever circuit is used will depend, largely, on the additional damping required on the transformer to achieve the required bandwidth or, perhaps, upon considerations of practical convenience. The general method of operation has been discussed in (i) above.

If complete valve characteristics are available then a preliminary design can be made, but the work involved is hardly worth the effort because of the ease with which the practical circuit can be made to give satisfactory results using experimental procedures. For a calculation of gain, or overall discriminator sensitivity, it is necessary to determine the mutual conductance under the actual operating conditions. This can usually be determined, with sufficient accuracy for a preliminary design, from the valve data sheets by ignoring the change in plate voltage (provided the change in plate current with plate voltage does not fall too far down on the knee of the plate characteristics). For example, a type 6AU6 is to be operated with 50 volts on the plate and screen, and zero grid bias. From the average characteristics relating grid No. 1 volts to transconductance, the g_m is 4000 micromhos for zero bias, 50 volts on the screen and 250 volts on the plate. For typical cases of the type being considered, the g_m so found is usually about 10% high, and so 3600 micromhos would be a closer approximation. Alternatively, the valve can be set up as a straight amplifier with the appropriate d.c. voltages applied, and a 1000 ohm resistor connected as the plate load. Then with 1 volt of a-f input (from a source of low d.c. resistance) the output voltage will equal the g_m in mA/volt; the actual input voltage is selected so that the stage just starts to saturate. However, overall measurements of actual circuit performance are preferable.

FIG. 29.3

(b) Cascaded limiters

A typical circuit for a two stage (cascaded) limiter is shown in Fig. 29.3. In this case the time constant of the grid resistance-capacitance combination is 1.25 micro-seconds for the first stage, and 20 microseconds for the second stage.

It should be noted that the limiters not only have to remove peaks of noise, but they must also remove the amplitude modulation introduced onto the frequency modulated signal by the receiver circuits which precede the limiters. Methods for estimating the percentage amplitude modulation introduced by tuned circuits are given in Chapter 26 Sect. 4. It will be realized that A-M introduced by the receiver itself makes it more difficult to effectively remove A-M introduced by external noise voltage sources.

For the transformer *T*, shown in Fig. 29.3, coupling the two limiter stages, it is essential that the amplitude modulation introduced by its selectivity characteristic should be as small as possible. However, its selectivity characteristic is helpful in removing harmonics of the i-f generated by the limiter, and so a practical compromise between the two conflicting factors is necessary. A critically-coupled transformer is recommended, and the primary and secondary *Q*'s (uncoupled) can be about 30 for an i-f of 10.7 Mc/s. The stage gain will be roughly 6 times depending on the circuit constants selected, and the magnitude of the input voltage.

From the circuit arrangements of Figs. 29.1 and 29.3 it will be noticed that the screen voltage is supplied from a voltage divider in each case. This arrangement is recommended in all cases, but in mobile communications receivers it will be found that many circuits use only a series screen resistor; the main advantage of this latter arrangement is economy in the total H.T. current drawn by the receiver.

SECTION 2 : AUTOMATIC FREQUENCY CONTROL

(i) General principles (ii) Discriminators for a.f.c. (iii) Electronic reactances.

(i) General principles

Although the description given below of automatic frequency control (a.f.c.) systems is confined to simple applications in broadcast receivers, it should not be overlooked that the same general principles are applied in many other types of equipment and are used, for example, to obtain frequency stabilization in F-M transmitters, micro-wave radar receivers and transmitters etc.

Automatic frequency control in a superheterodyne radio receiver is an arrangement for controlling the local oscillator frequency in such a way that, when a signal is being received the correct intermediate frequency will be produced. For example, if a receiver is manually tuned so that it is, say, 3 Kc/s away from a desired signal the oscillator frequency will be varied by the a.f.c. system so as to produce the correct intermediate frequency (or at least within 100 c/s or so of the correct value, since exact compensation is not possible). Alternatively, the oscillator frequency may drift because of temperature or humidity variations affecting the values of the circuit components, and a.f.c. will tend to compensate for this frequency variation. However, the frequency stability of the receiver should be made as good as possible without relying on the a.f.c. system.

The most useful application of the system in broadcast receivers is with those receivers having automatic tuning e.g. push-button station selection, and cam or motor driven variable capacitors. In cases of this type the tuning may not be accurate over extended periods of time, and a.f.c. may be used effectively to carry out the final adjustment when the respective capacitances and/or inductances have been selected by the automatic tuning system.

There are two devices necessary for any a.f.c. system. These are:—

- (1) A frequency discriminator, which must be capable of changing a frequency variation into a suitable direct voltage change which can be used for control purposes.
- (2) A variable reactance, whose value can be controlled by the direct voltage changes due to the frequency discriminator. The variable reactance is connected to the oscillator circuit in such a way as to control its frequency.

FIG. 29.4

The complete arrangement can be visualized with the aid of the block schematic of Fig. 29.4. It is seen that the additional elements to those normally found in a superheterodyne receiver are the frequency discriminator and the variable reactance. The variable reactance in the discussion to follow will be of the electronic type consisting of a valve (which can be a pentode, a hexode or a heptode) and its associated circuits. It will also be inferred from Fig. 29.4 that the frequency discriminator can be used for normal detection, since there are suitable audio voltages developed in this circuit by the applied modulated i.f. voltage.

Suitable voltages for a.v.c. are also available from the discriminator output, but in this regard it is necessary to point out that a very efficient a.v.c. system is helpful in obtaining satisfactory operation from the a.f.c. system. If reasonably constant input voltage to the discriminator is not maintained, there will be a variation in the "pull-in" and "throw-out" frequencies. Because of the stringent a.v.c. requirements it is fairly common practice to employ a separate diode coupled to the transformer primary, in the usual manner, to provide the a.v.c. bias voltage. There is also a disadvantage in taking the a-f voltage from the discriminator output as the distortion tends to be fairly high. However, in most commercial receivers the cost factor leads to some arrangement such as that of Fig. 29.8.

FIG. 29.5

A much more satisfactory method (although considerably more expensive) of obtaining a.f.c. is illustrated by the block schematic of Fig. 29.5. In this case the valve used as an a.f.c. converter and limiter is loosely coupled to the primary of the last i-f transformer. The 455 Kc/s signal is converted to 50 Kc/s to operate the a.f.c. discriminator, and the d.c. output voltage then controls the variable reactance in the usual manner. The use of limiting is helpful in maintaining a constant amplitude for the voltage to be applied to the discriminator. It will also be noticed that the functions of detection and a.v.c. have been separated from the a.f.c. system. A complete circuit using this arrangement can be found in Ref. 15 (page 103), together with a number of other commercial a.f.c. circuits of various types.

(ii) Discriminators for a.f.c.

The function of the frequency discriminator in an automatic frequency control system is to provide a suitable direct controlling voltage for application to the electronic reactance. When the receiver is tuned exactly to the signal frequency, the voltage output from the discriminator should be zero, or else have the same value as that provided in the absence of a signal, so that the controlled reactance will have its normal value. At frequencies above and below the correct frequency the controlling voltage should be appropriately above and below the mean voltage. The operation in connection with a phase discriminator has been discussed in Chapter 27 Sect. 2. The manner in which the output voltage will vary with the frequency change for either the amplitude or the phase discriminator can be seen from Fig. 29.6.

FIG. 29.6

The polarity of the output voltage with frequency change is all important, and, as the electronic reactance is practically always inductive in a.f.c. systems used in tunable broadcast radio receivers, the polarities of the direct output voltage with frequency change as indicated on Fig. 29.6 will be correct. One purpose in making the reactance inductive is so as not to limit the frequency coverage of the receiver. This follows because it is often difficult to keep the minimum capacitance of the tuning unit to a sufficiently low value, and it is hardly wise to deliberately increase this capacitance unnecessarily. However, if carefully designed, the undesired added capacitance due to the capacitive reactance unit can be made very small.

The effect of the added parallel inductance can usually be offset fairly readily by increasing the inductance of the oscillator coil. With receivers using push-button tuning where the circuits are of the preset type either the inductive or capacitive form of electronic reactance is satisfactory. For receivers with inductance tuning a capacitive electronic reactance is usually preferable. The degree of frequency correction is not constant over a band of frequencies, and this again suggests an inductive electronic reactance when the circuits are tuned by a variable capacitor, since the least error is obtained at the low frequency end of the tuning range where the receiver is most selective.

It may be helpful to follow through the steps leading to the polarities shown for the direct voltage with frequency change. Suppose the receiver is tuned to a signal of 1500 Kc/s. Then the oscillator will be set at 1955 Kc/s to give an i-f of 455 Kc/s, and there will be no direct voltage output from the discriminator. If now the oscillator drifts to 1957 Kc/s the i-f produced will be 457 Kc/s, and a direct voltage of negative polarity will be produced by the discriminator and applied to the reactance valve. The equivalent inductance of the electronic reactance is inversely proportional to mutual conductance (g_m) and so, as a more negative bias voltage reduces g_m , the

shunt inductance across the oscillator coil is increased, thus lowering the oscillator frequency as required.

The two most commonly used types of discriminator circuits are shown in Figs. 29.7 and 29.8. The first is generally known as the Round-Travis circuit (see Ref. 10), and is a typical example of an amplitude discriminator. The secondary circuits A and B are so tuned that A has its resonant frequency slightly above the intermediate frequency and B is set slightly below the i-f (say +5 Kc/s in one case and -5 Kc/s in the other). Each secondary circuit has its own diode detector and the diode loads are connected in d.c. opposition, so that when the i-f is greater than the required value of 455 Kc/s (and since the voltages developed across R_1 and R_2 have the polarities shown) the voltage across R_1 is greater than that across R_2 and the a.f.c. bias voltage is negative as is required for correction of the oscillator frequency. For example, the voltage across R_1 may be 4 volts when that across R_2 is 3 volts, then the available a.f.c. bias is -1 volt.

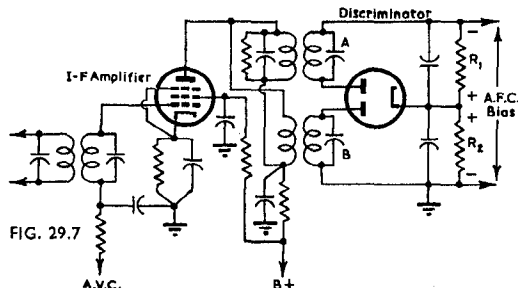

FIG. 29.7

The design procedure for an amplitude discriminator for a.f.c. is set out in detail in Ref. 8. Since this type of circuit is seldom used in modern a.f.c. systems the details of its operation will not be discussed further. There are a number of alternative arrangements for the amplitude discriminator, and some of these are discussed in Refs. 8, 9, 11, 15 and 13. It will be appreciated that a circuit of this type could be used for F-M detection as an alternative to the phase discriminator, and several manufacturers have produced F-M receivers using modified amplitude discriminators (see Ref. 39 given at end of Chapter 27, for typical examples).

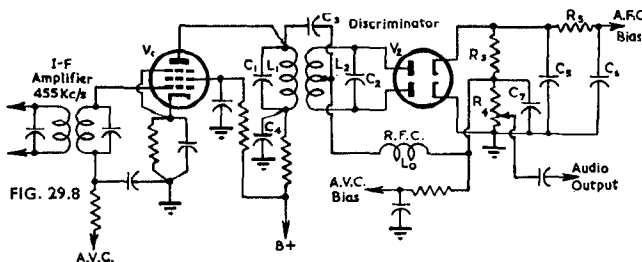

FIG. 29.8

Fig. 29.8 shows the most commonly used circuit, the phase (or Foster-Seeley) discriminator. In this circuit both primary and secondary circuits are tuned to the intermediate frequency. It will be seen that the circuit arrangement is identical with that of the F-M phase discriminator shown in Fig. 27.19, and the general discussion of its operation and the loading effects on the transformer apply equally well here. The de-emphasis circuit is not required here, of course, but the same general arrangements can be retained to provide r-f and a-f filtering, since only a direct control voltage is required. Suitable values for the filter circuit are R_s equal to 0.5 - 2 M Ω , and C_s is, say, 0.05 - 0.1 μ F. The considerations governing the choice of the component values can be compared with those for selecting filter components for auto-

matic volume control circuits, and a time constant for $R_5 C_6$ of about 0.1 second is usual. The circuit arrangement of Fig. 27.17 could also be used here, and, if the primary circuit is too heavily damped, an additional series resistor can be inserted between the transformer centre-tap and the junction of the diode load resistors R_3 and R_4 ; however, this will lead to some loss in available output voltage, depending on the value of series resistance selected. The difference in the by-pass capacitor arrangements (i.e. C_5 and C_7) for Figs. 27.17 and 27.19 (or Fig. 29.8) should be observed, and the discussion in Chapter 27 Sect. 2, in connection with Fig. 27.19 will be helpful, if the reasons for the arrangements are not immediately obvious. The considerations leading to the choice of actual circuit values will differ because the a.f.c. discriminator is usually designed for high sensitivity rather than for a very high degree of linearity.

The theory of the circuit for a.f.c. use has been discussed by Roder (Ref. 14) and design procedures have been treated in detail in Ref. 8. A brief discussion, which is quite helpful, is given in Ref. 13.

The method of obtaining a-f output and a.v.c. bias from the a.f.c. discriminator circuit is also shown in Fig. 29.8. To retain the same degree of selectivity as that obtained with a similar receiver not incorporating a.f.c. one extra tuned circuit is required. This is necessary because the discriminator provides very little selectivity as a result of the heavy loading effects produced by the diodes. There is some increase in gain over the usual arrangement where the a-f detector is connected across the i-f transformer secondary only.

The frequency at which the a.f.c. will come into operation when tuning a signal is called the "pull-in frequency." When tuning away from a carrier the frequency at which the a.f.c. loses control is called the "throw-out frequency," and it is always greater than the "pull-in frequency." It is desirable to make these two frequencies as close as possible, because stations which are received when tuning-in may be passed over when tuning-out. Many receivers incorporate arrangements for disconnecting the a.f.c. until a carrier has been approximately tuned-in (see Refs. 8, 15).

Some of the general details of the discriminator design will be set out here, and the reader is referred to Refs. 8, 9 and 14, in particular, for further information. Consider Fig. 29.8. Typical values for R_3 and R_4 are 0.5 M Ω . Capacitors C_5 and C_7 must give adequate by-passing at the intermediate frequency of 455 Kc/s, and suitable values would be 100 to 200 μ F. C_3 is usually 100 μ F. Values for R_5 and C_6 have been discussed previously. The valve V_1 is any of the usual voltage amplifier pentodes such as type 6SK7 etc., and V_2 is a double diode such as the types 6H6 or 6AL5. The next step is to select a suitable value for the inductance of the r-f choke.

FIG. 29.9

As the inductance and capacitance of the choke will affect the resonant frequency of the transformer primary ($L_1 C_1$) and its Q , care is necessary. The choke, in association with the transformer primary circuit, can be represented by the equivalent circuit of Fig. 29.9 in which $g_m e_g$ represents the equivalent constant current generator for the pentode voltage amplifier; r_p is the plate resistance; C_1 is the total primary capacitance including strays; L_1 is the primary inductance and R_1 its r-f resistance; C_3 is the capacitor connecting the plate circuit to the choke L_0 (whose r-f resistance is R_0); C_0 represents any distributed or stray capacitances across L_0 ; $R_{dc} = R_3 = R_4$ the diode load resistance. It should be apparent that three cases can arise with the choke (Ref. 14):—

- (1) The capacitance C_0 negligibly small.
- (2) The capacitance C_0 small enough to still allow the choke to be self resonant well above the intermediate frequency, but the value of C_0 to be such as to appreciably affect the resonant frequency of the complete primary circuit.

(3) The choke resonant at the intermediate frequency.

It follows from (1) and (2) that L_1 and C_1 should have a resultant capacitive reactance at the intermediate frequency, and in case (3) L_1 and C_1 should be resonant at the intermediate frequency.

Considering the above three cases in conjunction with Figs. 29.9 and 29.8, it can be seen that the derivation of the conditions for discriminator transformer primary resonance, voltage step down between the transformer primary and the choke, and the resultant Q 's for the complete discriminator transformer, will follow fairly readily. The derivations are available in Ref. 14, and the results, which are good approximations, are summarized below (with some modifications, as well as changes in notation).

Case (1) (Choke capacitance C_0 negligibly small).

Condition for primary circuit resonance,

$$\frac{X_{L_0} - X_{C_3}}{X_{L_1}} = \frac{X_{C_1}}{X_{L_1} - X_{C_1}} \quad (1)$$

Voltage step down,

$$\alpha = 1 - \frac{X_{C_3}}{X_{L_0}} \quad (2)$$

Reciprocal of equivalent primary circuit Q (this leads to simpler numerical evaluation),

$$\frac{1}{Q_p} = \frac{1}{Q_0} + \frac{X_{L_0}}{R_{de}/4} + \alpha^2 X_{L_0} \left(\frac{1}{Q_1 X_{L_1}} + \frac{1}{r_p} \right) \quad (3)$$

Secondary circuit Q (since the diode loading is R_{de}) is

$$Q_s = \frac{Q_2 R_{de}}{Q_2 X_2 + R_{de}} \quad (4)$$

and this equation applies for the three cases—

where $X_{L_0} = \omega_0 L_0$ = inductive reactance of choke L_0

$X_{C_3} = 1/\omega_0 C_3$ = capacitive reactance of C_3

$X_{L_1} = \omega_0 L_1$ = inductive reactance of L_1

$X_{C_1} = 1/\omega_0 C_1$ = capacitive reactance of C_1

$\omega_0 = 2\pi \times$ intermediate frequency

Q_0 = magnification factor of choke L_0

Q_1 = magnification factor of L_1

$R_{de} = R_3 = R_4$ = diode load resistance value

r_p = plate resistance of voltage amplifier valve

Q_2 = magnification factor of L_2

and $X_2 = \omega_0 L_2$ = inductive reactance of L_2 .

Case (2) (Choke capacitance small but not negligible).

The angular resonant frequency of the choke is

$$\omega_r = 1/\sqrt{L_0 C_0} \quad (5)$$

$$X'_{L_0} = X_{L_0} \left(\frac{\omega_r^2}{\omega_r^2 - \omega_0^2} \right) \quad (6)$$

$$Q'_0 = Q_0 \left(1 - \frac{\omega_0^2}{\omega_r^2} \right)^2 \quad (7)$$

where C_0 = distributed capacitance of the choke, and all the other symbols are exactly as before.

Equations (6) and (7) are used directly with eqns. (1), (2) and (3) substituting X'_{L_0} for X_{L_0} and Q'_0 for Q_0 .

Case (3) (Choke resonant at intermediate frequency).

The inductances L_1 and L_2 are connected in parallel, and α can be taken as unity (since X_{C_3} will be small, compared with the dynamic resistance of $L_0 C_0$), so that the equivalent primary circuit reactance required to give parallel resonance is

$$X_p = \frac{X_{L_1} X_{L_0}}{X_{L_1} + X_{L_0}} \quad (8)$$

The reciprocal of the equivalent loaded primary circuit Q is

$$\frac{1}{Q_p} = X_p \left[\frac{1}{Q_0 X_{L_0}} + \frac{1}{Q_1 X_{L_1}} + \frac{1}{r_p} + \frac{1}{R_{ac}/4} \right] \quad (9)$$

All notation exactly as for case (1).

It should be noted in all cases that the loaded Q 's refer to the case where the primary and secondary are uncoupled from one another. This is the usual definition.

We are in a position to proceed with the determination of suitable values for the primary and secondary circuits of the discriminator transformer, since all the external effects can now be taken into account. What is required next are methods for determining optimum values for Q_p , Q_s , L_p and $L_s (= L_2)$ where these factors have the meanings given by eqns. (1), (3), (4) etc. and $L_s (= L_2)$ is the secondary inductance (since its value is not changed by the presence of the choke). If the choke is not used $X_{L_1} = X_{C_1} = X_p$ and so $L_1 = L_p$; the procedure is then as for any other phase discriminator. The design factors, as well as the bandwidth and sensitivity calculations given below, apply equally well for all phase discriminators provided the values of Q , L and k (coefficient of coupling) so determined are those actually obtained in the receiver.

Optimum values for $k\sqrt{Q_p Q_s}$ for various values of L_s/L_p [see Refs. (8) and (9)] can be found from

$$k(Q_p Q_s)^{\frac{1}{2}} = \left[\frac{(Q_p^2 Q_s^2 + 2Q_p Q_s^3 L_s/L_p)^{\frac{1}{2}} - Q_p Q_s}{Q_s^2 L_s/L_p} \right]^{\frac{1}{2}} \quad (10)$$

Several values are listed below,

$L_s/L_p =$	1	2	4	6
$Q_p/Q_s = 1/2$	0.786	0.707	0.625	0.578
$Q_p/Q_s = 1$	0.856	0.785	0.707	0.657
$Q_p/Q_s = 2$	0.909	0.855	0.786	0.740

The sensitivity of the phase discriminator at the intermediate frequency (f_0) has been derived in Refs. (14) and (8). It is given by,

$$S = \frac{2g_m Q_p X_p \eta Q_s^2 (L_s/L_p)^{\frac{1}{2}}}{f_0} \left[\frac{k}{(1 + Q_p Q_s k)^2 \left(1 + \frac{Q_s^2 k^2 L_s}{4L_p}\right)^{\frac{1}{2}}} \right] \quad (11)$$

and is expressed in direct volts output per Kc/s off tune, for each 1 volt (peak) input to the i-f amplifier valve V_1 (Fig. 29.8).

The symbols are the same as those used previously, with the addition of g_m the mutual conductance of V_1 , and η is the detection efficiency of the diodes V_2 .

It is necessary to estimate the peak separation for the discriminator characteristic of Fig. 29.6. This can be found (Ref. 8) from,

$$2\Delta f = \frac{f_0}{Q_s} \tan \phi \quad (12)$$

where $\phi = \cos^{-1} \left[\frac{8}{16 + (Q_s k)^2 L_s/L_p} \right]^{\frac{1}{2}}$.

For many practical cases it will be found sufficiently accurate to take $\tan \phi = 1$ in eqn. (12).

(iii) Electronic reactances

There are a number of forms which electronic reactance circuits may take and a few of these are given below.

(1) **Resistance in series with a capacitance.** This arrangement is shown in Fig. 29.10, but since the circuit imposes severe resistive loading on the oscillator circuit its use is not advised. (See Ref. 10).

FIG. 29.10

(2) **Miller effect circuits.** These circuits (Fig. 29.11) rely on the change of input capacitance which occurs when the gain is varied. If the plate load can be tuned so that it behaves as a pure resistance, then the valve input resistance can be made very large. For the circuit shown there will be a resistive input component due to Miller effect because of stray capacitance across the load resistor. The application of the circuit is largely confined to use with fixed tuned oscillator circuits.

FIG. 29.11

FIG. 29.12

(3) **Quadrature circuits** (Figs. 29.12, 29.13). The grid is fed from a resistance reactance network connected between plate and cathode. This provides a voltage between the grid and cathode which is almost 90° out of phase with the plate to cathode voltage. The source of the alternating plate to cathode voltage is the voltage developed across the tank circuit of the oscillator (see Fig. 29.12). Since the plate current is in phase with the grid voltage (for valves having high plate resistance) the plate voltage and plate current will be approximately 90° out of phase. To the external circuit (oscillator tank circuit in this case) connected between plate and cathode of the reactance valve the behaviour is as though an additional reactance and resistance had been connected in parallel. Whether the valve circuit behaves like an inductive, or a capacitive reactance depends on the resistance-reactance network arrangement, as can be seen from Fig. 29.13.

The value of the apparent reactance and resistance, due to the electronic reactance (more correctly electronic impedance) depends on the mutual conductance (g_m) of the valve, and as the g_m can be controlled by alteration of the grid voltage the equivalent reactance and resistance can also be varied (the resistance variation is usually undesirable). The required grid voltage variation is obtained by utilizing the direct voltage changes at the discriminator output, when the reactance valve is used in a.f.c. circuits. Frequency modulation, using this method, is obtained by applying the audio frequency modulating voltage to the grid of the reactance valve, in the same way as the direct voltage changes are applied for obtaining a.f.c. The magnitude of the a-f voltage determines the change in the equivalent reactance shunted across the oscillator tank circuit, and so determines the frequency deviation from the nominal oscillator centre frequency. The number of times the frequency deviates around the central reference frequency will be determined by the frequency of the a-f modulating voltage. Variation in the value of the shunt resistance, due to the electronic reactance, across the oscillator circuit causes undesired amplitude modulation.

The quadrature circuits are the most widely used for a.f.c. and other purposes, and attention will be confined to discussing some of the possible arrangements. Fig. 29.12 shows the general circuit arrangement using a pentode valve. A hexode or heptode valve can also be used, with the phase shifting network connected to the signal grid and the control voltage to the oscillator grid. The impedances Z_1 and Z_2

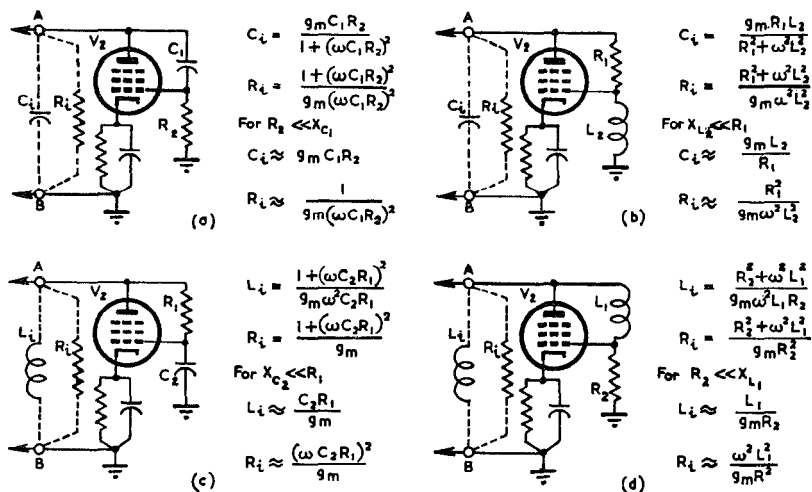

FIG. 29.13

in Fig. 29.12 comprise the phase shifting network. Depending on the form these impedances take it will be clear that an additional blocking capacitor may be required between plate and grid of the reactance valve, and also, since there must be a d.c. path between grid and cathode, an additional grid resistor may be necessary. The values for these additional components should be such as to have negligible effect on the performance of the circuit. Fig. 29.13 shows four possible arrangements for quadrature circuits, together with the equations for the additional resistance (R_i) and inductance (L_i), or capacitance (C_i), connected in parallel with the oscillator tuned circuit. Exact and approximate equations are given, but in most practical circuits the approximate conditions will hold. The equations apply equally well to quadrature circuits using pentode, hexode or heptode valves. The angular frequency ω is that at which the oscillator circuit is meant to operate e.g. $2\pi \times 1455$ Kc/s etc. (in the case of F-M this would be the nominal reference frequency). The circuit of Fig. 29.13(c) is the one most commonly used in practical a.f.c. circuits in which the oscillator is tuned by a variable capacitor. Care is necessary when using circuits (b) and (d) as self resonance effects, due to stray capacitances across the inductances L_2 and L_1 , often lead to difficulties. Further, the r-f resistances of L_2 and L_1 must be low if the circuits are to behave as relatively pure reactances. Stray capacitances across R_1 and R_2 can also affect performance, and should be kept small.

To carry out the design for an electronic reactance circuit it is necessary to know the manner in which g_m varies with grid bias. This information is generally available on valve data sheets, for a given set of operating conditions. If other operating conditions are required, then direct measurement of the $g_m - e_g$ characteristic is the usual procedure.

It is helpful when designing reactance valve circuits to be able to determine, directly, values for C_1R_2 , L_2/R_1 , R_1C_2 and L_1/R_2 in terms of the operating frequency, the frequency change required, and the oscillator tank circuit component values. The necessary conditions have been determined (Ref. 18) for the circuits (b) and (c) of Fig. 29.13, using the approximate relationships for C_i and L_i and assuming that the frequency variation is linear (or very nearly so). For circuit (b) the approximate expression is

$$\frac{L_2}{R_1} = \frac{2C_0f_2S}{f_1^2} \quad (13)$$

For circuit (c) the approximate expression is

$$C_2 R_1 = \frac{L_0 f_1^2}{2 f_2 S} \quad (14)$$

where C_0 = capacitance tuning the oscillator circuit in the absence of the reactance valve

L_0 = inductance of the oscillator tuned circuit in the absence of the reactance valve

S = sensitivity = $(f_2 - f_1)$ /corresponding change in mutual conductance (g_m)

f_2 = high frequency limit of frequency

and f_1 = low frequency limit of frequency

The design procedure is as follows :

- (1) Select f_2 and f_1 . Suppose the nominal oscillator centre frequency is 1455 Kc/s, and the oscillator frequency is to vary ± 5 Kc/s. Then $f_2 = 1460$ Kc/s and $f_1 = 1450$ Kc/s.
- (2) Select a suitable working range on the $g_m - e_o$ characteristics, for the valve type to be used, which is as nearly linear as is possible. With a valve type 6U7-G (250 volts on plate, 100 volts on screen) a suitable operating range is from -3 to -10 volts, giving a g_m change of $1600 - 275 = 1325 \mu\text{mhos}$.
- (3) Choose a suitable value for L_0 or C_0 if these are not already fixed by other circuit considerations. Suppose $L_0 = 110 \mu\text{H}$ is required in a typical case ; this value would be modified slightly in the final circuit, to take care of the additional parallel inductive reactance due to the normal value of the electronic reactance in the absence of additional bias from the discriminator. It is not necessary, usually, to take this inductance change into account during the preliminary design.
- (4) Compute the sensitivity (S) in cycles per mho. For our example $S = (10 \text{ Kc/s})/1325 \mu\text{mhos} = 7.54 \times 10^6 \text{ cycles/mho}$.

- (5) Determine L_2/R_1 from eqn. (13) or $C_2 R_1$ from eqn. (14). Using eqn. (14),

$$C_2 R_1 = \frac{110 \times 10^{-6} \times 1450^2 \times 10^6}{2 \times 1460 \times 10^3 \times 7.54 \times 10^6} = 10.5 \mu\text{F} \times \text{M}\Omega$$

- (6) Select particular values for L_2 , R_1 or C_2 to conform to the circuit requirements ; remembering the previous restrictions of $X_{L_2} \ll R_1$ and $X_{C_2} \ll R_1$.

This should lead to R_1 being at least 5 times X_{L_2} or X_{C_2} , but larger ratios are preferable (see below).

The most convenient procedure is to tabulate various values of R_1 , L_2 or C_2 and to select the most suitable combination giving the product found in step (5) e.g. $R_1 = 50,000 \Omega = 0.05 \text{ M}\Omega$, then $C_2 = 10.5/0.05 = 210 \mu\text{F}$, and so $X_{C_2} = 520 \Omega$. This makes $R_1 \gg X_{C_2}$ as required.

Of course, the actual values of L_2 and R_1 can be determined directly from the expressions given in Fig. 29.13. R_1 should always be so determined for the condition of maximum g_m , after the circuit values have been found, to ensure that the loading on the oscillator circuit is not excessive. The value of g_m to be used in these equations corresponds to the actual bias voltage for a particular operating frequency ; e.g. in the above example, with no additional external bias applied, the operating frequency is 1455 Kc/s, and the standing bias voltage can be taken as -6.5 volts, corresponding to a mutual conductance of $925 \mu\text{mhos}$. The total parallel inductance and resistance changes can be found, using the g_m values corresponding to -3 and -10 volts bias, which are the values required when the operating frequencies are 1450 Kc/s and 1460 Kc/s respectively.

Before completing a design it is necessary to check the amplitude of the oscillator voltage applied to the grid of the reactance valve by the phase shifting network. This check is necessary as the possibility of grid current might be overlooked. In

our example the minimum bias is -3 volts and so the peak r-f grid voltage should not exceed about 2 volts if grid current is to be avoided. The proportion of the r-f voltage developed across the oscillator tank circuit (and applied between plate and cathode of the reactance valve) which appears between grid and cathode of the reactance valve is for Fig. 29.13(c) $X_{C_2}/\sqrt{X_{C_2}^2 + R_1^2}$. For our example, the voltage step down is 0.0104, and so no possibility of grid current exists, as 2 volts peak r-f at the grid corresponds to 196 volts peak across the oscillator tank circuit. This is considerably in excess of the voltage likely to be encountered in a receiver oscillator circuit, where 60 volts peak is about the maximum to be expected with any of the usual arrangements (it is usually considerably less than this value, depending on the type of circuit used).

Further details of the design of reactance valve circuits for a.f.c. can be found in Refs. 8, 9 and 10. A graphical method for determining the "throw-out" and "pull-in" frequencies of an a.f.c. system is given in Ref. 8 (p. 260). The difference in these two frequencies is reduced by using an electronic reactance which gives correction for a limited range of discriminator voltages only; outside the correction range the added reactance should remain practically constant.

SECTION 1 : INTRODUCTION TO RECTIFICATION

(i) Principles of rectification (ii) Rectifier valves and types of service (iii) The use of the published curves (iv) Selenium and copper-oxide rectifiers.

(i) Principles of rectification

Most electronic equipment requires some form of plate voltage supply which has in the majority of cases to be derived from single-phase a.c. mains. It is the purpose of this chapter to outline the principles and calculations involved, with particular reference to those types of supply required for radio receivers and amplifiers.

The most general and accepted method of a.c. to d.c. conversion, where very large amounts of power are not required, is by valve rectifiers of either the high vacuum or mercury vapour type. Selenium and copper-oxide rectifiers are also used—see (iv) below.

Diagram A in Fig. 30.1 shows a sine wave voltage of which the peak and r.m.s. values are shown as \hat{E} and $|E|$. With ideal half-wave rectification and a resistive load with no filter, the positive or upper peaks would also represent the load current, while the negative or lower peaks would be suppressed; the average voltage would be shown by E_{dc} in the half-wave case. With full-wave rectification the current through the load resistance would be similar* each half cycle, the lower peak being replaced by the dashed line in A. The direct voltage would be the average voltage, i.e., 0.9 of the r.m.s. voltage for a sine wave. For half-wave rectification the average direct voltage over a period would be one half that for full-wave rectification under the same conditions.

Fig. 30.1B illustrates **ideal full-wave† rectification with a condenser input filter** (circuit as Fig. 30.1F in which choke L is assumed to have very high inductance and zero resistance). The voltage at the first filter condenser C_1 follows the line ABA'B', the condenser charging between A and B but discharging between B and A'.

*In practice there is always some lack of symmetry caused by a combination of small factors such as the use of one end of the filament as cathode return in place of a centre-tap, variations in characteristics between the two units in the rectifier and variations in transformer secondary voltages and impedances on both sides of the centre-tap. As a result there is usually a substantial amount of mains frequency ripple with full-wave rectification, although the twice-mains-frequency ripple voltage predominates.

†Also known as biphas half-wave.

Fig. 30.1. (A, B, C & D). Voltage and current waveforms of condenser input and choke input rectifier systems. The symbols on the left are those used in Section 2.

FIG. 30.1

The mean level of ABA'B' is the effective direct voltage. The shaded area above the curve AQB represents the voltage by which the transformer voltage exceeds that of C_1 . The current through the plate circuit of the rectifier only flows for the interval between A and B and between A' and B' because at other parts of the cycle the transformer voltage is below the voltage of C_1 . The current through the rectifier, shown in Fig. 30.1C, is similar in form to the difference in voltage between the curves APB and AQB in Fig. 30.1B.

The ripple voltage may be determined from the ABA'B' curve, and the values of the fundamental and harmonics may be determined by a Fourier analysis.

As the load resistance (R_L in Fig. 30.1F) is increased, BA' becomes more nearly horizontal and the area APB becomes smaller until in the extreme (theoretical) case when the load resistance is infinite the direct voltage is equal to the peak voltage. This graphical method may be applied to any rectifier with a condenser input filter followed by a high inductance choke. The assumption is made that the current through the inductance remains constant, that is to say that the lines BA', B'A' etc. are straight.

With a (full wave) **choke input filter*** the conditions are as shown in Fig. 30.1D assuming a very high inductance choke (L_1 in Fig. 30.1G), although with practical chokes there will necessarily be a certain amount of ripple in the load current.

* The term "choke input" is used for convenience in this Handbook to indicate a series inductance followed by a capacitance shunted across the load resistance.

FIG. 30.1G

Maximum ratings

Rectifier valves are usually rated for maximum direct-current per plate, maximum peak current per plate, maximum peak inverse plate voltage and maximum r.m.s. supply voltage per plate. In some cases a maximum rated hot-switching transient (or surge) plate current per plate (for a specified maximum time, e.g. 0.2 second) is also given. It is important to ensure that no one of these ratings is exceeded under the conditions of operation. If the ratings are design centre values—see pages 77 and 78—they apply to nominal mains voltages.

Maximum direct current per plate

This may be measured by a d.c. milliammeter in series with R_L (Figs. 30.1 E, F or G).

Maximum peak current per plate

This may either be measured by means of a C.R.O. or calculated by the method described in Section 2 or 3 for condenser or choke input respectively. It is largely influenced by the total effective plate supply impedance per plate, and in any case where the peak current is too high, it may be reduced by adding a resistor in series with each plate or by increasing the effective impedance of the transformer to give the same result. The method of calculating the plate supply impedance per plate for a transformer is given on page 99. In cases where no transformer is used, as in a.c./d.c. receivers, a resistor should be connected in the plate circuit to limit the peak current to a safe value. It is good practice in all cases to limit the peak current to a value below the maximum rated value, to give a margin for safety and longer life.

Maximum peak inverse plate voltage

This is 1.41 times the r.m.s. voltage of the whole secondary winding of the transformer in Fig. 30.1F or G, and twice this value in Fig. 30.1E.

Maximum r.m.s. supply voltage per plate

A higher r.m.s. supply voltage is usually permitted with a choke input to the filter than with condenser input to the filter. In some cases, with a condenser input to the filter, a higher r.m.s. supply voltage per plate is permitted provided that the

direct plate current is reduced below its maximum rating and that the total effective plate supply impedance per plate is increased for the higher voltage conditions (e.g. Fig. 30.2A). With a choke input to the filter, the maximum r.m.s. supply voltage per plate is sometimes only permissible provided that the direct plate current is reduced below its maximum rating (e.g. Fig. 30.2C). With a choke input to the filter, it is essential to have a **choke inductance** not less than the critical value for the particular operating condition in question. The critical inductance is a function of the load resistance and the frequency of the supply, as given by eqns. (1), (2) and (3) in Sect. 3.

For any value of inductance, with constant r.m.s. supply voltage, there is a value of current below which operation is not permitted. This is shown in Fig. 30.2C where boundary lines for choke sizes are included.

Equivalent circuit of high vacuum rectifier

The high vacuum rectifier can be considered as being an ideal switch in series with a non-linear resistance and a source of potential which is connected by the switch to the load when the polarity is that required by the load (Ref. 7). As the switching gives rise to pulsating currents (and voltages) it is necessary to assume a linear resistance which is equivalent to the non-linear effective resistance of the rectifier during this pulsating or conduction period. The conduction period (ϕ), and therefore also the magnitude of the current pulse, will depend on the loading and the type of filter connected to the rectified supply. Certain approximations which must be made for the first calculation should be readjusted when the results are known, in order that a second and more accurate calculation can be made.

Mercury vapour rectifiers

In the case of mercury vapour rectifiers the voltage drop in the valve is a constant value of the order of 10 to 15 volts over a wide range of currents. These rectifiers are generally used with choke input filters to provide good regulation for class B amplifiers.

The direct voltage output of such a system is equal to 0.9 times the r.m.s. value of the input voltage minus the valve voltage drop—

$$\text{e.g. Output voltage} = (0.9 E_{r.m.s.} - 15) \text{ volts.}$$

(ii) Rectifier valves and types of service

Rectifier valves may be subdivided into the following groups :—

- (1) High vacuum
 - (a) High impedance (e.g. 5Y3-GT)
 - (b) Medium impedance (e.g. 6X4, 5R4-GY)
 - (c) Low impedance (e.g. 5V4-G, 35Z5-GT)
- (2) Mercury vapour—(e.g. 82, 83).

The choice of a rectifier valve for a particular service must take into account the maximum permissible ratings for peak current, average current, and peak inverse voltage. The design of the following filter will influence these last two factors particularly; the type of filter, either choke or condenser input, will be determined partly by the demands of power supply regulation. In supplies feeding Class A output stages the choice will probably be a condenser input filter, but where Class AB₁ and AB₂ output stages are to be supplied, the regulation of the power supply becomes a significant feature and choke input filters with low impedance rectifiers must be used.

The following examples represent typical practice—

A.C. radio receivers with Class A power stage :—

High vacuum full wave (e.g. 6X4, 5Y3-GT, 5U4-G).

A.C. radio receivers with Class AB₁ power stage :—

With self bias—high vacuum full wave (e.g. 5Y3-GT, 5U4-G, 5R4-GY, 5V4-G)

With fixed bias—low impedance high vacuum full wave (e.g. 5V4-G).

A.C./D.C. radio receivers :—

Indirectly-heated low impedance high vacuum half-wave types with heaters operating at 0.3 A or 0.15 A (e.g. 25Z6-GT or 35Z5-GT).

In England, heaters operating at 100 mA are widely used.

Battery operated radio receivers with non-synchronous vibrators :—

Indirectly-heated low or medium impedance high vacuum full-wave types (e.g. 6X4).

Amplifiers :—

As for radio receivers except that mercury vapour types may also be used.

In general for radio receiver and small amplifier design high vacuum rectifiers are to be preferred to mercury vapour types because of—

- (1) long and trouble-free service ;
- (2) the lower transformer voltage which can be used for the same d.c. output voltage when a condenser input filter may be used ;
- (3) self protection against accidental over-load due to the fairly high internal impedance of the rectifier. Use can only be made of this last point when the supply is for use with a Class A output stage, when good regulation is not a major consideration and a high impedance rectifier may be used.

With directly-heated rectifiers it is generally found preferable to connect the positive supply lead to one side of the filament rather than to add the further complication of a centre-tap on the filament circuit.

Parallel operation of similar types of vacuum rectifiers is possible but it is preferable to connect together the two sections of a single full wave rectifier and to use a second similar valve as the other half-rectifier if full-wave rectification is required. With low impedance rectifiers as used in a.c./d.c. receivers (e.g. 25Z6-GT) it is desirable to limit the peak current by some series resistance. When two units are connected in parallel it is also desirable to obtain equal sharing, and in such cases a resistance of 50 or 100 ohms should be connected in series with each plate, then the two units are connected in parallel.

Mercury vapour rectifiers may only be connected in parallel if a resistance sufficient to give a voltage drop of about 25 volts is connected in series with each plate, in order to secure equal sharing of the load current.

(iii) The use of the published curves

From published curves on rectifier valves it is possible to predict the output voltage of a rectifier system when provided with the knowledge of the transformer voltage. For this purpose, use may be made of either the constant voltage curves or the constant current curves.

A family of curves is normally published both for condenser-input and for choke-input filters. In the former case the source impedance must be known ; it is usually published as the total effective plate supply impedance per plate.

An example of constant voltage curves, in this case applying to a condenser-input filter, is given in Fig. 30.2A. Each curve is for a specified constant supply voltage per plate ; for intermediate voltages it is possible to interpolate with sufficient accuracy.

In this particular case there is the rather unusual feature of one value of total effective plate supply impedance per plate for the lower voltage curves (1 to 5) and a higher value

for the higher voltage curves (6 to 8). It is always permissible to adopt a higher value of total effective plate supply voltage per plate than that shown on the curves, but the direct voltage output will thereby be decreased somewhat. Operation is only permissible on, and below, the line formed by the highest curve and the "current and voltage boundary line" ADK. These curves only apply to one specified value of capacitance input to the filter, in this case $10\ \mu\text{F}$.

Fig. 30.2A. Operation characteristics for a typical full-wave rectifier (5Y3-GT) with condenser input filter.

The effect of change in the value of capacitance input to the filter is indicated typically by Fig. 30.2B, where curves for 3 values of capacitance are drawn. A higher capacitance gives better regulation and a higher output voltage, but increase in capacitance beyond a certain value (here about $16\ \mu\text{F}$) has only a very slight effect. If curves are only drawn for one specified value of input capacitance, operation with a higher value is not permissible unless this has been demonstrated by measurement or calculation to be within the peak current rating of the rectifier.

Curves for a typical full wave rectifier with choke input are given in Fig. 30.2C. Operation is only permissible in the area to the right of the boundary line corresponding to the proposed choke size, to the left of the current and voltage boundary line CEK, and below the highest curve for a choke of infinite inductance. If the direct current varies between two limits, it is important to select a value of inductance at least equal to, or preferably higher than, the value required for the lower limit of direct current; the inductance should be measured at the lower limit of direct current.

The constant current curves (of which an example is given in Fig. 30.3) are very helpful for deriving certain information. If it is required to find the input voltage

FIG. 30.2B

Fig. 30.2B. Operation characteristics for a typical full-wave rectifier (5T4) with condenser input filter, showing effect of input capacitance (C).

to give 250 volts 100 mA direct current, a vertical is drawn upwards from an output voltage of 250 volts to point P on the 100 mA curve. From here a horizontal line is drawn which intersects the vertical axis at 277 volts, which is the desired value.

The line OD is for equal input and output voltages. Above and to the left of this line the output voltage is less than the input voltage; below and to the right of this line the output voltage is greater than the input voltage.

Each of the points A, B, C etc. at which the several current lines cut the vertical axis indicates the combined effective voltage drop in the valve and the transformer;

FIG. 30.2C

Fig. 30.2C. Operation characteristics for a typical full wave rectifier (5Y3-GT) with choke input filter.

Fig. 30.3. Constant current curves for a 5Y3-GT rectifier; condenser-input filter with capacitance $8\mu F$ and effective plate supply impedance 80 ohms per plate.

in other words it is the input voltage required to maintain the specified load current with the load terminals short-circuited.

The line OE is the theoretical limit of output voltage with no load-current, and is drawn to correspond to an output voltage of 1.414 times the r.m.s. input voltage.

The regulation of the output voltage with varying load currents is indicated by Fig. 30.3. If the input voltage is 250 volts, a horizontal line may be drawn as in XY and vertical lines may be drawn at each intersection with the constant current curves. Line FG is for no load-current, while LM is for 100 mA load current. For this example the output voltage will be seen to drop from 354 volts at no load-current to 213 volts at 100 mA load-current.

It should be noted that the results given by any form of valve curves are only correct for the set of conditions for which the curves were derived.

(iv) Selenium and copper oxide rectifiers

Selenium and copper oxide rectifiers have been used for miscellaneous applications such as for grid bias supplies and instrument rectifiers. Recently, selenium rectifiers have been widely used as plate supply rectifiers in radio receivers.

Both types differ from thermionic rectifiers in that they have appreciable reverse current. When used within their ratings, selenium rectifiers normally have a long life, although a small percentage of breakdowns occurs throughout life.

Copper oxide rectifiers are limited to a temperature rise of about 15°C while selenium rectifiers may be operated at higher temperatures. Selenium rectifiers are smaller and lighter than copper oxide types, for the same operating conditions.

For further information see Refs. 14, 17, 21, 23, 24, 25, 26, 33.

SECTION 2: RECTIFICATION WITH CONDENSER INPUT FILTER

(i) Symbols (ii) Rectification with condenser input filter (iii) To determine peak and average diode currents (iv) To determine ripple percentage (v) To determine the transformer secondary r.m.s. current (vi) Procedure when complete published data are not available (vii) Approximations when the capacitance is large (viii) Peak hot-switching transient plate current (ix) The effect of ripple.

(i) Symbols and definitions

\hat{r}_d	Effective peak resistance of diode, defined as the anode voltage at the conduction peak divided by the anode current at that time.
\bar{r}_d	Effective average resistance of diode, defined as the average anode voltage during the conduction period divided by the average anode current during that time.
$ r_d $	Effective r.m.s. resistance of diode, defined as the diode anode dissipation divided by the square of the r.m.s. anode current.
R_s	Total resistance in series with diode including transformer winding resistance and any series resistance added to limit the diode peak current.
\hat{R}_s	Equal to $\hat{r}_d + R_s$
\bar{R}_s	Equal to $\bar{r}_d + R_s$
\hat{i}_d	Peak diode current (one anode)
\bar{i}_d	Average diode current (one anode)
$ i_d $	r.m.s. diode current (one anode)
\hat{e}_d	Diode anode voltage at peak of conduction period
R_L	Load resistance presented to rectified supply
I_L	Load current from rectified supply
E_{dc}	Rectified direct output voltage across load resistance
\hat{E}_\sim	Peak value of alternating input voltage to rectifier
$ E_\sim $	R.M.S. value of alternating input voltage to rectifier
C	Capacitance of first filter capacitor in farads
ω	$2\pi \times$ supply frequency in c/s
$ E_R $	R.M.S. value of ripple voltage existing across condenser C
E_p	Peak-inverse voltage across diode
$ I_R $	R.M.S. value of ripple current through condenser C
$\frac{ E_R }{E_{dc}}$	$\frac{\text{r.m.s. ripple voltage}}{\text{direct voltage across load}} = \text{ripple factor.}$
$ R_s $	$= r_d + R_s.$

(ii) Rectification with condenser input filter

It has been stated in Sect. 1(i) that the nature of the rectified current is pulsating and that it is necessary for the purpose of this simple equivalent circuit to convert the non-linear resistance of the diode to an equivalent linear resistance. For condenser input filters it can be shown (Ref. 6) that the relationship is:—

$$\hat{r}_d = 0.88 \bar{r}_d = 0.93 |r_d|$$

is correct within 5% for all circuits of this type and from the following graphs it is possible to assess the characteristics of a condenser input rectifier system.

Fig. 30.4 gives curves for a number of high vacuum rectifiers from which values of their peak resistance \hat{r}_d can be found. Figs. 30.5—30.7 (based on Schade, Ref. 6)

Fig. 30.4. Average anode characteristics of some rectifier valves (based on Ref. 6, with additions). The value of r_a for any rectifier at any diode current may be determined by dividing the diode anode voltage by the diode current.

*Includes G or GT equivalents.

Fig. 30.5. Ratio of rectified (direct) output voltage to peak a.c. rectifier input voltage expressed as a percentage, as a function of ωCR_L for a half-wave rectifier with a condenser input filter (Ref. 6).

are curves from which can be found the relationship between E_{dc} and \hat{E}_m for half-wave, full-wave and full-wave voltage doubler circuits in terms of other circuit parameters. Curves of the ratios of effective $|i_d|$ and peak \hat{i}_d diode currents to the direct current per anode \bar{i}_d are given in Fig. 30.8 ; Fig. 30.9 gives details of the ripple factor and Fig. 30.10, the peak inverse voltage (all based on Ref. 6).

The design considerations to be borne in mind when using these curves are :—
 (1) The value of the capacitance C is usually chosen with regard to the maximum permissible ripple in the output (see below) but if $|E_m|$ is limited to a certain value and the maximum E_{dc} is to be achieved, C may be increased above this value. In doing this due regard must be given to the maximum permissible peak current of the rectifier and, if necessary, limiting resistors placed in series with the anodes of the rectifier.

(2) In order that the direct voltage should not be closely dependent upon the value of C , the value of ωCR_L must be on or to the right of the knee of the appropriate curve in Fig. 30.5, 30.6 or 30.7 as required by the type of rectification.

Fig. 30.6. Ratio of rectified (direct) output voltage to peak a.c. rectifier input voltage, expressed as a percentage, as a function of ωCR_L for a full-wave rectifier with a condenser input filter (Ref. 6).

(iii) To determine peak and average diode currents

This method is for use when complete published data are available such as are usually supplied by the operation characteristics or equivalent published data.

The procedure is illustrated by an example based on type 5Y3-GT as a full wave rectifier under the following conditions :

r.m.s. voltage $= |E_{\sim}| = 350$ volts,

Fig. 30.7. Ratio of rectified (direct) output voltage to peak a.c. rectifier input voltage, expressed as a percentage, as a function of ωCR_L for a condenser-input voltage doubler (Ref. 6).

load current = $I_L = 125$ mA

voltage across load = $E_{dc} = 350$ volts (from Fig. 30.2A),

load resistance = $R_L = 350/0.125 = 2800$ ohms,

total effective plate supply impedance per plate = $R_s = 50$ ohms (from Fig. 30.2A),

$C = 10$ μ F (from Fig. 30.2A),

$f = 60$ c/s (from Fig. 30.2A), whence $\omega = 378$.

$\omega CR_L = 378 \times 10 \times 10^{-6} \times 2800 = 10.6$.

Step 1. Determine $\frac{E_{dc}}{\hat{E}_m} \% = \frac{350}{350\sqrt{2}} = 70.7\%$.

Step 2. From Fig. 30.6, knowing $\omega CR_L = 10.6$, we obtain

$$\bar{R}_s/R_L = 13.5\%,$$

whence $\bar{R}_s = 13.5 \times 2800/100 = 378$ ohms.

Step 3. $\bar{r}_d = \bar{R}_s - R_s = 378 - 50 = 328$ ohms.

Step 4. $\hat{r}_d = 0.88 \bar{r}_d = 0.88 \times 328 = 288$ ohms.

Step 5. $\hat{R}_d = R_s + \hat{r}_d = 50 + 288 = 338$ ohms.

Fig. 30.8 (above). Ratio of r.m.s. diode current to average diode current for one anode, expressed as a function of ωCR_L ; (below) Ratio of peak diode current to average diode current for one anode, expressed as a function of ωCR_L (Ref. 6).

Step 6. $\frac{\hat{R}_s}{R_L} \% = \frac{338}{2800} \times 100 = 12.1\%.$

Step 7. Knowing that $n = 2$ for full wave rectification,

$$\frac{\hat{R}_s}{nR_L} = \frac{12.1}{2} \% = 6.05\%.$$

Step 8. From Fig. 30.8 (lower) where $n\omega CR_L = 21.2$ we may obtain

$$\frac{\hat{i}_d}{\bar{i}_d} = 6.$$

Step 9. The **average diode current** \bar{i}_d :

$\bar{i}_d = I_L$ for half-wave circuits and full-wave voltage doubler circuits,

$\bar{i}_d = \frac{1}{2}I_L$ for full-wave circuits.

In this example $\bar{i}_d = 125/2 = 62.5$ mA.

Step 10. The **peak diode current**, is obtained by substituting the value of \bar{i}_d given by Step 9 in the result of Step 8. In the example

$$\hat{i}_d = 6 \bar{i}_d = 6 \times 62.5 = 375 \text{ mA}.$$

(N.B. the maximum rating is 400 mA).

Fig. 30.9. Curves for the determination of the ripple factor of condenser input filter rectifier circuits (Ref. 6).

(iv) To determine ripple percentage

Having determined the peak diode current, we may then proceed to calculate the other unknowns. The same example as in (iii) above is also used here.

Step 1. $|r_d| = \hat{r}_d / 0.93 = 288 / 0.93 = 310$ ohms.

Step 2. $|R_s| = R_s + |r_d| = 50 + 310 = 360$ ohms.

Step 3. $\frac{|R_s|}{R_L} \% = \frac{360}{2800} \times 100 = 12.8\%$.

Step 4. Applying this value to Fig. 30.9 (note the values shown in the inset, applying to the various curves), and using the value of ωCR_L determined above, the percentage of ripple voltage to direct voltage is given.

In the example, $\frac{|R_s|}{R_L} = 12.8\%$ (full wave) and $\omega CR_L = 10.6$ giving
 $\frac{\text{ripple voltage}}{\text{direct voltage}} = 5.5\%$.

The ripple voltage $|E_R| = \text{ripple percentage} \times \text{direct voltage}$.

(v) To determine the transformer secondary r.m.s. current $|i_d|$

Knowing the value of \hat{i}_d as determined in (iii) Step 9 above, also the values of n , ωCR_L and $|R_s|/R_L$, Fig. 30.8 (upper curves) will give the value of $|i_d|$.

In the same example $\hat{i}_d = 62.5$ mA ; $n = 2$; $\omega CR_L = 10.6$ and $|R_s|/R_L = 12.8\%$, so that $|i_d|/\hat{i}_d = 2.25$ and $|i_d| = 62.5 \times 2.25 = 140$ mA.

(vi) Procedure when complete published data are not available

Step 1. To determine \hat{i}_d .

$$\hat{i}_d = I_L \text{ for half-wave circuits and full-wave voltage doubler circuits,}$$

$$\hat{i}_d = \frac{1}{2} I_L \text{ for full-wave circuits.}$$

Step 2. The diode peak current \hat{i}_d is tentatively assumed to be $6 \hat{i}_d$. Alternatively, if the output voltage is known, the current ratio may be derived from Fig. 30.10A.

Step 3. From Fig. 30.4, and knowledge of the valve type, the diode peak plate voltage \hat{e}_d corresponding to \hat{i}_d can be found. Therefore $\hat{r}_d = \hat{e}_d / \hat{i}_d$ can be evaluated.

Fig. 30.10. Ratio of operating peak inverse voltage to peak applied a.c. for rectifiers used in condenser input filter circuits.

Step 4. Calculate $\hat{R}_s = \hat{r}_a + R_s$.

Step 5. Using Fig. 30.8 (lower curves), and knowing $n\omega CR_L$, \hat{R}_s and nR_L , determine \hat{i}_a/\bar{i}_a . If this differs appreciably from the assumed value, repeat steps 3, 4 and 5.

Step 6. Calculate $|r_a| = \hat{r}_a/0.93$.

Step 7. Calculate $|R_s| = R_s + |r_a|$.

Step 8. Calculate the percentage $|R_s|/R_L$ and apply to Fig. 30.9 to determine the ripple percentage.

Step 9. Calculate $|R_s|/nR_L$ and apply to Fig. 30.8 (upper curves) to determine \hat{i}_a/\bar{i}_a and thence $|i_a|$ which is the transformer secondary r.m.s. current.

Step 10. Calculate $\bar{r}_a = \hat{r}_a/0.88$.

Step 11. Calculate $\bar{R}_s = R_s + \bar{r}_a$.

FIG. 30.10A

Fig. 30.10A. This curve is for full-wave, half-wave and voltage-doubler rectifiers with condenser-input filters. It applies for any size of condenser so long as the condenser is large enough to give maximum output voltage for the given output current and r.m.s. voltage input. For half-wave and voltage-doubler rectifiers the direct current per anode $\bar{i}_a = I_L$; for full wave rectifiers $\bar{i}_a = \frac{1}{2}I_L$.

$n = 1$ for full-wave and half-wave rectifiers.

$n = 2$ for voltage doubler rectifiers.

Step 12. Calculate the percentage \bar{R}_s/R_L .

Step 13. Using Fig. 30.5 for half wave rectification,
or Fig. 30.6 for full wave rectification,
or Fig. 30.7 for voltage doubler circuits,

determine the percentage E_{dc}/\hat{E}_m .

Step 14. The transformer secondary r.m.s. voltage per plate is given by

$$|E_m| = \frac{70.7 E_{dc}}{\text{percentage } E_{dc}/\hat{E}_m}$$

Step 15. The peak inverse voltage under operating conditions is given by Fig.

30.10, but the peak inverse voltage under no-load conditions is equal to $2\hat{E}_m$ and the latter must not exceed the valve rating.

Step 16. It is then necessary to confirm that none of the maximum valve ratings has been exceeded.

Example of procedure when complete published data are not available.

Assume type 5Y3-GT as full wave rectifier with $E_{dc} = 350$ volts, $I_L = 125$ mA, $R_s = 50$ ohms, $f = 60$ c/s, $C = 10$ μ F. We may derive directly $R_L = 2800$ ohms, $n = 2$, $\omega = 378$, $\omega CR_L = 10.6$.

Step 1. $\bar{i}_a = \frac{1}{2} I_L = 62.5$ mA.

Step 2. Assume $\hat{i}_a = 6 \bar{i}_a = 375$ mA.

Step 3. From Fig. 30.4, curve 14, $\hat{e}_a = 123$ volts.

Therefore $\hat{r}_a = \hat{e}_a/\hat{i}_a = 123/0.375 = 328$ ohms.

Step 4. $\hat{R}_s = \hat{r}_a + R_s = 328 + 50 = 378$ ohms.

Step 5. Fig. 30.8 (lower curves), where $n\omega CR_L = 21.2$

$$\text{and } \frac{\hat{R}_s}{nR_L} \% = \frac{378 \times 100}{2 \times 2800} = 6.75\%,$$

gives $\hat{i}_a/\bar{i}_a = 5.8$, which differs so slightly from the assumed value of 6 that the calculated values of effective diode resistance may be taken as sufficiently accurate.

If the value of \hat{i}_a/\bar{i}_a , as calculated above, differed appreciably from the assumed value, it would be necessary to repeat steps 3, 4 and 5.

Peak current $\hat{i}_a = 5.8 \times 62.5 = 362$ mA.

Step 6. $|r_a| = \hat{r}_a/0.93 = 328/0.93 = 352$ ohms.

Step 7. $|R_s| = R_s + |r_a| = 50 + 352 = 402$ ohms.

Step 8. $(|R_s|/R_L) \times 100 = 402 \times 100/2800 = 14.4\%$.

Applying to Fig. 30.9 with $\omega CR_L = 10.6$ gives ripple percentage = 5.5%.

Step 9. $(|R_s|/nR_L) \times 100 = 7.2\%$. Applying this to Fig. 30.8 (upper curves) gives $\hat{i}_a/\bar{i}_a = 2.2$.

Therefore transformer secondary r.m.s. current = $2.2 \times 62.5 = 138$ mA.

Step 10. $\bar{r}_a = \hat{r}_a/0.88 = 328/0.88 = 373$ ohms.

Step 11. $\bar{R}_s = R_s + \bar{r}_a = 50 + 373 = 423$ ohms.

Step 12. $(\bar{R}_s/R_L) \times 100 = 423 \times 100/2800 = 15.1\%$.

Step 13. Using Fig. 30.6, $E_{dc}/\hat{E}_m = 68.8\%$.

Step 14. The transformer secondary r.m.s. voltage per plate is equal to

$$\frac{70.7 \times 350}{68.8} = 360 \text{ volts.}$$

It will be noticed that these values agree within 3% with those determined by the other procedure.

(vii) Approximations when the capacitance is large

Figs. 30.5, 6 and 7 indicate that, when a certain value of ωCR_L has been reached, all curves flatten out. In other words, if we increase the value of the input capacitance C , the output voltage and hence the output current remain constant above a certain value of C . Similarly with the peak current, as indicated by Fig. 30.8.

It is therefore possible to adopt a simplification when the input capacitance is sufficiently large so that any further increase in C does not have much effect on the direct voltage output. Fig. 30.10A enables the ratio of peak to average (direct) currents to be calculated from a knowledge of the voltage ratio and the type of circuit. It may be used as a fair approximation for most typical radio receivers in which $C \geq 16 \mu\text{F}$ for full-wave or $32 \mu\text{F}$ for half-wave operation. It should not be used in cases where the circuit impedance is very low, such as a half-wave rectifier in transformerless receivers with no added resistance.

A further approximation, which holds under the same conditions as outlined above, may be used when it is desired to reach the maximum rated direct current per plate and the maximum rated peak current per plate simultaneously, when the latter is six* times the former. Under these conditions

$$\hat{R}_s \approx 0.06 n R_L$$

$$\text{where } \hat{R}_s = \hat{r}_d + R_s$$

$$\hat{r}_d = \text{effective peak resistance of diode}$$

$$R_s = \text{total effective plate supply impedance per plate}$$

$$n = 1 \text{ for half-wave rectification}$$

$$= 2 \text{ for full-wave rectification}$$

$$\text{and } R_L = \text{load resistance.}$$

Also under the same conditions

$$E_{dc} = 0.69 \times \text{peak supply voltage}$$

$$= 0.975 \times \text{r.m.s. supply voltage.}$$

N.B. These relationships are derived from Figs. 30.8 and 30.10A.

(viii) Peak hot-switching transient plate current

The peak hot-switching transient plate current is the current which the diode must carry if the load resistance R_L is short-circuited. This occurs in a practical case when a diode is "hot-switched." The peak hot-switching transient plate current is given by (Ref. 15):

$$\hat{I}_{max} = \frac{\hat{E}_s}{R_s + \hat{r}_{ds}}$$

$$\text{where } \hat{I}_{max} = \text{peak hot-switching transient plate current in amperes}$$

$$\hat{E}_s = \text{peak alternating voltage per plate}$$

$$R_s = \text{total effective plate supply resistance per plate}$$

$$\text{and } \hat{r}_{ds} = \text{diode resistance when hot-switching current is at its maximum.}$$

The value of \hat{r}_{ds} may be derived from Fig. 30.4, by extending the curves upwards if necessary. If the hot-switching current is greater than 1 ampere, but less than 10 amperes, the resistance may be read from the curves at one tenth of the current value, and the resistance value so derived must then be multiplied by 0.47 (this has an accuracy within about 2% for curves 1 to 17 inclusive). For example, type 5Y3-GT has a rated maximum hot-switching transient plate current of 2.2 amperes per plate. The diode resistance at a plate current of 220 mA is given by Fig. 30.4 curve 14 as

$85/0.22 = 386$ ohms. The diode resistance \hat{r}_{ds} at a plate current of 2.2 amperes is therefore $386 \times 0.47 = 182$ ohms. Continuing with the same example, if the peak

*This ratio is very commonly used in diode ratings.

alternating voltage per plate is $350\sqrt{2}$, and the peak hot-switching transient current is not to exceed 2.2 amperes, then

$$R_s + \hat{r}_{ds} = 350 \times 1.41/2.2 = 225 \text{ ohms.}$$

But $\hat{r}_{ds} = 182 \text{ ohms.}$

Therefore $R_s = 43 \text{ ohms minimum.}$

(ix) The effect of ripple

The filter condenser C is required to carry a substantial ripple current, the value of which is given approximately by

$$\text{or } |I_R| = |E_R| \omega C \text{ for half-wave rectification}$$

$$\text{or } |I_R| = |E_R| 2\omega C \text{ for full-wave rectification}$$

where $\omega = 2\pi f$

f = supply frequency

$|E_R|$ = ripple voltage r.m.s.

$|I_R|$ = ripple current in amperes r.m.s.

and C is measured in farads.

For example, with a supply frequency of 60 c/s, full-wave rectification and $C = 10 \mu\text{F}$, a ripple voltage of 20 volts r.m.s. will cause a ripple current of 150 mA. This is the maximum permissible for a dry electrolytic condenser with 450 V working voltage, under JAN-C-62 specification [Chapter 38 Sect. 3(x)]. The maximum permissible ripple currents vary with the capacitance, the working voltage, manufacturer and type. Ripple current ratings of a typical English manufacturer are given on page 194; they differ considerably from JAN-C-62.

For any predetermined choice of condenser, temperature voltage and value of R_s/R_L there is a maximum load current which can be drawn from the rectifier without exceeding the ripple current ratings. Based on JAN-C-62, with $(R_s/R_L) = 10\%$ and 60 c/s full wave rectification we have :

Capacitance	350 volt (d.c.) working			450 volt (d.c.) working		
	max. ripple current	max. load current	$\frac{\text{load curr.}}{\text{ripple curr.}}$	max. ripple current	max. load current	$\frac{\text{load curr.}}{\text{ripple curr.}}$
10 μF	140 mA	120 mA	86%	150 mA	130 mA	86%
20 μF	180 mA	154 mA	85%	180 mA	150 mA	83%
30 μF	200 mA	168 mA	84%	200 mA	168 mA	84%

Based on English T.C.C. condensers, 450 volt (d.c.) working, ambient temperature 40°C , $(R_s/R_L) = 10\%$ and 50 c/s full wave rectification we have :

Capacitance	Plain foil			Etched foil		
	max. ripple current	max. load current	$\frac{\text{load curr.}}{\text{ripple curr.}}$	max. ripple current	max. load current	$\frac{\text{load curr.}}{\text{ripple curr.}}$
8 μF	—	—	—	67 mA	57 mA	85%
16 μF	260 mA	220 mA	85%	122 mA	103 mA	85%
32 μF	405 mA	344 mA	85%	—	—	—

In the cases listed above, the load current is approximately 85% of the maximum ripple current ; this only applies for $(R_s/R_L) = 10\%$. Values for three conditions are given below :

(R_s/R_L)	1%	10%	30%
$\frac{\text{load current}}{\text{ripple current}}$	73%	85%	102% approx.

In practice, in radio receivers and a-f amplifiers, (R_s/R_L) is usually well within the extreme limits 1% and 30%.

If the ripple current for any desired condition is greater than the permissible limit, the capacitance of a single unit condenser may be decreased and/or the value of R_s may be increased either by selecting a different valve type or adding resistance in series with each plate. Either method of increasing R_s will require a higher transformer voltage. Alternatively two condensers may be connected in parallel, with the total capacitance unchanged, each of which will carry part of the ripple current ; however, equal sharing of current cannot be guaranteed and a large safety margin is desirable. The parallel arrangement confers no appreciable benefits with the T.C.C. ratings, as compared with an increase in capacitance of a single unit.

In general, load currents up to 120 mA may safely be employed with plain foil or 70 mA with etched foil without any investigation.

SECTION 3 : RECTIFICATION WITH CHOKE INPUT FILTER

(i) Rectification with choke input filter (ii) Initial transient current.

(i) Rectification with choke input filter

Where good voltage regulation is required, choke input filters are to be preferred. In this type of circuit, providing the first choke L_1 (Fig. 30.1G) is above a certain critical value L_c , the rectifier valve works under conditions of continuous current flow and in the ideal case where L_1 is of infinite inductance there would be no fluctuations in this current.

It has been shown (Ref. 6) that L_c should be equal to or greater than

$$\frac{R_s + R_L}{6\pi f} \text{ for full-wave operation} \quad (1)$$

where R_s = total resistance in series with diode

R_L = load resistance presented to rectified supply

and f = supply frequency.

As an approximation, if R_s is small compared with R_L ,

$$L_c \geq \frac{R_L}{940} \text{ for a 50 c/s supply} \quad (2)$$

$$\text{and } L_c \geq \frac{R_L}{1130} \text{ for a 60 c/s supply.} \quad (3)$$

The above formulae are only stated for full wave rectification as it is not normal practice to use a choke input circuit with a half-wave rectifier owing to the low output voltage which would result.

In applications where the load resistance varies considerably, for example in Class B amplifiers, it is usual to place a bleeder across the supply, thereby reducing the initial value required for L_1 . As the required critical value of L_1 decreases with increased load current, the choke can be made with a smaller air gap than necessary for constant inductance at all loads ; the drop in inductance due to d.c. polarization is permissible providing the inductance does not drop below L_c at any load.

This is known as a **swinging choke** ; its design is covered on pages 249 and 250.

The peak diode current is given approximately by

$$\hat{i}_d = I_L + \frac{\hat{E}_\sim \times 0.425}{2\omega L_1 - 1/(2\omega C_1)} \quad (4)$$

or, if $1/(2\omega C_1)$ is very much less than $2\omega L_1$, then

$$\hat{i}_d \approx I_L + \frac{\hat{E}_\sim \times 0.212}{\omega L_1} \quad (5)$$

$$\text{If } L_1 = L_c = R_L/6\pi f, \text{ then } \hat{i}_d \approx 2I_L. \quad (6)$$

$$\text{If } L_1 = 2L_c = R_L/3\pi f, \text{ then } \hat{i}_d \approx 1.5 I_L. \quad (7)$$

The approximation in equation (4) is due to the neglect of ripple frequencies higher than twice the supply frequency.

If the rectifier valve has a peak current rating equal to or greater than twice the maximum direct load current rating, and if the value of L_1 never falls below L_c , it is not necessary to calculate peak diode currents. The same holds when the peak current rating is equal to or greater than twice the maximum direct current to be drawn from the rectifier. Owing to the desire to limit the rectifier peak current, it is preferable to make the inductance at least $2L_c$ at the highest load current. The drop in inductance at maximum load current will result in a reduction of filtering, but this is not likely to cause any trouble. As the choke will normally be followed by a filter capacitance (C_1 in Fig. 30.1G), any reduction in the inductance of L_1 below L_c at any value of load will cause the rectifier system to take on the characteristics of a condenser input filter and the output voltage will rise.

It is important to remember, when measurements are being made on a filter choke to determine its suitability for use in choke input circuits, that due consideration should be given to the large value of a.c. potential which will exist across it under working conditions. This potential will increase the inductance at low values of d.c. polarization provided that the sum of the a.c. and d.c. fluxes does not cause saturation of the core.

For the accurate calculation of voltage output and regulation of a choke input type filter, the voltage drop due to the resistance of the choke, rectifier and supply must be taken into consideration. The choke resistance can be easily ascertained and the rectifier resistance may be derived from the curves of Fig. 30.4 using the method outlined below. The supply resistance in series with the anode, in a.c. operated equipments, will be equal to the transformer winding resistance [for calculation see pages 99 and 100] plus any added series resistance. In a.c./d.c. equipment it will be equal to the value of the limiting resistor in series with the anode. It is assumed that the rectifier will be operating under conditions of continuous current flow; it can be shown (Ref. 6) that $\hat{i}_d \approx \bar{i}_d \approx |r_a|$ also that the average anode current (one anode) $\bar{i}_d = I_L/2$. The procedure is best illustrated by an example.

Example :—It is desired to design a power supply with choke input filter to deliver 0 to 200 mA at 350 volts using a 5U4-G rectifier at 50 c/s. The choke is assumed to have 100 ohms resistance and the effective supply resistance per anode is 75 ohms. In order to reduce the initial value of L_1 , a bleeder to take 20 mA is assumed.

At 20 mA : $R_L = 350/0.02 = 17\,500$ ohms

$$L_1 = L_c = 17\,500/940 = 18.6 \text{ H (minimum).}$$

$$\bar{i}_d = 20/2 = 10 \text{ mA.}$$

$$\hat{i}_d = 2 \times 20 = 40 \text{ mA.}$$

Average anode current during conduction = 20 mA.

Referring to Fig. 30.4 (curve 10) : anode voltage corresponding to 20 mA is 11.7 volts.

$$\bar{r}_a = 11.7/0.02 = 585 \text{ ohms.}$$

$$\text{At 220 mA : } R_L = 350/0.22 = 1590 \text{ ohms.}$$

$$L_1 = 2L_c = 2 \times 1590/940 = 3.4 \text{ H (minimum).}$$

$$\bar{i}_a = 220/2 = 110 \text{ mA.}$$

$$\hat{i}_a = 1.5 \times 220 = 330 \text{ mA.}$$

Average anode current during conduction = 220 mA.

Referring to Fig. 30.4 (curve 10): anode voltage corresponding to 220 mA is 59 volts.

$$r_a = 59/0.22 = 268 \text{ ohms.}$$

Voltage drop due to resistance of supply, valve and choke

$$\text{At 220 mA: } = 0.22 (75 + 268 + 100) = 98 \text{ volts}$$

Fig. 30.11. Curves for the determination of the ripple factor of choke input rectifier circuits (based on Ref. 27), applying to the circuit of Fig. 30.1G for full wave rectification on a 50 c/s supply. The curves may be applied to any other supply frequency by multiplying values of inductance and capacitance by 2 for 25 c/s, 1.25 for 40 c/s, or 0.83 for 60 c/s. The ripple curves may be used independently of the K curves and load resistance curves to derive the ripple factor (i.e. ripple voltage E_{R1} expressed as a percentage of the direct load voltage). The operating point at any value of load resistance which occurs in practice should be above (preferably well above) the corresponding load resistance curve, thus determining the inductance L_1 . In order to limit the initial (starting) transient current to the maximum peak current rating of the rectifier valve, the operating point should be above and to the left of the corresponding K curve, where

$$K = \frac{r.m.s. \text{ voltage per anode } |E_{R1}|}{1110 \times \text{peak plate current rating of diode}}$$

At 20 mA : = 0.02 (75 + 585 + 100) = 15 volts.

R.M.S. transformer voltage = (350 + 98)/0.9 = 498 volts.

Voltage across load at 20 mA = (498 × 0.9) - 15 = 449 volts.

Value of C_1 : Assume 10% ripple at maximum current, and referring to Fig. 30.11 for $L_1 = 3.4$ H, we obtain $C_1 = 5.7 \mu\text{F}$ ($8 \mu\text{F}$ would probably be used).

These results, which show a change of output of 350 to 449 volts when the load is changed from 220 to 20 mA, appear greater than the figures given by the valve curves ; this is because the choke voltage drop has also been taken into consideration.

From the example above it can be seen that the rectifier voltage drop is neither negligible nor constant ; in the case of a 5U4-G it varies from 11.7 volts at 20 mA to 59 volts at 220 mA.

If a lower impedance rectifier such as a 5V4-G had been used, this would have been reduced to 5.4 volts at 20 mA and 27 volts at 220 mA. For practical purposes of calculating the voltage output, a constant value of 16 volts could then be assumed, which would give an error of not more than 3.2%.

Also from the example it can be seen that the effect on output voltage produced by the 75 ohms supply resistance is fairly small, reducing the output by 1.5 volts at 20 mA and 16.5 volts at 220 mA.

When calculations have been completed, a check should be made to see that none of the maximum ratings given in the published data has been exceeded. This will include the value of peak inverse voltage E_p , which in a choke input rectifier system will not be greater than $1.65 \hat{E}_m$ provided that L_1 does not drop below L_c at any point. If L_1 is lowered below its critical value for any reason, E_p will approach the value for a condenser input rectifier system (see Sect. 2).

(ii) Initial transient current

When initially switching the anode circuit, with the cathode hot, there is a transient current in excess of the steady direct load current. It may be limited to a value equal to the peak anode current rating of the rectifier if the value of the inductance in henrys is equal to, or greater than

$$\left(\frac{|E_m|}{1110 \times I_{max}} \right)^2 C_1$$

where I_{max} = peak anode current rating of the valve, in amperes

and C_1 = capacitance in microfarads.

This requirement may be met by ensuring that the L_1 and C_1 values applied to Fig. 30.11 meet at a point on or above the corresponding K curve.

SECTION 4 : TRANSFORMER HEATING

For purposes of calculating transformer heating it is necessary to know the equivalent r.m.s. current in the winding supplying the rectifier.

In the case of **condenser input filters** the r.m.s. value of the anode current can be obtained from Fig. 30.8 (upper curves).

For **choke input filters** in which the inductance L_1 is constant, the r.m.s. value of each anode current is given approximately by (Ref. 31)

$$|i_a| = 0.707 \left(1 + \frac{\alpha^2}{2} \right)^{\frac{1}{2}} I_L \quad (1)$$

where $\alpha = \frac{R_L}{3 \omega L_1} = \frac{L_c}{L_1}$.

The following table has been calculated from eqn. (1) :

L_1	α	i_d
$= L_c$	1	0.87 I_L
$= 2L_c$	0.5	0.75 I_L
$= 4L_c$	0.25	0.72 I_L
$= \text{infinity}$	0	0.707 I_L

For design purposes it seems reasonable to calculate on the basis of conditions at maximum current. If $L_1 = 2L_c$ at maximum current, as recommended in Sect. 3, the heating current in the transformer may be taken as 0.75 I_L .

For further information on transformer heating, see Chapter 5 Sect. 5 pages 236-237.

SECTION 5 : VOLTAGE MULTIPLYING RECTIFIERS

(i) General (ii) Voltage doublers (iii) Voltage tripler (iv) Voltage quadruplers.

(i) General

Where it is required to obtain a higher direct voltage from a given a.c. input than is possible with normal rectifier circuits and where for reasons of weight, economy or other factors it is not desired to use a transformer, voltage multiplying rectifier circuits may be used.

These circuits involve the principle of charging condensers in parallel from the input and adding them in series for the output, the switching being accomplished by the rectifier valves.

(ii) Voltage doublers

The voltage doubler can take one of two forms, half- or full-wave.

Half-Wave. In the half-wave circuit (Fig. 30.12) on one half of the cycle the condenser C_1 is charged through V_1 ; this voltage is then added in series on the next half cycle to the voltage of the condenser C_2 charged through V_2 . A voltage of approximately $2\hat{E}_m$ will appear across R_L depending upon the rectifier type, load resistance and values of C_1 and C_2 . The ripple frequency, as in all half-wave circuits, will be the same as the supply frequency. C_1 must be rated at the value of \hat{E}_m and C_2 at $2\hat{E}_m$.

Full-Wave. In this circuit (Fig. 30.13) C_2' and C_2'' are charged on alternate half cycles, approximately $2\hat{E}_m$ appearing across the two in series. The ripple frequency will be equal to twice the supply frequency and the condenser ratings should be each equal to \hat{E}_m .

Comparing the two circuits

The voltage regulation is better for the full wave circuit at low values of ωCR_L and the rating of both condensers need only be \hat{E}_m but the circuit suffers the disadvantage of not having a common input and output terminal. The filtering is easier with the full wave circuit as the ripple frequency is twice the supply frequency, the ripple percentages being approximately equal.

FIG. 30.12

Fig. 30.12. Half wave voltage doubler rectifier circuit.

FIG. 30.13

Fig 30.13. Full wave voltage doubler rectifier circuit.

In both circuits, the larger the capacitance of the condensers the nearer the output voltage will be to $2\hat{E}_{\sim}$ and the better the voltage regulation, but care must be taken that the peak current ratings of the rectifiers are not exceeded.

It can be shown (Ref. 10) that at values of ωCR_L greater than 10, the values of \hat{i}_a/\hat{i}_d , E_{ac}/\hat{E}_{\sim} , ripple etc. for a half-wave voltage doubler are for all practical purposes the same as the values for the full-wave voltage doubler and calculations of both types can therefore be made by means of the graphs in Sect. 2.

From these graphs it can be seen that if a voltage multiplication of 1.6 or greater is required, the value of ωCR_L should not be less than 100, also that \bar{R}_s/R_L should not be greater than 1.5%. This means that if a voltage doubler is to give a high output and to be of good regulation, the maximum output current is strictly limited.

(iii) Voltage tripler

This circuit (Fig. 30.14) combines in series the outputs of a half-wave doubler and an ordinary half-wave rectifier, giving an output approximately three times \hat{E}_{\sim} . The ripple frequency will be equal to the supply frequency and the condenser ratings will be as for the individual circuits,

$$\text{i.e. } C_1'' \text{ rating} = \hat{E}_{\sim}; \quad C_2' \text{ rating} = \hat{E}_{\sim}; \quad C_2'' \text{ rating} = 2\hat{E}_{\sim}.$$

FIG. 30.14

Fig. 30.14. Voltage tripler rectifier circuit.

(iv) Voltage quadruplers

There are two suitable circuits as given in Figs. 30.15A and B. (B) is essentially the same as (A) except for the connection of one of the input leads. This alteration results in a supply which has a common input and output lead, the only other alteration being that C_1'' must now withstand $3\hat{E}_{\sim}$, while C_2' and C_2'' are (as in Fig. 30.12)

FIG. 30.15(A)

FIG. 30.15(B)

Figs. 30.15(A) and (B). Voltage quadrupler rectifier circuits.

rated at $2\hat{E}_m$ and C_1' at \hat{E}_m . Another advantage of (B) is that it lends itself to increasing further the number of times the voltage can be multiplied.

For further details on voltage multiplying rectifiers, see References in Sect. 7.

In all cases the polarity of the output can be reversed by reversing the polarity of the rectifiers and condensers.

SECTION 6 : SHUNT DIODE BIAS SUPPLIES

Where a supply of negative bias is required in an amplifier or receiver, as for example the fixed bias operation of an output stage, this can be obtained by the use of a shunt diode without the addition of many components.

If it is desired to make use of a high voltage winding on the power transformer for negative bias, the voltage so obtained is generally much greater than is required

FIG. 30.16

FIG. 30.17

for bias. In such a case power would be wasted in voltage dividers. The shunt diode system allows the use of a 6H6 type rectifier since the cathode is at earth potential. It is often possible to use a spare diode in one of the valves already in the equipment, thus doing away with the need for an extra valve.

Two versions of the circuit are shown in Figs. 30.16 and 30.17, Fig. 30.16 being suitable for the bias on r-f, i-f and a-f voltage amplifier valves. Fig. 30.17 is a voltage doubling circuit useful for the bias voltage of output stages. It has a maximum output voltage of 18 volts when supplied from a 6.3 volt heater line.

Fig. 30.22. Shunt diode bias supply with r.c. filtering.

When more than 18 volts are required the condenser C_1 may be fed from the transformer winding supplying the main rectifier in the equipment. This is shown in Fig. 30.18 and typical values are given together with the measured performance (Figs. 30.19-21) in order that the magnitude of the various quantities may be assessed. The irregularities in the curves of output voltage for various values of C_1 are due to the resonance of C_1 and L , but apart from modifying the shape of rectifier current pulses no other undesirable effects are evident. Care must be taken that the filter condenser C_2 is isolated from C_1 by a high value of impedance or large currents will be drawn from the transformer windings. In cases where only low output currents are required, L may be replaced by a resistor of not less than 100 000 ohms. This circuit arrangement is shown in Fig. 30.22, the output voltage for various values of capacitance being given in Fig. 30.23.

FIG. 30.23

SECTION 1 : INDUCTANCE-CAPACITANCE FILTERS

Consideration has already been given in Chapter 30 to the value of ripple voltage E_R in the output of condenser- and choke-input rectifier systems. This chapter takes into consideration the filter components required to reduce the value of ripple given by the graphs in Chapter 30, to the value that is allowable for the equipment under consideration. The latter value will be designated as E_{R1} for one additional filter section, as in Fig. 31.1A, or E_{R2} for two additional filter sections.

Fig. 31.1A. Circuit diagram of full-wave choke-input rectifier system, followed by single section filter L_2C_2 to give reduced ripple voltage E_{R1} .

It can easily be shown that for a given total value of LC , maximum filtering is obtained when all the filter sections are similar. Increasing the number of sections for a given total value of LC also increases the filtering, but there is little gained in breaking up the filter into more sections than that number which makes $X_L = 10X_C$. This is only appropriate if there is a definite limitation in the maximum value of LC . In general, better economy will be achieved by using not more than two sections, and increasing the value of C to give the required filtering.

The filter factor $\alpha = E_R/E_{Rn} = (\omega_R^2 LC - 1)^n$
 where n is the number of additional similar sections.

LC is the value of LC for one section (henrys and farads)

and $\omega_R = 2\pi f_R$

where f_R = ripple frequency.

This can be expressed as :—

$$LC = ({}^n\sqrt{\alpha} + 1)/\omega_R^2 = 0.0254 ({}^n\sqrt{\alpha} + 1)/f_R^2.$$

The formula above assumes that $X_L \geq 20X_C$, the usual practical case.

For quick reference, a graph has been prepared (Fig. 31.1B) for a single section filter to give the relationships between the values of E_R , E_{R1} and L_2C_2 based on the

Fig. 31.1B. Approximate relationships between ER , ER_1 and L_2C_2 for 50 c/s full-wave rectification (i.e. 100 c/s ripple frequency) and single section filter. For other ripple frequencies, the value of the LC scale should be multiplied by the appropriate factor as follows.

40 c/s ripple—6.25 ; 50 c/s ripple—4 ; 60 c/s ripple—2.78 ; 80 c/s ripple—1.56 ;
120 c/s ripple—0.695.

approximate formula $\alpha = \omega_R^2 LC$ which is sufficiently accurate for most applications. The values of L_2C_2 in Fig. 31.1B only hold for full-wave 50 c/s, but may be adapted to other conditions by multiplying by a factor (see title).

With either a condenser-input (Fig. 30.1F) or choke-input filter having a second filter section (Fig. 31.1A) it is important to avoid resonance between the choke L (or L_2) and condensers C_1 and C_2 in series. The inductance should be sufficiently large to avoid resonance, with a comfortable margin, over the whole frequency range of the amplifier and at least down to the ripple frequency (e.g. 100 c/s for 50 c/s mains and full wave rectification). This may be accomplished by ensuring that in Fig. 31.1A

$$L_2 \geq \frac{C_1 + C_2}{C_1 C_2} \cdot \frac{25\,000}{f^2} \text{ henrys}$$

where f = minimum rated frequency of amplifier in c/s,
and C_1 and C_2 are in microfarads.

$$\text{When } f = 100 \text{ c/s, } L_2 \geq \frac{C_1 + C_2}{C_1 C_2} \times 3.5.$$

$$\text{When } f = 50 \text{ c/s, } L_2 \geq \frac{C_1 + C_2}{C_1 C_2} \times 14.$$

$$\text{When } f = 25 \text{ c/s, } L_2 \geq \frac{C_1 + C_2}{C_1 C_2} \times 56.$$

For example, when $C_1 = C_2 = 8 \mu\text{F}$ and $f = 25 \text{ c/s}$, $L = 14$ henrys minimum.

SECTION 2 : RESISTANCE-CAPACITANCE FILTERS

In cases where filtering of a low-current supply is required, as in the case of the early stages of an audio-frequency amplifier or for certain applications in electronic instruments, resistance-capacitance filters can be used. The filter factor $\alpha = E_R/E_{R1} = \omega CR + 1$ and for ripple frequencies of 50, 60, 100 and 120 c/s this can be read directly from Fig. 31.2, for a single section filter.

See also Chapter 4 Sect. 8(ii) and (iii).

Fig. 31.2. Curve for determining the value of $\alpha = E_R/E_{R1}$ of a resistance-capacitance type single section filter for frequencies of 50, 60, 100 and 120 c/s. This curve is based on the formula, $E_R/E_{R1} = \omega CR + 1$.

SECTION 3 : PARALLEL T FILTER NETWORKS

A useful filter network is that shown in Fig. 31.3(a). This can be transposed, for any one frequency, to its equivalent Π network as in (b) and, by correct choice of the values of circuit components, the attenuation can be made theoretically infinite at any one frequency (f_∞). Conditions for infinite attenuation are—

$$1/C_1\omega = KR_2$$

$$2R_1 = K^2R_2$$

$$2/C_2\omega = R_2/K \text{ where } K \text{ is a constant.}$$

When the parallel T network is used for power supply filtering, the value of K to be used depends upon a number of considerations :—

Fig. 31.3. Resistance-capacitance parallel T network and its equivalent Π network.

1. The d.c. resistance of the filter (i.e. $2R_2$) should be as low as possible.
2. The total capacitance should be as low as possible.
3. Standard value components may be used.

Table 1 : Showing the relationships between R_1 , R_2 , C_1 and C_2 for various K values.

K	Resistances	Capacitances	f_∞
$1/2$	$R_2 = 8R_1$	$C_2 = 0.5C_1$	$1/(\pi R_2 C_1)$
$1/\sqrt{2}$	$R_2 = 4R_1$	$C_2 = C_1$	$1/(\sqrt{2}\pi R_2 C_1)$
1	$R_2 = 2R_1$	$C_2 = 2C_1$	$1/(2\pi R_2 C_1)$
$\sqrt{2}$	$R_2 = R_1$	$C_2 = 4C_1$	$1/(2\sqrt{2}\pi R_2 C_1)$

Table 2 : Showing the total capacitance values required for various values of K with $f_\infty = 100$ c/s, $R_2 = 200$ ohms.

K	Capacitance in μF		
	C_1	C_2	$2C_1 + C_2$
$1/2$	15.9	7.95	39.75
$1/\sqrt{2}$	11.25	11.25	33.75
1	7.95	15.9	31.8
$\sqrt{2}$	5.625	22.5	33.75

FIG. 31.4

Fig. 31.4. Values of $R_2 C_1$ required for various values of K to obtain infinite attenuation at frequency f_∞ .

FIG. 31.5

Fig. 31.5. Typical complete filter circuit using a parallel T filter network.

By reference to Fig. 31.4, it will be seen that the minimum value of R_2C_1 will be required for $K = \sqrt{2}$. When $f_\infty = 100$ this gives a value of R_2C_1 not easily obtainable with standard values of components, and $K = 1$ will give more easily obtained values. Also when $K = 1$, the total capacitance required is a minimum. Where use is made of this filter, some attenuation must be provided for the ripple frequency harmonics, and this may be accomplished by means of a resistance-capacitance filter (see Sect. 2). A typical complete circuit is shown in Fig. 31.5.

For the theory of parallel T filter networks reference should be made to Chapter 4, Sect. 8(iii). See also Ref. 1.

SECTION 4 : HUM—GENERAL

(i) Hum due to conditions within the valves (ii) Hum due to circuit design and layout (iii) Hum levels in receivers and amplifiers.

Hum in the output of an a.c. operated receiver or amplifier may be due to many causes. These may be sub-divided into two main groups, hum due to conditions within the valves, and hum due to circuit design and layout.

(i) Hum due to conditions within the valves

This is caused by the use of a.c. for the heater supply and can give rise to hum in the output in several ways :

- (1) capacitive coupling from the heater to any electrode
- (2) heater-to-cathode conduction
- (3) heater-to-cathode emission (or vice versa)
- (4) modulation of the electron stream by the magnetic field of the filament
- (5) conduction (i.e. leakage) from any electrode, with ripple voltage applied, to another electrode
- (6) hum due to operating valve in magnetic field from external source.

Explaining these in more detail :—

(1) The amount of hum appearing at the plate of a valve due to capacitive coupling between the valve heater and an electrode, will depend upon the electrode to which this coupling takes place. The most serious case is that between heater and control grid as the voltage transferred will be subject to the full gain of the valve. In fairly high gain amplifiers it is advisable to use a potentiometer of 100 to 500 ohms resistance across the heater supply close to the valve socket ; the slider is earthed and its position adjusted for minimum hum output. In this way the hum voltages fed from each side of the heater to the control grid can be made equal and opposite.

In lower gain amplifiers a centre-tapped heater winding may be used or, more usually, a centre-tapped resistor across the heater supply. In the latter case the resistor may have a resistance of $50 + 50$ ohms for 6.3 volt heaters. In some cases it is practicable to omit any form of tapping, and in these cases one of the heater terminals should be earthed. In the case of types in which the control grid or plate pin is adjacent to one heater pin, the latter should be earthed. Where the grid pin is separ-

ated from one heater pin only by one other pin, the latter should preferably be earthed directly, or else by-passed to earth by a large condenser. In other cases the heater terminal to be earthed should be chosen to provide minimum hum with regard to the position of un-earthed or unbypassed terminals.

Valves with the grid connection brought out to a top cap have less capacitance coupling between heater and grid circuits, but there may be appreciable electromagnetic coupling into the loop formed by the cathode-to-grid path and the return path through the valve. For this reason it is sometimes found that a double-ended valve gives more hum in a low level amplifier than a well designed single-ended stage.

When single-ended valves are used, the all-glass (e.g. miniature) construction gives less capacitance coupling from heater to grid or plate than an equivalent single-ended valve with a "pinch" (stem press) construction.

Reduction of the grid resistor value will also reduce the hum due to capacitive coupling, as the grid resistor and the heater-to-grid capacitance form a potential divider which determines the proportion of the heater voltage fed to the grid, unless there is a large grid coupling condenser and a low impedance to earth from the other side of it.

Diode-heater capacitance can also cause high hum levels in diode-triodes and diode-pentodes as the diode is effectively coupled to the control grid. For this reason it is recommended that the diode used for signal detection should, in the case of double-diode valves, be the diode further from the heater pins on the valve base.

(2) Conduction from heater to cathode will cause a current to flow from the heater to the cathode, thence through the impedance between cathode and earth. The resultant hum may be minimized by reducing the effective voltage applied to the circuit, and by reducing the impedance between cathode and earth. The voltage may be reduced by a potentiometer connected across the heater supply, with the slider earthed and its position adjusted for minimum hum output—as for hum due to capacitive coupling. The impedance between cathode and earth may be reduced by the use of a large capacitance by-pass condenser across the cathode bias resistor, or may be made zero by earthing the cathode and obtaining negative bias from some hum-free source.

See also Ref. 7.

(3) Emission from heater to cathode is caused by impurities in the heater insulation material or from the deposit, during valve manufacture, of cathode material on to the heater. To overcome this fault the heater should be biased positively with respect to the cathode. As the voltage required may be of the order of 50 volts, the minimum required to give satisfactory hum reduction should be used to avoid exceeding the maximum permissible heater-cathode voltage.

Cathode-to-heater emission can also take place and cause hum, although it is not common. The cure for this is the biasing of the heater negatively with respect to cathode.

In the general case hum may be due to two or more causes, and minimum hum may be obtained in any particular case by connecting the moving arm of the potentiometer to a point of positive (or sometimes negative) voltage of the order of 5 to 50 volts and by experimentally obtaining optimum adjustment of both potentiometer and voltage.

(4) Modulation of the electron stream by the magnetic field will depend on the type of heater and the electrode construction. If the centre-point of the heater circuit is earthed, the double helix gives noticeably less hum than the folded heater, but when one side of the heater is earthed the reverse may occur, depending on the electrode arrangement—see Ref. 6, Fig. 47.

Heater-induced hum in a-f amplifiers—summary*

The amplifier designer has to make allowance for the total hum, effective at the grid of the valve, due to the use of a.c. supply to the heater. There are very few valve types for which information is available in this regard—see Chapter 18 Sect. 2(v) for hum data on types 12AY7 and 5879. Tables have been published (Ref. 10) giving values of the 60 c/s component of the hum voltage of a fairly wide range of types with

*Contributed by the Editor.

cathode by-passed and unbypassed, grid resistor zero and 0.5 megohm, and with different heater earthing arrangements but this does not give any indication of the total hum and is likely to be misleading since the ratio of total hum to 60 c/s component varies widely from type to type.

By the choice of a suitable valve type (e.g. 5879, triode operation) it is possible to achieve a median hum voltage effective on the grid of less than 4 microvolts under optimum conditions, with only a small percentage exceeding 10 microvolts, with grid resistor 0.1 megohm. On the other hand, with other types of valves and with other than optimum conditions, the hum may exceed 500 microvolts.

See also Chapter 12, Sect. 10(vi) and Chapter 18, Sect. 2(iii).

Refs. 5, 6, 7, 9, 10.

(ii) Hum due to circuit design and layout

The most common of hum troubles due to circuit design is caused by insufficient smoothing in the power supply. Where hum is introduced in the early stages of an amplifier, a simple *RC* filter can often be used (see Sect. 2). *RC* filters can also be used to supplement conventional filtering when lack of filtering in r-f and converter stages causes modulation hum.

Modulation hum can also be caused by capacitive coupling between primary and secondary windings of the mains transformer. The cure is the addition of an earthed electrostatic screen between the windings, or in some cases filters can be fitted in the mains leads as in a.c./d.c. receivers. Every care should be taken to eliminate r-f pickup from all sources other than the aerial, and receivers should be earthed directly rather than connected to the mains conduit which may have a high resistance earth connection. Capacitive coupling between the mains lead and aerial can also cause a mains frequency modulated carrier to be passed through the receiver.

In a.c./d.c. receivers care must be taken in the series connection of heaters. Usual practice is to place the a-f valve heater right at the earthy end, with the converter (which is particularly susceptible to modulation hum) next to it. In a.c./d.c. audio frequency amplifiers the earliest stages should be at the earthy end.

Electrostatic pick up of hum voltages by high impedance circuits from nearby leads carrying alternating currents may be avoided by the fitting of electrostatic shields or, where the capacitance of screened lead is permissible (as in the case of filament wiring) the use of screened a.c. leads is recommended. The use of twisted filament leads tends to cancel out the magnetic field around the leads.

The magnetic fields surrounding power transformers can give rise to induced currents in filter chokes and in a steel chassis. For this reason the use of a separate chassis in the case of high gain amplifiers is to be preferred. Alternatively the chassis may be made of non-magnetic metal. The placing of the power transformer laminations vertically usually gives rise to less hum than when they are placed in the same plane as the chassis, particularly when the chassis is of a magnetic material. Thorough screening of intervalve transformers (and more particularly microphone input transformers) from the magnetic field of the power transformer is also necessary, and high permeability shields or astatic type windings may be necessary in extreme cases to reduce hum to the required level. By orientating transformers and chokes with respect to each other a position of minimum coupling can be found which may avoid the necessity for taking more elaborate measures. If the position of minimum coupling is at all critical, it is recommended that an individual adjustment be made for each amplifier. The filter choke and transformer fields must also be kept away from high gain valves to prevent modulation of the electron stream.

The reason for high hum-level output in a receiver or amplifier can often be determined by the pitch of the note. If it is due to poor filtering, the 50 or 60 c/s in the case of half-wave rectification or the 100 or 120 c/s note with full-wave rectification will predominate. If the hum is induced from the power transformer the note will be 50 or 60 c/s while with capacitive hum pick up the note will be rough owing to the accentuation of the harmonics of the supply frequency.

When tracing hum it may be found that the reduction of hum in one part of the circuit may increase the overall hum level as, when the hum is due to more than one cause, a certain amount of cancellation may be taking place.

See also Chapter 18, Sect. 2(iii) on pre-amplifiers.

Hum caused by heater-cathode leakage with an unbypassed cathode resistor is dealt with in Chapter 7, Sect. 2(ix)B.

The effect of the output valve on hum originating in the plate supply voltage*

(See Chapter 7, Sect. 2(ix) for the effect of feedback).

Case (1)—Triode with transformer-coupled output

The hum output voltage across the primary of the output transformer is

$$E_{h0} = E_h R_L / (R_L + r_p)$$

where E_h = hum voltage in plate supply

R_L = load resistance reflected on to primary of output transformer

and r_p = plate resistance of valve.

If $R_L = 2r_p$ (as is typical)

then $E_{h0} = 0.67 E_h$.

Case (2)—Triode with parallel-feed (series inductor)

This is an excellent circuit for low hum provided that the choke L_1 has a reactance at the hum frequency at least several times the impedance of r_p and R_L in parallel.

See Chapter 7, Sect. 2 equation (55).

$$E_{h0} = \cos \theta, E_h$$

where $\theta = \tan^{-1} L_1 / R$

and $R = r_p R_L / (r_p + R_L)$.

Case (3)—Pentode with transformer-coupled output

See Chapter 7, Sect. 2, equation (53).

$$E_{h0} = E_h [R_L / (R_L + r_p) + R_L \mu_{g2p} / (R_L + r_p)].$$

The screen and plate effects are additive. The second term would become zero if the screen were perfectly filtered.

Case (4)—Pentode with parallel-feed (series inductor)

The hum due to the plate circuit is low, but that due to the screen is high. Screen filtering is required for low total hum.

See Chapter 7, Sect. 2, equation (57).

$$E_{h0} \approx E_h \cos \theta - R_L \mu_{g2p} / (R_L + r_p)$$

where θ and R are as in Case (2).

Typical values (all cases)

Typical values for types 2A3 and 6V6 are given in Chapter 13, Sect. 10(v).

(iii) Hum levels in receivers and amplifiers*

It is convenient to express hum levels in dbm, rather than as so many db below maximum power output. This hum is measured with zero signal output.

Hum should, ideally, be completely inaudible. This ideal is capable of achievement, although at a price, so far as the hum introduced by the receiver or amplifier is concerned. Audible hum is a defect which, while it may not prevent the sale of the equipment, will certainly be an annoyance to a critical user.

Hum is objectionable firstly because of its direct effect with zero signal, and secondly because of its indirect effect in modulating the signal.

The maximum acceptable hum level may be determined by a listening test in a quiet residential area, or under actual conditions for a custom-built equipment. The listener for the test should be one having at least average, and preferably higher than average, acuity of hearing for the lower frequencies.

Alternatively, the maximum permissible hum level may be calculated. For example if the predominant hum frequency is 120 c/s, the loudspeaker efficiency at 120 c/s is 3%, the angle of radiation at 120 c/s is 180°, and the listener is 1 foot from the

*Contributed by the Editor.

loudspeaker, then the limit of audibility is about -35 dbm for an average listener, and -45 dbm for a very critical listener. A good quality receiver or amplifier should therefore have a hum level less than -35 dbm for 3% loudspeaker efficiency at the hum frequency. This quoted loudspeaker efficiency of 3% is a fairly typical average value over the a-f frequency band, but the effective efficiency at the hum frequency may be higher or lower than the average value. The efficiency at the hum frequency will be higher than the average value if bass boosting is used, or if the cabinet/loudspeaker combination accentuates the hum frequency. The efficiency at the hum frequency will be lower than the average value if the hum frequency is lower than the loudspeaker bass resonance or if the cabinet attenuates the hum frequency. In cases where the loudspeaker efficiency is higher or lower than 3%, the permissible hum level should be adjusted accordingly.

This calculation for hum is somewhat unrealistic since it is based on the supposition that the hum is predominantly a single frequency. Any higher frequency components will give a higher acoustical hum level without appreciably affecting the measured value.

Summing up

For critical home listening with low room noise and with loudspeakers of normal sensitivity, the hum level should not be above -40 dbm, with -50 dbm as a preferred limit.

Under other conditions, with higher background noise or a less critical audience, a somewhat higher hum level may not be found objectionable.

SECTION 5: HUM NEUTRALIZING

(A) One form of hum neutralizing is that using a hum-bucking coil in series with the voice coil in speakers where the field coil is used as the filter choke.

(B) A valve hum neutralizing system which has certain applications where a substantially constant load is to be supplied is shown in Fig. 31.6. This circuit has been explained in detail elsewhere (Ref. 3) and neutralization is dependent upon the valve producing a hum voltage of the same value and 180° out of phase with that already existing in the plate supply voltage. The valve must therefore be capable of producing a gain of unity between grid and plate, the feedback resistance $R_c (= R_b + R_f)$ being adjusted to obtain this balance.

Fig. 31.6. Valve hum neutralizing circuit.

Fig. 31.7. Practical valve hum neutralizing circuit.

A typical circuit is shown in Fig. 31.7 and the value of ripple reduction α obtained together with the values of R_c are plotted in Fig. 31.8 as a function of R_s .

The lowest ripple frequency which this circuit will suppress depends upon the time constant of $R_c C_g$, which for this circuit is given by $T = R_c C_g / (1 - R_g/R_s)$ provided $\mu \gg 1$, and the internal resistance $R_g = R_s \mu / (\mu + 1)$.

As the condition for neutralization does not involve the load impedance, the relatively high impedance of the regulator can be reduced to a low value for a.c. voltages by shunting the output by a large condenser.

Fig. 31.8. Values of α and R_c as a function of R_s for the circuit of Fig. 31.7.

In this way coupling between stages due to a high common impedance can be reduced.

Care must be taken that the value of input ripple to the circuit does not swing the valve beyond the linear position of its characteristics.

(C) Another form of neutralization, which is limited to pentode voltage amplifiers, is described in Chapter 12 Sect. 10(vi)D and Fig. 12.57.

(D) A form of neutralization suitable for use with multistage amplifiers is described in Ref. 4. Another form is described in Ref. 11.

(E) Various types of neutralizing are commonly used in radio receivers, for example, hum from the back bias supply may be neutralized at the grid of an output valve by hum from the B supply, with a suitable choice of output valve grid leak and plate load resistor for the a-f amplifier. In other cases the balance of these hum components may be adjusted so that the resultant neutralizes hum in the plate circuit of the output valve. More complicated neutralizing circuits even include hum components from the control and screen grids of the a-f amplifier in the balance at the grid of the output valve.

SECTION 1 : VIBRATORS—GENERAL PRINCIPLES

(i) Operation (ii) Vibrator types (iii) Choice of vibrator (iv) Coil energizing
(v) Waveform and time efficiency (vi) Standards for vibrators for auto-radio.

(i) Operation

The vibrator consists essentially of a vibrating reed upon which are mounted switching contacts. By the method of connection in a battery circuit, these contacts enable the direct battery voltage to be converted into an approximate square wave. This can then be transformed and rectified to obtain a plate voltage supply. The standard type vibrators operate at a frequency between 100 and 120 c/s. High frequency types operating about 250 c/s are available for special applications.

FIG. 32.1 INTERRUPTER TYPE VIBRATOR.

(ii) Vibrator types

There are three basic types of vibrator and these are shown with their circuit connections in Figs. 32.1—32.3.

Fig. 32.1 shows the interrupter (non-synchronous) vibrator which acts as a single pole double throw switch, leaving rectification to be performed by a separate rectifier.

FIG. 32.2 SELF-RECTIFYING TYPE VIBRATOR.

The short-circuited secondary is used by some vibrator manufacturers to reduce the inductance of the energizing winding and hence the sparking of the starting contacts.

Fig. 32.2 gives the circuit arrangement for the self-rectifying (synchronous) vibrator which in addition to switching the primary circuit has a further pair of contacts to provide mechanical rectification of the transformer secondary voltage.

The third type, Fig. 32.3, is a modification of the synchronous type in which, by splitting the vibrating reed, the primary and secondary circuits are isolated from each other.

FIG. 32.3 SPLIT-REED SELF-RECTIFYING TYPE VIBRATOR.

(iii) Choice of vibrator

The choice of the type of vibrator to be used will depend upon the application for which it is required.

Where vibrator equipment has to operate with either positive or negative earthed systems, either the interrupter type with a valve rectifier or the reversible self-rectifying type must be used. This latter type is a standard self-rectifying vibrator which can be fitted into its socket in two positions, by rotation through 180°. The use of

these two positions enables the correct output polarity to be obtained from either positive or negative earthed supplies.

In the self-rectifying type, the elimination of the rectifier valve reduces the overall size, power consumption* and heating of the equipment, although at the expense of increased difficulty in hash elimination and, perhaps, of some of the reliability of the non-synchronous type.

The use of split-reed synchronous vibrators allows greater circuit flexibility, particularly in cases in which one model of radio receiver is to be used with dry-battery or vibrator-operated power supplies.

Fig. 32.4. *Separate driver system energizing.*

(iv) Coil energizing

There are three possible methods—Fig. 32.4 shows the separate driver system energizing while Fig. 32.5A shows shunt energizing with separate starting contacts, and Fig. 32.5B is the conventional shunt energizing arrangement. With the separate driver system, the coil is operated by only the battery voltage; in the conventional shunt connection the coil is operated by greater than the battery voltage due to the auto-transformer action of the transformer primary.

Fig. 32.5. *Two alternative methods of shunt coil energizing; (A) with separate starting contacts (B) conventional shunt energizing.*

The advantage claimed for the separate driver system energizing and also for the arrangement shown in Fig. 32.5A, is that as the coil current is not switched by the power contacts, good starting will be obtained even towards the end of life or at low battery voltages. This is not the case in Fig. 32.5B in which the starting performance is dependent upon the condition of the power contacts.

*If a cold-cathode rectifier is used the power consumption of synchronous and non-synchronous types should be the same.

(v) Waveform and time efficiency

The general waveform of a vibrator output voltage is given in Fig. 32.6 ; the periods t_2 and t_4 are referred to as the " off contact " time interval. For reasons of consistent operation with life, these times $t_2 + t_4$ are made from 10% to 30% of the total duration of the cycle. The remaining part of the cycle $t_1 + t_3$, which is the " on contact " time, is therefore from 70% to 90% of the cycle and its value is known as the " time efficiency."

The relationships between the peak, average and r.m.s. values of the vibrator waveform are given below—

$$\text{Peak value} = E_b$$

$$\text{R.M.S. value} = \sqrt{\omega_t E_b}$$

$$\text{Average value} = \omega_t E_b$$

$$\text{Form factor} = \sqrt{\omega_t / \omega_i}$$

where E_b is the battery voltage and ω_t is the time efficiency expressed as a decimal.

The rectangular waveform will be modified to a certain degree by the timing capacitance (see Sect. 3) and will take the approximate form of the dotted curve in Fig. 32.6. This change will not greatly affect the relationships given above.

FIG. 32.6

SECTION 2 : VIBRATOR TRANSFORMER DESIGN

(i) General considerations (ii) Transformer calculations (iii) Standards for vibrator power transformers.

(i) General considerations

There are many considerations in vibrator transformer design which require particular attention as against a similar transformer used on a sinusoidal supply. However see also Chapter 5 Sect. 5 for power transformer design.

For a given power output the vibrator transformer will be of greater size for a number of reasons. Half the primary is inactive at any instant due to the need for a centre-tapped winding to obtain the necessary flux reversal. The primary winding should be designed to have the minimum possible resistance, in order that as large a portion of the battery voltage as possible is available for transformation. This means the use of a wire of large diameter with a correspondingly poor space factor. Electrostatic shields between the windings, which are sometimes used to assist in the elimination of hash, also add to the size.

An important point in the transformer design which affects the life of the vibrator is the value of primary leakage inductance. This leakage inductance component in the primary circuit can resonate with the reflected value of the timing capacitance

to produce an undesired damped oscillation, while possible insulation breakdown and contact arcing may result. Therefore where practicable a winding of the pancake type should be used, or else the winding shown in Fig. 32.7, the windings being arranged so that the active sections of the primary and secondary are always adjacent. When manufacturing economy requires the use of the cheapest form of winding, best results are obtained by winding the two halves of the primary first and then the two halves of the secondary. This gives lower leakage reactance than the reverse type of winding.

FIG. 32.7

The secondary insulation should be good enough to prevent the risk of a voltage breakdown caused by any irregularity occurring in the vibrator during life which may cause high transient voltages to be developed.

As the magnetizing current of a vibrator transformer has to be supplied by the battery, this represents a power loss and it should be reduced to the minimum possible value—for further details see Sect. 3(iv). This can be done by keeping the flux density B at a low value. The value of B will depend upon the primary voltage, all other quantities being fixed. This value of primary voltage is subject to considerable variations; e.g. from 5.5 to 7.5 volts on a car radio input when a voltage regulator is fitted to the battery charging system, and this may rise to 9.0 volts without the regulator. In the general case the transformer may be designed to have satisfactory characteristics at a maximum of 8 volts.

A high value of magnetizing current also limits the maximum output available from the vibrator. This is because the magnetizing current has to be handled by the primary contacts whose current carrying capacity is limited, thus reducing the current rating available for the load.

(ii) Transformer calculations

The equation for vibrator transformers is

$$N_p = \frac{E \cdot \omega_i \cdot 10^8}{4f \cdot B \cdot A} \quad (1)$$

where E = highest battery voltage at which satisfactory operation is required

ω_i = vibrator time efficiency expressed as a decimal

f = vibrator frequency in cycles per second

A = effective cross sectional area (i.e. actual cross sectional area \times the stacking factor) in sq. inches

B = flux density in lines per sq. inch

and N_p = "effective" number of primary turns (i.e. $\frac{1}{2}$ total primary turns).

The value of A can be estimated from the relationship

$$A = \sqrt{W}/5.58 \text{ sq. ins.} \quad (2)$$

where W = primary watts under full load.

The r.m.s. value of the transformer primary current is given by

$$|I_b| = (\sqrt{\omega_i}/\omega_i) \bar{I}_b \quad (3)$$

where \bar{I}_b = average battery current in amperes.

For values of $\omega_t \geq 0.8$, $\sqrt{\omega_t/\omega_t} \approx 1$ and $|I_b| = \bar{I}_b$.

This value of current can be used in the calculation of the required wire diameter.

As the primary is of heavy gauge wire, and has to be centre tapped, it is of advantage to have an even number of primary layers; this brings the centre tap to the outside of the winding. Therefore when commencing the design, where possible it is of advantage to choose the total number of turns ($2N_p$) to give an even number of layers. The required effective cross sectional area of the core is then given by

$$A = E \omega_t 10^6 / (4fBN_p). \quad (4)$$

(iii) Standards for vibrator power transformers

R.M.A. Standard REC-119 "Vibrator power transformers" (Sept. 1948) gives purchase specifications, performance specifications, test equipment and procedure.

SECTION 3 : TIMING CAPACITANCE

- (i) The use of the timing capacitance (ii) Calculation of timing capacitance value
(iii) Percentage closure (iv) Effect of flux density on timing capacitance value.

(i) The use of the timing capacitance

The usual simplified form of the vibrator voltage wave is shown in Fig. 32.8. The dotted curve shows the damped oscillation obtained by the addition of the timing capacitance. In actual operating this oscillation will be suppressed at C when the other contacts connect the battery to the other half of the transformer. The oscillation is shown in full in Fig. 32.8 to illustrate how the first part of the cycle is operative in automatically reversing the battery voltage, so that there is zero potential across the contacts when they make.

FIG. 32.8

(ii) Calculation of timing capacitance value

The value of the timing capacitance, to give the correct frequency of oscillation for the conditions above, is given by

$$C_s = \frac{H.l_m(1 - \omega_t)10^6}{8N_p f E} \mu F \quad (5)$$

where l_m = length of magnetic path in inches

and H = the value given by the BH curves for the transformer iron being used, at the value of B corresponding to the voltage E in the equation above.

The equation will give the required value of timing capacitance C_p to be used across the primary. For reasons of size and economy, it is usual for the timing capacitance to be placed across the secondary. The value of the equivalent secondary capacitance C_s will be $C_p/(N_s/N_p)^2$ microfarad.

While these equations will give an approximation to the required value of timing capacitance, some modification of this value will be required in practice. The final

value should not be decided, until after examination of the voltage waveform obtained. This test should be carried out with a number of samples of the vibrator which it is intended to use.

(iii) Percentage closure

When the waveform of Fig. 32.8 is obtained, by the correct choice of timing capacitance, there is said to be 100% closure. Figs. 32.9 and 32.10 illustrate the effects of over- and under-closure respectively.

FIG. 32.9

As the effect of overclosure is to produce high transient voltages, and as during life the tendency is for t_1 and t_2 to become shorter, the vibrator will rapidly deteriorate. By aiming at slight under-closure the effect during life is for conditions to approach 100% closure.

For this reason a value of approximately 65% closure is chosen for an average case, as shown in Fig. 32.10A—this means a larger value of timing capacitance than indicated by eqn. (5).

FIG. 32.10

FIG. 32.10 A

(iv) Effect of flux density on timing capacitance value

The equation for the timing capacitance shows the need for the careful choice of the value of flux density used in the transformer design. For it will be seen that a change in the ratio of H/E in eqn. (5), such as will take place when working on the curved characteristic of the BH curve, will result in different values of timing capacitance being required at different loads. If the value of H/E is to be kept constant, B must be directly proportional to H over the working range. Examination of Fig. 32.11 will show that this is not the case, even on the straight portion of the BH curve, as a line drawn through the straight portion of the curve would not originate at the junction of the X and Y axes. A more exact approximation to the desired condition can be obtained by working around the knee of the curve; operation at this point will result in greater economy of iron.

In Fig. 32.11 the line OY has been drawn so that the deviation of the BH curve from the ideal curve OY is such that the values AA' , BB' and CC' when transferred to the H scale, represent equal values—in this case $7\frac{1}{2}\%$ of the nominal value. Thus the timing capacitance does not vary by more than $7\frac{1}{2}\%$ for a variation in flux from

32.3 (iv) EFFECT OF FLUX DENSITY ON TIMING CAPACITANCE 1209

53 to 81 kilolines/sq. inch. Point A at 71 kilolines/sq. inch would appear to be, in this particular case, the optimum point where a variation of plus 14% and minus 25.5% can be allowed in the value of B . If this value of B results in an excessive value of magnetizing current, point X corresponding to 61 kilolines/sq. inch could be used.

Likewise any other point could be selected providing other design considerations are satisfied, but the point A represents the optimum as regards the change of timing capacitance with input voltage. The point A can be found for any BH curve by suitable positioning of the line OY.

It should be noted that having decided on the position of OY, and from this deriving the operating centre point, the values of B and H required for the timing capacitance calculation should be read from the line OY.

FIG. 32-11

SECTION 4 : ELIMINATION OF VIBRATOR INTERFERENCE

The methods of eliminating vibrator interference can only be stated in general terms and the final arrangement will depend upon the layout and characteristics of the particular power supply. Where the vibrator power supply is not used with a receiver or similar sensitive equipment, the requirements of 'hash' elimination are less stringent provided that there is no danger of interference being introduced into adjacent equipment.

With sensitive receivers, particularly those covering short wave ranges, it is desirable to use a separate shielded chassis for the vibrator power supply as it may otherwise be impossible to eliminate hash at all points in the tuning range with the receiver aerial wrapped around the battery cable and battery, and with the receiver at maximum sensitivity. Such a chassis may be mounted on the main receiver chassis if desired, and in any case a flexible mounting (such as rubber grommets) is useful in reducing mechanical vibration and hum.

When a separate chassis is used a satisfactory method of construction is to have all hot components, vibrator, vibrator transformer and timing capacitors, in a shielded compartment with the leads from this compartment—normally either two or three—by-passed at or near the point of exit and connected to a r-f choke immediately after leaving the compartment. R-F chokes are less useful on the other side of the shield. A common earthing point can still be used for all components by having a solder lug accessible from both sides of the chassis.

It is sometimes found that better hash reduction is obtained with one or more components earthed in isolated places. However the improved results at one frequency are usually at the expense of increased hash at some other frequency. If this is not the case, the earthing point is liable to be critical and perhaps variable from unit to unit, i.e. the improvement is due to cancellation of hash and not to elimination. This is undesirable in prototypes of equipment which is later to be mass-produced.

R-F chokes are liable to have an appreciable field around them and layout must be such as to avoid introducing hash from such fields into circuits which have already been filtered. Special types of by-pass capacitors are available with braided leads to reduce their r-f impedance. These can give a considerable improvement over standard types with wire pigtailed. "Spark plates" are also useful. These are by-pass capacitors using the chassis as one plate, a thin sheet of mica as the dielectric and a sheet of say brass as the "hot" plate, the assembly being held together with insulated eyelets.

Vibrator design is rarely a matter for ingenious circuits. Once the transformer and timing capacitors are correctly specified, layout and shielding are the most important considerations and a minimum cost circuit is usually adequate. If trouble is experienced from hash it is not usual for a cure to result from a mere addition of by-pass capacitors to a circuit which already has a normal complement. For instance a unit in which all outgoing leads are "hot" is more likely (assuming reasonable filtering) to suffer from shielding troubles than from insufficient filtering of the leads in question.

A convenient method for investigating the presence or absence of interference at a particular point in a receiver is to use a probe of shielded wire with the end bared and connected through a capacitor to the aerial terminal of the receiver used with the vibrator unit.

Before hash elimination from a prototype vibrator unit can be considered complete it is necessary to carry out the standard tests with a number of vibrator cartridges, some of which have been in service for long periods. Units in which hash suppression is only sufficient to silence the hash from new vibrator cartridges in good condition may give poor apparent cartridge life owing to the need for replacement as soon as sparking and the consequent interference occur due to slight wear.

In Fig. 32.12 are shown the more usual arrangements and typical circuit values are given as a guide to the choice of suitable components. The timing capacitance is centre-tapped and its centre point is earthed. The two 100 ohm resistors, R_1 and R_2 ,

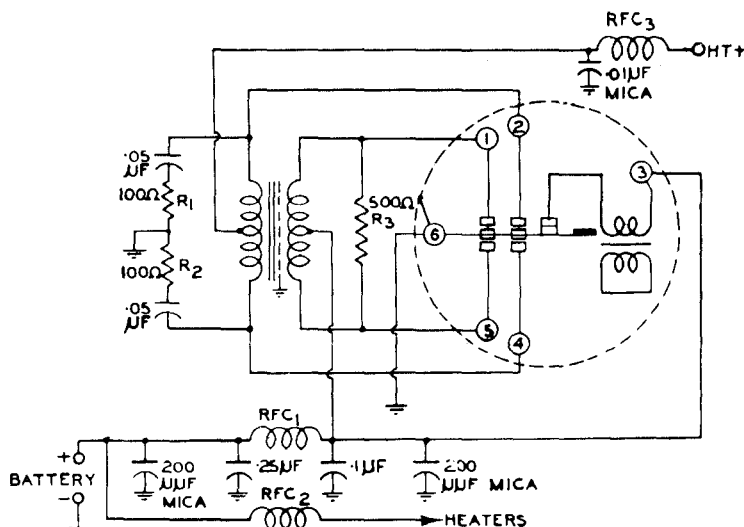

FIG. 32-12 TYPICAL VIBRATOR POWER SUPPLY SHOWING INTERFERENCE SUPPRESSION COMPONENTS

are not for hash elimination but to protect the vibrator transformer in the event of a timing capacitance short-circuiting. RFC_1 and RFC_2 are low resistance r-f chokes made of heavy gauge wire. RFC_1 prevents interference being fed back along the battery leads which could result in these leads radiating interference to the aerial. RFC_2 prevents interference entering the r-f section of the receiver through the heater wiring. RFC_3 , a standard receiver r-f choke, is to eliminate interference frequencies in the plate voltage supply. The resistor R_3 is useful in eliminating the strong impulse interference which usually exists, although at the expense of some battery current. Alternatively, two separate resistors in series may be used across the primary contacts, the centre point of these being earthed.

In 12, 24 and 32 volt systems where part of the timing capacitance is usually placed across the primary circuit to aid starting, this capacitance has been found to be effective in reducing interference. This method can be used for 6 volt systems to reduce the interference, but if the transformer has considerable leakage inductance increased trouble may be experienced with spurious resonances—see Sect. 2(i).

SECTION 5 : 12, 24 and 32 VOLT VIBRATOR SUPPLIES

While the higher voltage of the 12, 24 and 32 volt systems has some advantages over the 6 volt systems, special precautions are necessary if successful vibrator operation is to be obtained.

The higher voltage and consequently lower current, for the same power input, reduce the percentage voltage drop in the battery leads. The larger number of primary turns which are required results in an improved space factor and the centre tapping of the primary winding is made easier because of the larger number of layers and smaller wire diameter.

Against these advantages are the disadvantages of the additional circuit arrangements required for limiting the current during the starting period. Owing to the higher voltages existing across the contacts, ionization of the air between them will

more readily take place. This condition is particularly serious on starting where the correct conditions for the vibrator have not stabilized and heavy currents may flow.

Fig. 32.13 shows a method of overcoming this difficulty, a three position switch being used to introduce some resistance into the battery lead for the starting condition.

FIG. 32.13 STARTING ARRANGEMENTS FOR 24 AND 32 VOLT VIBRATORS.

Condensers across the contacts to suppress the arc are not to be recommended unless the minimum value that just suppresses the arc is used. By splitting the timing capacitance and placing part of it across the primary, arcing can be reduced. If this is done, consideration should be given to possible resonances with the primary leakage inductance due to imperfect addition of the split timing capacitance—see Sect. 2(i).

We wish to give acknowledgment to P. R. Mallory and Co., Inc., for much of the information and some of the diagrams in this Chapter, which have been adapted from their publication "Fundamental Principles of Vibrator Power Supply Design."

SECTION 1 : CURRENT REGULATORS

(i) *Barretters* (ii) *Negative temperature coefficient resistors (Thermistors).*

(i) Barretters

In a.c./d.c. receivers, the valve heaters are wired in series and connected across the mains supply. If the total of the heater voltages is less than the mains voltage a current-limiting fixed resistor or a barretter is used in series with the heater circuit to absorb the extra voltage.

The disadvantage of the fixed resistor is that the current variations through the heater circuit are greater than if the circuit consisted of valve heaters alone.

See Chapter 35 Sect. 6 for the application of series resistors and barretters to a.c./d.c. receivers.

To maintain a constant current through the series heater circuit, with widely varying mains voltages, a barretter is generally employed. This consists of a hydrogen-filled tube containing an iron filament and has the property of nearly constant current flow for wide variations in voltage across it. The actual voltage limits between which satisfactory current regulation is obtained are stated by the manufacturers, and the barretters should be chosen with regard to these values.

Fig. 33.1. *The characteristic of a typical barretter.*

A typical barretter characteristic is shown in Fig. 33.1 ; the portion of the curve within the dotted rectangle showing the useful operating voltage range and the tolerances on the current regulated by the barretter.

It should be noted that the barretter is subject to a large surge current when switching on as the resistance of the valve heaters is then only about one seventh or one tenth of their hot (running) resistance.

In certain cases, a maximum total of heater voltage to be connected in series with the barretter is specified on the manufacturer's data sheets. This then protects the regulator against excessive surge currents which would shorten its life.

Owing to the iron filament, barretters should be kept well clear of any magnetic field which could damage them and for this reason a magnetic screen is sometimes used around them. As considerable power is dissipated in the barretter, the magnetic shield should be perforated and good ventilation provided. The barretter should always be operated in a vertical position, base down.

Occasionally it is desired to increase, by a small amount, the current controlled by a barretter and this may be done, within certain limits, by operating it in parallel with a fixed resistance. This is not normally recommended since the effectiveness of the barretter is reduced. It may be used fairly satisfactorily for an increase of current up to about 10% of the current in the barretter.

If the barretter is required to control a current which is smaller than its current rating, this may be accomplished by shunting the current-regulated device by a resistor to bring the total load current up to the normal barretter current.

As with any other device, a barretter has manufacturing tolerances, but these are such that if a design is based on an average sample then no damage is likely to be done to the valves with any individual barretter.

(ii) Negative temperature coefficient resistors (Thermistors)

These are described in Chapter 4 Sect. 9(i)n.

SECTION 2 : VOLTAGE REGULATORS

(i) Gaseous tube voltage regulators (ii) Valve voltage regulators.

In cases where stability of plate voltage supply is essential, some form of voltage regulation must be provided to prevent changes due either to mains input or load current variations.

(i) Gaseous tube voltage regulators

The electronic voltage regulator is shown in its simplest form in Fig. 33.2. In this circuit a gas-filled two electrode tube is used as the voltage regulator. The characteristics of this tube are such that quite large variations of current through the tube do not greatly alter the potential drop across it.

The circuit of Fig. 33.2 regulates the output voltage within certain interdependent limits of input voltage and load resistance. If the input voltage increases for constant load resistance or the load resistance increases for constant input voltage then in either case the voltage across R_L tends to increase. As E_R tends to rise, the regulator tube takes more current and increases the voltage drop across R_1 , maintaining the voltage E_R at nearly its original value. The resistor R_1 is essential to obtain voltage regulation. Furthermore, as the striking voltage of the regulator tube is higher than its operating voltage, R_1 is necessary to prevent excessive tube current. Table 1 gives values of minimum supply voltages required for starting the regulator tube, together with starting and operating voltages of typical tubes.

Referring to Fig. 33.2, if E_{in} = input voltage and I_t = regulator tube current, the following equation holds

$$E_R = E_{in} - (I_L + I_t) R_1 \quad (1)$$

The range of regulation or the maximum change in E_{in} or R_L within the region of regulation can be determined accurately for any conditions of operation by substituting in eqn. (1) the limits of the variables E_{in} , I_L , I_t , R_L . The regulator tube must operate between the published limits of current rating. The change in one of the variables E_{in} , or R_L , can be much greater than in the other and when one of these changes is small the approximate range of regulation can be simply obtained by considering either E_{in} or R_L constant. If these conditions apply and E_R is constant it follows by equating the partial differentiations of eqn. (1) to zero

$$\text{that } \frac{\Delta E_{in}}{E_{in}} = \frac{R_1 \Delta I_t}{E_{in}} \quad (R_L \text{ constant}) \quad (2)$$

$$\text{and } \frac{\Delta I_L}{I_L} = - \frac{\Delta I_t}{I_t} \quad (E_{in} \text{ constant}) \quad (3)$$

where ΔE_{in} , ΔI_L , ΔI_t are the small increments in E_{in} , I_L , I_t . The range of regulation is obtained by inserting in these equations the maximum value of ΔI_t .

TABLE 1

Regulator Tube Type	Approximate Operating Voltage	Approximate Starting Voltage	Minimum Supply Voltage
OA2 (miniature)	150	160	185
OA3	75	100	105
OB2 (miniature)	108	115	133
OC3	105	115	133
OD3	150	160	185

Operation about the midpoint of the type OD3 characteristic gives ΔI_t (max.) = $(40 - 5)/2 = 17.5$ mA. Consider the regulator subject to small changes in load. If for example $I_L = 175$ mA, from eqn. (3) the range of regulation $\Delta I_L/I_L = 17.5/175 = 10\%$. Equation (2) shows that a large range of regulations with variable E_{in} is obtained when R_1 is large, i.e. when a large part of E_{in} appears across R_1 .

When small load currents are required and variations in E_{in} and R_L are small, satisfactory regulation can be obtained by operating the regulator tube at low average current.

Regulation is frequently desired when R_L varies over the very large range from no load to full load. In this case R_1 is adjusted so that at no load the maximum tube current at maximum input voltage does not exceed the tube's rating, i.e., 40 mA for type OD3. Load voltage regulation is then obtained from zero load current to nearly 35 mA if changes in E_{in} are small.

The tube voltage of types OD3, OC3 can change over their operating range by approximately 3% and this represents their limit of regulation under wide range conditions.

If higher regulated voltages are required two or more tubes can be connected in series as in Fig. 33.3. Additional stabilized voltages may be taken off the individual tubes as shown. Tapping points may be provided on R_{L2} to give lower voltages, however if the load varies, good regulation will be obtained only if the current drawn from the tapping point is very small compared with the current through R_{L2} . Grid bias supplies for class A amplifiers may be effectively stabilized by the circuit of Fig. 33.2 with tapings as required—see chapter 13 Sect. 10(ii).

The use of gaseous regulator tubes in parallel is not to be recommended as resistors must be put in series with each tube so that all tubes will start and share current equally. These resistors impair voltage regulation. Therefore when large currents have to be handled, grid controlled valve voltage regulators must be used.

FIG. 33.2

Fig. 33.2. Simplest form of gaseous tube voltage regulator.

FIG. 33.3

Fig. 33.3. Higher regulated voltage provided by two gaseous tubes in series.

(ii) Valve voltage regulators

A typical valve voltage regulator is shown in Fig. 33.4. The valve V_1 acts as a variable resistance whose value is varied by a change in bias. When the output voltage tends to decrease, the grid voltage of V_2 becomes less positive. As the cathode voltage

and positive with respect to the grid, the fall in the positive value of the grid will increase the negative bias on the valve, and I_b will decrease. This decrease of plate current will cause an increase in the voltage at the plate of V_2 . The plate of V_2 being directly connected to the grid of V_1 will cause a drop in the negative bias on V_1 and the plate-cathode voltage will decrease, tending to restore the original voltage drop across E_R .

The complete mathematical analysis of voltage regulator performance is fairly complex and for detailed information reference should be made to the bibliography at the end of this chapter.

For practical purposes of voltage regulator design, the following method may be used.

Fig. 33.4. A typical valve voltage regulator.

Referring again to Fig. 33.4. If constant output voltage is to be maintained across the load, the valve V_1 must be capable of adjusting its voltage drop to compensate for voltage input changes. A similar condition exists if the input voltage is constant and variable output voltage is required. The valve has therefore to satisfy conditions at four points as set out in Table 2.

TABLE 2

Point	Output	Valve V_1	
		Plate Voltage	Plate Current
1	Maximum Voltage Maximum I_L	Supply Voltage Maximum Output Voltage	Maximum I_L
2	Maximum Voltage Minimum I_L	Supply Voltage Maximum Output Voltage	Minimum I_L
3	Minimum Voltage Maximum I_L	Supply Voltage Minimum Output Voltage	Maximum I_L
4	Minimum Voltage Minimum I_L	Supply Voltage Minimum Output Voltage	Minimum I_L

Each of these four points has its particular limitations as regards the operation of the valve to maintain the correct operating conditions without exceeding the maximum ratings. Reference should be made to Fig. 33.5 in which these four points are plotted for a triode-connected type 807 valve.

Point 1—this point must be kept in the negative grid-bias region of the curve and a bias of not less than -3 volts may be taken as the design minimum. This point must also be kept below the maximum plate or screen dissipation curve (whichever is first reached), and below the recommended value of current for a steady d.c. oper-

Fig. 33.5. Plate characteristics of triode-connected 807 valve to illustrate operation of the valve as a voltage regulator.

ting condition. It is important that point 1 be kept above a certain minimum value of plate voltage if linear characteristics are to be obtained from V_{11} , a value of not less than 125 volts on the plate being recommended.

Point 2—In order that this point should not come in the non-linear portion of the plate characteristics, a bleed should be arranged across the supply to limit the minimum current. This also aids power supply regulation (see Chapter 30 Sect. 3).

Point 3—This point should be kept below the maximum dissipation curve and below the maximum rated plate voltage for the valve being used.

Point 4—This point should be kept above the non-linear portion of the characteristics by means of a bleed as in (2) and also kept below the maximum plate voltage value for the valve being used.

The maximum recommended usable section of the valve characteristic for type 807 is shown enclosed by ABCD in Fig. 33.5.

While it is possible to use higher plate current values at low plate voltages than appear in the diagram before the plate dissipation is exceeded, this is not to be recommended as reduced valve life may result.

From the graphical construction can be seen the effect of large variations of input voltage to the regulator with varying output currents (i.e. poor regulation of the power supply). This will cause the point 2 to move along the plate voltage axis, which results in a reduction of the maximum variation of output voltage obtainable. When the power supply has good regulation and the input voltage is substantially constant, an output variation of ± 125 volts is obtainable about a nominal value. With a constant output voltage the same tolerances may be allowed in the input voltage i.e. ± 125 volts. In each case it is assumed that the circuit conditions are set so that the valve is operating at its centre point for the nominal input or output voltage.

It will be seen from this description that a choke input power supply is advisable. Reference should be made to Chapter 30 Sect. 3 for further information on choke input power supply design.

For minimum voltage loss across V_1 a valve with a high g_m should be used. If the load current required from the regulated supply is greater than that obtainable with one series valve, then two or more valves may be placed in parallel.

TABLE 3

*Screen connected to plate through 500 ohm 1 watt resistor.

Having now determined the operating conditions for V_1 , the design may be extended to consider the operating conditions for the amplifier valve V_2 .

From the knowledge of the voltage drop in V_1 required for the four operating points, the corresponding bias values can be determined. The voltage drop across the resistor R_1 is then given by the voltage drop across V_1 plus the required grid bias for V_1 .

Having determined these voltages, the resistance R_1 can be chosen to have a value which will give plate current values for the amplifier valve which are on the linear portion of its plate characteristics.

The higher the gain of V_2 , the better will be the regulation, as a smaller change in output will be effective in adjusting the voltage drop across V_2 to correct the output voltage change. For this reason a pentode is recommended, the additional complication of adding a screen supply being small for the improvement obtained.

In general, the plate voltage for V_2 should be derived, through its plate load resistance R_1 from the input voltage to the regulator, so that even at low output voltages not less than the minimum voltage drop of V_1 plus its grid bias voltage will exist across R_1 . The exception to this connection will be when the output voltage of the regulator is to be constant at a value of 200 or greater and the input voltage is to be varying over wide limits; the effect of connecting R_1 to the input in this case would be to reduce the effective gain of the valve.

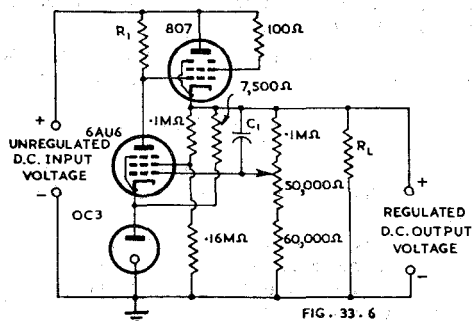

Fig. 33.6. Simplest form of series valve voltage regulator.

The connection of the gaseous voltage regulator tube V_3 also requires some consideration. It has been mentioned in Sect. 2(i) that changing the current through a voltage regulator tube will produce a small change of voltage across it. As this tube is used as the reference voltage for the regulator, any change in potential across it will have an adverse effect upon the regulator performance. For this reason, if a constant output voltage regulator is being designed, the series feed resistor for this tube should be supplied from the output side of the regulator, the extra current drawn by this tube being taken into account when considering the current rating for V_1 . In cases where the regulator has to supply varying output voltages, V_3 may be supplied from the input if this is sufficiently constant; preferably, V_3 should be supplied from a separate source.

Fig. 33.7. Operation characteristics of circuit Fig. 33.6—output versus input voltage.

Circuits of typical voltage regulators and their performance figures are given in Figs. 33.6 to 33.14.

In Fig. 33.6 is shown the simplest form of series valve voltage regulator, which, however, with the circuit components and values shown, is capable of good performance. The results obtained with this regulator are shown in Figs. 33.7 and 33.8, from which several points should be noted. The variation of heater voltage as well as the input

Fig. 33.8. Operation characteristics of circuit Fig. 33.6—output voltage versus load current.

direct voltage, the usual practical case, results in better regulation than that obtained with only direct voltage changes. This is due to a slight change of plate current in V_s together with other minor circuit changes caused by the variation of cathode temperature in the valves. For rapid input voltage changes the regulation characteristic will be as for direct input voltage changes only since the cathode temperature cannot change rapidly. A value of 250 000 ohms for R_1 will be found to be sufficient for most purposes as little increase in gain is obtained by increasing R_L above this value.

Fig. 33.9. Valve voltage regulator in which the screen is used to correct for input voltage changes.

Such a value will allow this resistor as well as all others to be wire wound if particularly stable operation is required.

No advantage is gained in the circuit of Fig. 33.6 in stabilizing the screen supply, this already being supplied from a substantially constant source. However screen stabilization is necessary when the screen is used to correct for input direct voltage changes. A circuit of this type is shown in Fig. 33.9 and a constant or overcorrected output is obtainable.

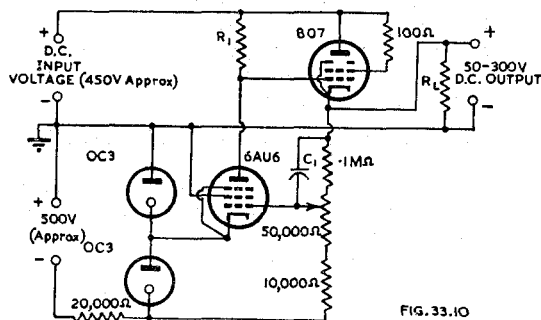

FIG. 33.10

Fig. 33.10. Valve voltage regulator with a controllable output voltage.

The circuit of Fig. 33.10 is useful where a controllable output voltage is required and is suitable for output voltages from 50 to 300. Regulation characteristics for this regulator are shown in Figs. 33.11 and 33.12.

Fig. 33.11. Regulation characteristics for circuit of Fig. 33.10—output versus input voltage.

FIG. 33.12

Fig. 33.12. Regulation characteristics for circuit of Fig. 33.10—output voltage versus load current.

To draw a constant value of bleed current from the variable voltage supply, in order to prevent soaring of the output voltage on no load, some form of constant current device must be used. Refer to explanation of points 2 and 4 under Table 2. A suitable circuit is shown in Fig. 33.13 in which a 6V6-GT type valve is used as a constant current pentode; with plate voltages from 50 to 300 the plate current will only vary from 18.5 to 19.0 mA.

FIG. 33.13

Fig. 33.13. Valve voltage regulator with a controllable output voltage as Fig. 33.10 but including constant current pentode to draw constant bleed current for varying output voltages.

The condenser C_1 in all circuits assists in the reduction of ripple from the regulated supply as the grid of V_2 then obtains the full ripple voltage from the supply instead of the fraction determined by the values R_3 , R_4 and R_5 (Fig. 33.4). This condenser should have a value not greater than that required for satisfactory ripple suppression as large values will cause a time lag in the operation of the output voltage control, a value of .01 to .1 μF being satisfactory for most purposes.

The need for negative voltage supplies for several of the given circuits need not require the addition of a separate power supply; reference should be made to Chapter 30 Sect. 6 which gives details of shunt diode bias supplies which would be suitable for this purpose. The regulator tube current in typical circuits, except Fig. 33.14,

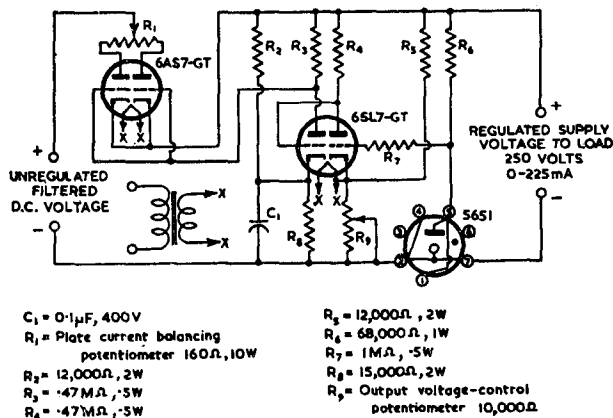

FIG. 33.14

Fig. 33.14. Voltage regulator utilizing a special voltage reference tube (type 5651) to give extremely good voltage regulation.

may be adjusted to have a value of approx. 10 mA at the normal operating point of the regulator.

For most applications these circuits will give adequate regulation but for details on compensated and the more complicated regulators reference should be made to the bibliography at the end of this chapter.

The main limitation of all these regulators is the difficulty of obtaining a completely stable reference voltage, as gaseous voltage regulator tubes may stabilize at slightly different voltages when the unit is switched off and on again. This means that, although nearly perfect voltage regulation may be obtained, the voltage about which this regulation takes place is not always a constant value.

This defect may be minimized by the use of a special voltage reference tube such as R.C.A. type 5651 as, for example, in the circuit of Fig. 33.14. The unregulated input is approximately 375 volts at zero load current and 325 volts at 225 mA load current. The variation of output voltage is less than 0.1 volt for a variation of $\pm 10\%$ in input voltage when operated at maximum load current. When adjusted to an output of 250 volts, the variation in output voltage is less than 0.2 volt over the current range from 0 to 225 mA.

SECTION 1 : INTRODUCTION AND SIMPLE RECEIVERS

(i) *Types of receivers* (ii) *Crystal sets* (iii) *Regenerative receivers* (iv) *Super-regenerative receivers* (v) *Tuned radio-frequency receivers.*

(i) Types of receivers

Radio receivers may be divided into several categories as the following tabulation shows :—

- (a) crystal
- (b) regenerative
- (c) superregenerative
- (d) tuned-radio-frequency
- (e) superheterodyne
- (f) synchrodyne.

(ii) Crystal sets

The simplest type of receiver employs a crystal such as galena, plus a “catwhisker,” for a detector. This, together with a suitable tuned circuit and a pair of headphones, forms a satisfactory local station receiving set. Its disadvantages are poor sensitivity and selectivity, together with low output. Modern developments have made available “fixed” germanium crystals which are being used satisfactorily as detectors. The transistor, or three element crystal, recently announced, offers the advantage of amplification as well as detection in the one unit.

(iii) Regenerative receivers

Higher sensitivity can be obtained by using a valve as a grid or plate circuit detector. Additional amplification can be obtained by means of reaction ; the feeding back of signal from plate to grid in the correct phase to aid the existing circuit gain. Oscillation will occur if too much feedback is used, hence the necessity for judicious use of the reaction control, particularly for speech modulated signals, which would otherwise be rendered unintelligible. When operated near the point of oscillation, i.e. at maximum sensitivity, the selectivity is such that serious side-band cutting occurs and distortion of the a-f signal results ; this is usually the limiting factor in the amount of feedback that can be successfully employed. As the input circuit is coupled directly to the aerial, should the circuit oscillate, radiation will occur with the risk of interference to other receivers operating nearby—hence the limited use of this circuit. An r-f stage between the aerial and detector assists in minimizing this trouble.

SECTION 2 : THE SUPERHETERODYNE

The superheterodyne receiver as illustrated in Figs. 34.3 and 34.4, has several important advantages over other types of receivers. In the superheterodyne circuit, the incoming signal frequency is changed to a lower frequency, known as the intermediate frequency. The major part of the amplification then takes place at this frequency before detection in the normal manner. The typical superheterodyne tuner consists of several distinct sections. These are :—

- (a) Preselector or r-f amplifier
- (b) 1st detector or mixer
- (c) Oscillator
- (d) I-F amplifier
- (e) 2nd detector.

Section (a) may or may not employ one or more r-f amplifiers. Its main functions are to improve the signal-to-noise ratio and to provide a sufficient degree of selectivity to avoid "double-spotting." This latter is the term applied to the reception of one station transmitting on a certain definite frequency, at more than one point on the tuning dial.

FIG. 34.3

Fig. 34.3. Superheterodyne receiver—block diagram.

The first detector stage receives the modulated signal from the preselector and also an unmodulated signal from a local oscillator. These two r-f signals are arranged to differ by a constant frequency by suitable design of the preselector and oscillator tuning circuit constants. The output of the first detector is tuned to this difference frequency and as a result the original signals and their sum frequency are suppressed.

Various types of first detectors have been used, the most popular being the pentagrid and triode hexode converters (Refer Chapter 25). The tickler-feedback oscillator is very commonly used and optimum adjustment of this circuit minimizes harmonic production with its attendant whistles and spurious responses. It also ensures maximum conversion conductance from the first detector circuit and optimum signal-to-noise ratio.

The fixed frequency amplifier, called the intermediate frequency or i-f amplifier, usually consists of 1 stage, i.e. a valve and two i-f transformers, input and output.

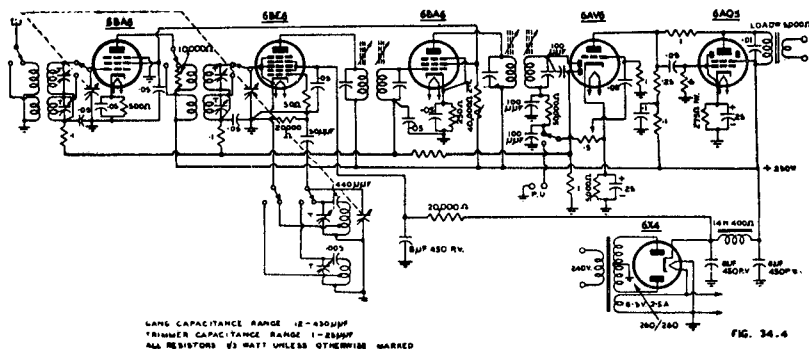

FIG. 34.4

Fig. 34.4. Typical dual-wave superheterodyne receiver.

In wide band and communication receivers, two or more stages are commonly used. The intermediate frequency in general use is 455 Kc/s. Earlier receivers used 175 Kc/s but with the appearance of powdered iron cores and the development of high slope amplifier valves, the previous objection to the use of higher intermediate frequencies, i.e. lower gain, was nullified.

The higher i-f now in use considerably reduces the incidence of "double-spotting" i.e. the reception of the same station at two points on the receiving dial, one removed from the other by twice the intermediate frequency. Thus with an intermediate frequency of 455 Kc/s the first "double-spot" would be at 1460 Kc/s, which is near the upper limit of the broadcast band if this is taken as from 550 to 1600 Kc/s.

As most of the receiver amplification occurs at the intermediate frequency, which is fixed in frequency, the overall gain does not change appreciably with signal tuning. Similarly the selectivity remains approximately constant as this is largely predetermined by the i-f channel.

From the i-f amplifier the signal passes into a second detector stage where the audio frequency modulation is separated from the carrier and then amplified in the normal manner by a conventional a-f amplifier. If, as is usual, a diode detector is employed, the rectified carrier provides a direct voltage which can be used for various control purposes. The principal use is for automatic volume control, or, more exactly, automatic gain control. In this circuit the negative direct voltage, which increases with an increase in signal, is applied through suitable decoupling networks to the r-f, i-f and first detector grids as required. This overcomes, to a considerable degree, the effect known as "fading."

For the reception of continuous wave code signals another oscillator is necessary. The output from this is fed into the second detector and adjusted to give a suitable audio difference frequency, say 1000 c/s, when beating with the incoming code signals.

The advantages of the superheterodyne over the tuned-radio-frequency receiver are :—

- (a) more uniform sensitivity and selectivity over the tuning range,
- (b) stability is greater, as the major part of the amplification takes place at a low radio frequency,
- (c) the i-f amplifier can be designed for minimum sideband cutting, while preserving reasonable gain,
- (d) greater selectivity.

It should be noted that the superheterodyne contains more tuned circuits than the t.r.f. receiver, but fewer tuned circuits are continuously variable.

See References (B).

SECTION 3 : THE SYNCHRODYNE

A newer type of receiver is the "synchrodyne" (Fig. 34.5). In this design, selectivity is obtained without resort to tuned circuits or band-pass filters. The block diagram of Fig. 34.5 will facilitate the understanding of the operation of this circuit which requires no tuning circuits other than that of the oscillator. Here, the desired incoming modulated signal is heterodyned with a local unmodulated signal of the same carrier frequency. The output from the detector, consisting of the required modulation plus unwanted higher frequency components from stations operating on adjacent channels, is then fed to an a-f amplifier through a low-pass filter.

This simple filter can readily be designed to cut off sharply at any requisite point whereas the usual superheterodyne band-pass filters require many elements and generally reduce the response at a considerably lower frequency than that desirable for optimum results.

FIG. 34.5

Fig. 34.5. Synchronodyne receiver—block diagram.

The selectivity of the synchronodyne depends upon the oscillator circuit and a restriction of the frequency band there does not affect the a-f response.

To avoid beats in the output signal the local oscillator must be synchronized or "locked" with the wanted carrier. One advantage of this receiver is that it is either correctly tuned or not tuned at all. Distorted output due to mistuning is thus impossible. The only effect of altering the oscillator tuning within the synchronizing range is to change the volume level.

If necessary, a broad-band r-f amplifier can precede the detector to avoid strong stations overloading the receiver. As in the typical superhet, a.v.c. voltage derived from the detector output can be used for gain control.

The main disadvantage of this receiver is that loud heterodyne whistles are heard when tuning in a station. This defect can be readily overcome by the use of push-button tuning, and hence the synchronodyne is likely to be most popular for high-quality local-station reception.

SECTION 1 : INTRODUCTION

The design of A-M receivers as discussed in this chapter is taken as design for quantity production, since it is normally only under these conditions that a signal generator, a wave analyzer, a low-distortion beat frequency oscillator and suitable valve voltmeter and other meters are available.

The design of the individual stages in a receiver has been covered in the earlier chapters of this Handbook. It is assumed here that the receiver designer has already studied these earlier chapters or has equivalent knowledge. The present chapter covers the design procedure and certain general features which affect more than a single stage.

The first stage in a design is the drawing of the circuit of the receiver. This statement contrasts with the views of those who believe the circuit to be the last stage, but whereas most engineers can readily draw a usable circuit for any normal type of receiver, there are few conscientious engineers who could build such a receiver and not find that after alignment and adjustment they did not wish to make some modifications to remove faults or to improve the performance in some way. Accordingly the circuit is the first stage, modifications to layout and perhaps to the circuit as a result of measurements and operating tests are the second stage, the measurement of all performance figures and checking of all ratings and tolerances the third stage and the making of a final sample the last stage.

The fact that after the final sample is finished it frequently becomes necessary to revert to stage two again, should not be taken as a reflection on the design engineer but rather as an illustration that there is far more to a receiver than the circuit (Ref. 29). What are (apparently) minor changes in layout may introduce unforeseen difficulties with, say, the symmetry of the i-f amplifier, a tendency to instability due to feedback from the i-f amplifier to the aerial terminal or any one of a dozen other possible sources of trouble.

In a good design preliminary calculation will have been carried far enough to ensure that the circuit as first drawn will be such as to allow the specifications to be met with a minimum of components and the model will have been built with an adequate knowledge of the practical troubles likely to be encountered so that they may be a minimum.

SECTION 2 : SPECIFICATIONS AND REQUIREMENTS

The designer of a commercial radio receiver has in general three sets of specifications to meet. Firstly there are the specifications of the relevant authorities in the countries concerned.

Secondly a brief technical specification is usually supplied to the designer. This will include the more obvious electrical features of a receiver such as

1. Power supply details ; a.c., a.c./d.c., accumulator or dry battery, with the required range of operating voltages in the first two cases.
2. Frequency coverage of various wave ranges, including any bandspread ranges.
3. Sensitivity at three points on each wave range covered.
4. Noise ratio, usually at one input only, say 5 μ V.
5. I-F selectivity for an attenuation of 2 times, 10 times, and 1000 times, and perhaps figures for similar conditions on the broadcast band.
6. Image ratio at three points on each wave range covered.
7. Battery consumption for battery receivers and perhaps power consumption for a.c. receivers.

Thirdly, there is usually a large number of requirements which are unwritten and taken for granted as being part of a good design, but which are all-important from the point of view of the ultimate buyer and user of the receiver. These requirements include such details as

8. Suitable a.v.c. and noise performance of the receiver, as discussed later in this chapter.
9. A-F fidelity, including the response of the loudspeaker as mounted in the cabinet.
10. A satisfactory tuning response, i.e., a minimum of unpleasant effects as the receiver is tuned to a strong or weak station or even when tuned between stations.
11. An absence of objectionable hum under all conditions, such as, for instance, with a strong unmodulated carrier tuned in and the volume control well advanced.
12. A low volume level when the volume control has been turned to its minimum position.
13. An absence of microphonic effects under normal conditions of use.
14. An absence of unnecessarily objectionable effects when the volume control is turned up to or past the a-f overload point.
15. A satisfactorily low heat rise in the power transformer and other components after long periods of continuous operation, and operation of all components within their maximum ratings under all conditions.
16. Satisfactory performance from battery operated receivers even when the battery voltage under load has fallen by at least one-third of the original voltage.

SECTION 3 : GENERAL DESIGN

(i) *A.V.C. and noise* (ii) *Audio-frequency response* (iii) *Hum* (iv) *Microphony* (v) *Instability* (vi) *The local oscillator* (vii) *Cabinet design* (viii) *Ratings* (ix) *Field testing*.

(i) A.V.C. and noise

(A) Noise measurements as such can conveniently be made by the e.n.s.i. method as described in Chapter 37 ; however a.v.c. and noise are grouped together in this section as they are plotted on the same a.v.c. curve, around which a large part of the design of a receiver may take place. Such curves are preferably taken by Scroggie's method (Ref. 50) as described in Chapter 27 Sect. 3(xiv) ; Fig. 35.1 shows typical curves which might have been taken during the development of a receiver.

Before the curves are studied in detail it is proposed to discuss briefly the way in which overall receiver noise may vary with the application of a.v.c. bias to different valves in a receiver. Shot noise is generated essentially in the plate circuit of a valve. The expression connecting noise current in the anode circuit, and direct anode current is

$$I_n = A\sqrt{I_a\Delta F} \quad (1)$$

where I_n = noise component of anode current,

I_a = direct anode current

ΔF = bandwidth

and A = a factor which varies with different valve types, triodes having the lowest values, and converters or mixers the highest.

Since the multiplication by g_m of the signal at the grid of a valve gives the plate current due to the signal, so the division of a plate current component by g_m gives the magnitude of an equivalent signal at the grid. Thus the equivalent shot noise at the grid is

$$E_{shot} = \frac{A\sqrt{I_a\Delta F}}{g_m} \quad (2)$$

from which it can be seen that for an equivalent valve type the lower the ratio of $\sqrt{I_a}$ to g_m the lower will be the shot noise of the valve.

It will be found with remote cut-off valves that as the grid bias is increased above the value used to obtain maximum gain the shot noise is also progressively increased. A convenient demonstration of this can be found in Fig. 27.39 which gives characteristics of the 6SK7, a type frequently used as a r-f amplifier. With 5 volts bias the numerical value of the factor $\sqrt{I_a}/g_m$ is 1.6 whilst with 10 volts bias the value is 3.5. Thus the shot noise of the valve has more than doubled when the bias is increased from 5 to 10 volts.

In addition, the gain of the stage is of course also decreased, and if the following stage is contributing to the total noise of the receiver it will add a larger amount to the total equivalent noise as increased negative bias is applied. This is because the noise voltage of the second stage is divided by the gain of the first stage to refer it to the grid of the first valve.

It is worth noting that, if noise calculations are carried out in terms of noise resistance, then the noise resistance of the second stage will be divided by the square of the voltage gain when being referred to the first stage. This follows from eqn. (2) in Chapter 23 Sect. 6 which expresses thermal agitation as a voltage e_n in series with a resistor R where

$$e_n^2 = 4KT\Delta FR.$$

Thus as noise voltages are directly multiplied, or divided, by stage gains, noise resistances must be multiplied, or divided, by the square of the stage gain to give the same result.

With an ideal receiver a ten times increase of signal input would give a ten times increase of signal-to-noise ratio. In addition the output of the receiver would be unchanged (because of the ideal a.v.c. curve) so that the gain of the receiver must decrease ten times and the noise must also decrease ten times. This could be accomplished by decreasing the a-f gain ten times, or by decreasing the gain of any stage which made no contribution to the equivalent noise at the first grid. Such a stage would be one with a large amount of gain between its own grid and the grid of the first stage. If however the gain of the input stage were decreased by a.v.c. bias, even in conjunction with a reduction in gain of other stages, then the noise of the input stage could increase and the improvement in signal to noise ratio be less than the maximum possible.

This applies particularly when the input valve is a converter. From Fig. 23.20 it will be seen that the noise resistance of a 6SA7 is 240 000 ohms whereas the impedance of an aerial coil secondary of 200 microhenries and with an effective Q of 50 is approximately 60 000 ohms when resonated at 1000 Kc/s. With such an input valve and coil, receiver noise would be determined by the input valve noise alone—

see Chapter 23 Sect. 6(iv) for method of adding noise voltages—so that any increase in valve noise would decrease the signal-to-noise ratio.

However if the input valve were a 6SK7 r-f amplifier its noise resistance of 11 000 ohms would be appreciably less than the tuned circuit impedance (at 1000 Kc/s) and an increase in valve noise resistance of 14 db due to a.v.c. application would make less than 3 db difference to the receiver's signal-to-noise ratio. At the low frequency end of the band the tuned circuit impedance would be only about 30 000 ohms and a correspondingly smaller increase in valve noise resistance would be permissible.

On the short wave band, where tuned circuit impedances are of the order of 5000 ohms in the middle of the tuning range, noise from valves must always be considered.

Thus from the point of view of signal-to-noise ratio, the best point of a.v.c. application is the last i-f valve. However with a.v.c. applied to the last i-f valve alone, severe overloading of this valve would occur with quite small inputs. The result therefore must be a compromise and a solution is to delay the application of a.v.c. to the first stage of a receiver until the desired signal-to-noise ratio has been achieved for the smallest possible input, and to apply as much a.v.c. as possible to the stage as the input increases above this point.

The importance of this is not always realized, but money and time spent on improving aerial coils to obtain chiefly a good signal-to-noise ratio at, say, 5 μ V input, can be largely wasted by poor a.v.c. circuit design which at larger inputs wastes the advantage gained. Consider two receivers, A and B. A has a good aerial coil giving a 1000 Kc/s signal-to-noise ratio of 15 db at 5 μ V input and its a.v.c. characteristic is such that a 20 db increase in input gives a 14 db increase in signal-to-noise ratio. B has a poorer input circuit giving a 9 db signal-to-noise ratio at 5 μ V and an a.v.c. characteristic giving 19 db increase in signal-to-noise ratio for each 20 db increase in input. The signal-to-noise ratios of the two receivers for various inputs are tabulated below.

SIGNAL TO NOISE RATIO (db)

Input (μ V)	Receiver A	Receiver B
5	15	9
50	29	28
500	43	47
1000	47	53

It will be seen that although the noise ratio of A is twice as good (6 db difference) as that of B at 5 μ V, yet for an input of 1000 μ V B is twice as good as A. Far more use is made of a receiver with inputs above 80 μ V—where B is superior—than with inputs below 80 μ V where A is superior. In receivers with average a-f characteristics the signal-to-noise ratio cannot be ignored until it is in excess of 40, and preferably 45 db.

A typical a.v.c. design problem is illustrated in Fig. 35.1 where curves A1 and B1 represent the output of a receiver with an input modulated 30% at 400 c/s, and curves A2 and B2 represent the noise output with unmodulated input.

Curves A1 and A2 could be taken on a receiver with high i-f gain, low a-f gain and with a.v.c. obtained from the primary of the 2nd i-f transformer and applied to the converter and i-f amplifier without any delay. The curves show the following faults in the receiver.

(a) The sensitivity of the receiver (for 50 mW output) could readily be improved. As the output is 6 db below 50 mW for 1 μ V input, it could be increased to 50 mW by doubling the input, if the effects of noise were neglected. As some of the output from the 1 μ V input is noise, somewhat more than 2 μ V input would be needed, but the existing sensitivity of the receiver (6.5 μ V) could at least be doubled.

(b) An output of even two watts cannot be obtained from the receiver for a 30% modulated signal less than 1000 μ V. Although all normal signals have a maximum

Fig. 35.1. A.V.C. and noise characteristics.

modulation depth greater than this, experience shows that if the impression of insufficient output on a weak signal is to be avoided, a receiver should deliver its full a-f output from a 30% modulated signal.

(c) The signal-to-noise ratio of the receiver could be improved at any input between 5 μ V and 1000 μ V with the greatest improvement at the higher inputs.

Faults (a) and (b) could be removed by increased a-f gain, perhaps by reduction of negative feedback, or by substituting a pentode a-f amplifier for a triode. For instance the curve A1 shows that with another 6 db of a-f gain the receiver would have a sensitivity of 1 μ V and would give a power output of 2 watts with 80 μ V input. A-F gain is specified since additional i-f gain would alter the a.v.c. characteristic.

However a different modification to the receiver would simultaneously correct faults (a) (b) and (c). Fault (c) is due to the fact that at all inputs above 1 μ V, a.v.c. is applied to input valve of the receiver. This is known because the rate of increase of signal-to-noise ratio is appreciably worse than the ideal. Accordingly an obvious remedy is to use delayed a.v.c., and with the object of obtaining the maximum possible signal-to-noise ratio up to 100 μ V, the delay might be removed at this figure, with results as shown in B1 and B2. From these curves the following information is obtained.

(a) The sensitivity of the receiver (for 50 mW output) is now slightly better than 3 μ V.

(b) An input of 20 μ V will give an output of 2 watts.

(c) The noise ratios of the receiver before and after modification are as tabulated below.

SIGNAL-TO-NOISE RATIO (db)

Input μ V	Original receiver	Modified receiver
5	9	10
10	14	15½
10²	29	34½
10³	—	43

Correction of the three previous faults has however introduced other troubles.

(d) Although the a.v.c. characteristic of the receiver is now flat within ± 2 db for inputs varying between 100 and 100 000 μ V, severe modulation rise occurs with inputs

of the order of 1 volt. This is because the much larger signal at the plate of the last i-f valve (3 times larger with 0.1 volt input) is causing overloading.

(e) With any input from 100 μV upwards, the a-f system will be severely overloaded if the volume control is turned to maximum. In other words the useful range of the control is decreased and the receiver will behave unpleasantly if carelessly handled.

Depending on the amount of design time and component expenditure which can be afforded, a compromise between the various faults might take the form of

(a) No delay to the a.v.c. and only a fraction (say one half) of the developed a.v.c. voltage applied to the controlled grids. This would allow curve A1 to rise more rapidly, and would minimize the increase in noise in the first valve with a.v.c. application.

(b) A smaller amount of delay than that used for curve B1. An appropriate amount would allow the receiver output to reach its maximum just as the delay disappeared. This would give maximum possible signal-to-noise ratio up to about 30 μV only.

(c) A better solution might be to use a fraction of simple a.v.c. on the i-f valve and full delayed a.v.c. on the first valve. By this means the signal-to-noise ratio could increase at the maximum rate until say 500 μV input, without the maximum output rising excessively, and for larger inputs the first valve could be heavily controlled.

For further information which can be obtained from curves such as those shown in Fig. 35.1 see Chapter 27 Sect. 3.

(B) Miscellaneous matters

1. Consideration of a typical a.v.c. curve will show that it is quite possible to have too much a-f gain (Refs. 26, 31) or too much i-f gain in a normal receiver. Too much a-f gain will merely move the whole a.v.c. curve upwards, and after full output from a receiver can be obtained for some reasonably small input, any further increase in a-f gain will allow severe overloading to occur with the volume control at maximum, and increase any hum troubles.

On the other hand as i-f gain is increased, so developed a.v.c. voltages are increased and an extremely sensitive i-f channel could develop sufficient a.v.c. to bias the valves back appreciably for 1 μV input. As a result the signal handling capabilities of the valves would be seriously reduced at large inputs due to their having unnecessarily high bias.

It is even possible to have too much r-f gain, at least on a particular band. If the gain of a r-f stage is 50 on the broadcast band, and 10 at the low frequency end of the short wave band, then the a.v.c. curves for the two bands can only be a compromise, and if there is sufficient sensitivity on the short wave band, excessive a.v.c. voltages will be developed with large inputs on the broadcast band, leading to i-f overloading.

A convenient method of reducing broadcast band r-f gain is to tune the high impedance r-f transformer primary to a very low frequency by using an additional capacitance, say 80 μF , across a 4 mH primary. This method has the advantage of reducing the pulling of the primary on the tuned secondary circuit which may minimize tracking problems. Also it needs no additional switching as the wave ranges are changed.

2. Mention has previously been made of the necessity for having a suitable time constant for the a.v.c. system [Chapter 27 Sect. 3(xii)]. One type of distortion which can be very distressing is caused by a time constant which is too small. Under these conditions the potential on the a.v.c. line follows the a-f modulation on the diode load, although because the filter used is a resistance capacitance type, only low frequencies are present and the lower the frequency the less the attenuation by the a.v.c. filter. As a result the i-f gain of the receiver is varied at an a-f rate and while the effect on a single low frequency is to reduce its amplitude, the effect on a musical programme is to modulate the whole a-f output with its lower frequency components. The resulting reproduction sounds very rough, broken up and unpleasant. A time constant of 0.1 second must be regarded as a minimum if this effect is to be avoided and larger values are preferable.

3. Unpleasant tuning effects are usually due to the a-f frequency characteristics of a receiver, the a.v.c. system or a combination of the two (assuming that the receiver is stable under all conditions). So far as the a.v.c. is concerned it can be appreciated that with the a.v.c. voltage derived from the signal diode it is quite possible to overload the first valve in a receiver while a strong station is being tuned in. Signals of 0.5 volt are quite frequently met, and as a receiver having a resonant aerial coil gain of 10 is tuned towards such a station the signal voltage on the grid of the first valve where the selectivity is very poor compared with the selectivity of the i-f channel might reach 4 volts before any appreciable a.v.c. voltage is developed. Since the first valve might be operating with only 3, or even 2, volts of standing bias severe overloading and distortion would occur, although with the receiver tuned in correctly the valve would probably receive enough bias to allow it to handle the signal without distortion. To minimize this trouble a.v.c. is best developed from a less selective source, the primary of the last i-f transformer, even at the expense of another few components. Some advantage in smoothness of tuning is obtained on all stations, apart from extreme cases such as mentioned above, since whenever the receiver is detuned from a station, a larger a.v.c. voltage is obtainable from the less selective source, so that the volume of sound distorted by the mistuning of the receiver is reduced.

4. Although the ideal often aimed at is a flat a.v.c. curve, it must be realised that too close an approach to such an ideal has disadvantages, and is in fact undesirable for a normal A-M commercial receiver. Many receivers are used in situations with high noise levels, although in most cases the noise is of lower amplitude than the local stations. Under these conditions an a.v.c. curve flat from say 10 μV to 1 volt input will be responsible for the receiver making far more noise than is necessary when being tuned between stations.

For the purpose of providing minimum noise between stations, an a.v.c. curve would be designed to be reasonably flat over the range of inputs covering most of the local stations, and at lower inputs would decrease as rapidly as possible. Of course the minimum tuning noise requirement for an a.v.c. curve is not the only one, or even the main one, but it should not be overlooked.

It will be found that the flattest a.v.c. curve that is desirable is one which rises perhaps 20 db between 1 μV and say 250 μV input and increases between 250 μV and the maximum input at the rate of 2 or 3 db for each 10 times increase in input. The noise and static heard on stations below 250 μV give the illusion of a curve much flatter than is actually the case.

(ii) Audio-frequency response

(A) The design of the a-f end of a radio receiver is of particular importance, as its 'tone' is the one feature of a receiver's performance which is continually evident to the user. In spite of flat-frequency-response ideals, the object to be aimed at is always to provide pleasing performance, and consideration of the intended use of a receiver is necessary before it can be known what constitutes pleasing performance.

For the majority of its working life an A-M broadcast receiver provides background music for people whose main attention is concentrated on something else, and the chief purpose of a receiver is consequently to sound pleasant under all conditions.

As a secondary requirement, the frequency range of the receiver should be as great as possible, so long as this does not introduce any undesirable effects. For instance a restricted frequency range is preferable to an extended one with added distortion.

If a receiver were designed with a very flat frequency response the listener's reaction would probably be that it was lacking in bass. This is readily explainable from the effects of scale distortion as discussed in Chapter 14 Sect. 8, and the designer's first modification to the response of the a-f end of a receiver is to increase the bass. This can be done in three ways; an increase which is not affected by any of the receiver's controls; an increase which can be altered by means of a tone control; and an increase which is dependent on the setting of the volume control so that at maximum volume there is little or no bass boost. A circuit of the last type is shown in Fig. 35.2,

or negative feedback can be used as in Fig. 35.3. In each case the values of components shown are typical, but final sizes are governed by the acoustical qualities of the cabinet and loudspeaker, and the response of the remainder of the receiver. See also Chapter 15 Sects. 3 and 10.

There is a limit both in frequency and amplitude to the amount of bass boosting that can be used. Considering frequency first, if the response is too high in the region of 150 c/s, reproduction becomes boomy and is very annoying to listen to for a period of time. Even worse is excessive gain at frequencies lower than the bass resonant frequency of the loudspeaker. These frequencies cannot be reproduced as fundamentals and any output is due to frequency doubling.

In addition the primary impedance of the output transformer falls to such a low value, due to insufficient primary inductance in a normal cheap transformer, that the output valve can only provide a small fraction of its mid-frequency undistorted output before distortion becomes serious at frequencies appreciably below 100 c/s.

Even if these objections are overcome it is found that a good response below 50 c/s in the great majority of radio receivers is a liability rather than an asset, as hum, turntable rumble, wow and extraneous noises from broadcasting stations become objectionable. Within the receiver itself microphonic and hum troubles are increased.

From the aspect of the amplitude of the bass boost it must be remembered that a receiver, with say 4 watts maximum undistorted output and a 12 db bass boost at some frequency below 100 c/s will overload very readily at the bass boost frequency. Assuming power output at low frequencies equal to that at mid-frequencies [which is certainly not the case in an average radio receiver owing to the reduced load impedance and the elliptical load line of the output valve (see Chapter 2 Sect. 4)] then an input which will give 300 milliwatts of output at the mid-frequency will overload the amplifier at the bass boost frequency. Although the overloading is due to low frequency excitation, intermodulation products will occur throughout the a-f spectrum when music is being reproduced.

On the other hand excessive high frequency response can also have undesirable effects. The frequency range from 2500 c/s to 3500 c/s is very unpleasant if over-

Fig. 35.2. Bass boost varied with volume control setting.

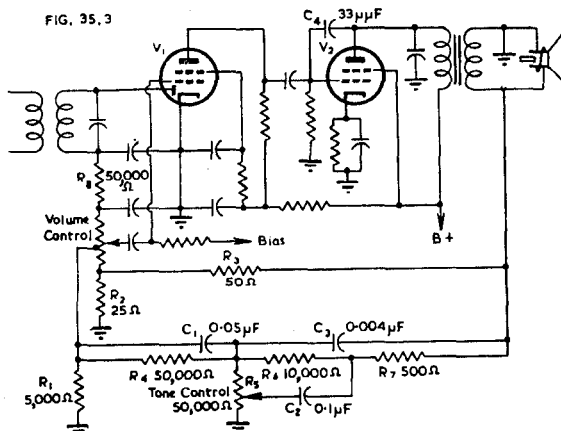

Fig. 35.3. A-F end of receiver with compensated negative feedback and feedback tone control.

accentuated, and where higher frequencies are to be emphasized it is essential that distortion throughout the system be kept to a minimum (Ref. 32).

Particular care must be paid to the tuning characteristics of the receiver if the a-f response is to be extended above 5000 c/s. When listening to a correctly tuned station the selectivity of the receiver normally limits the high frequency input to the a-f end, but during tuning both distortion and emphasis of high frequencies occur, and these effects are exaggerated with an extended high frequency response.

Since in a normal superheterodyne receiver the selectivity is such as to give an attenuation of 6 db at about 3500 c/s and 20 db at about 7500 c/s, it is obvious that the upper end of an a-f response which is flat to 7500 c/s is useless. If any serious attempt is to be made to reproduce frequencies above 5000 c/s the first step to be taken is to broaden the i-f amplifier—Chapter 11 Sect. 3(iii).

It was mentioned above that under conditions of reasonably extended a-f response the distortion throughout the system must be kept to a minimum. The system, of course, can include a recording, a pick-up, and a transmitter, in addition to the receiver, and as only one link in the chain needs to cut the high frequencies from the reproduction—or add distortion—to make extended high frequency response in the receiver either useless or a liability, it is seldom that it is desirable to extend the response of the a-f end of a typical radio receiver beyond about 5000 c/s.

(B) It sometimes becomes necessary to design the frequency response of a receiver to do more than provide the most pleasing tone. For instance, in small battery receivers the a-f output is always restricted because of the small output valve used and the need to economize on battery current, and it is usually desirable to modify the frequency response to make the most of the output that is available. This can be done by providing a comparatively high level between 1000 c/s and 2500 c/s compared with the 400 c/s output. This emphasis should not of course be carried to the stage of making the receiver sound unpleasant either when playing normally, or when overloaded, as receivers with small output are often operated in this latter condition.

(C) In addition, the frequency and damping of the loudspeaker low frequency resonance and the frequency and prominence of the high frequency resonance can have a considerable effect on the apparent maximum output when no electrical frequency compensation is used. If the low frequency resonance is too heavily damped, there will be loss of bass response. In mantle battery-operated receivers the damping is often reduced to the minimum by the use of a power pentode either without feedback or with negative current feedback (e.g. Fig. 35.4). In the latter case there will also be reduction of distortion. Care should be taken when using this circuit that the high frequency response does not extend to frequencies where it is undesirable. A suitable value of resistance for R would be 0.1 or 0.2 ohm (depending on the gain of the a-f amplifier) so that the loss in output power is more than offset by the advantages.

Fig. 35.4 Simple current feedback.

Where frequency compensation is used in a receiver, the speaker resonances are chosen with a different object in view. The electrical response can, owing to the compensation, be raised to any desired level at any frequency within reason, but the loudspeaker will not reproduce satisfactorily frequencies below its main resonance.

Accordingly the frequency of the main resonance is chosen to be as low as possible consistent with the type of receiver—and speaker—being used. For instance the resonance for a 12 inch speaker to operate in a large console model might possibly be as low as 55 to 60 c/s, for an 8 inch speaker in a table model receiver 65 to 70 c/s, and a 6 inch speaker in a small mantel model perhaps 110 c/s.

The high frequency resonance is made as high as possible although for different reasons. When a receiver's high frequency response is increased, a distressing screech occurs if the response between 2500 and 3500 c/s is too high. Many loudspeakers have a peak of sound output in this range of frequencies and when this is the case only a very small amount of high frequency boosting can be used. However if the frequency of the peak can be increased to say 4500 c/s, preferably with a dip between 2500 and 3500 c/s, more high frequency boosting up to say 5000 c/s can be used, and improved results obtained.

(D) The correct application of negative feedback to a radio receiver can reduce the distortion, permit the boosting of appropriate frequencies and provide damping of the loudspeaker bass resonance, but it must be realised that the greater the number of features expected from the feedback, the more critical will be the design. For example bass boosting is usually required at about the same frequency as the loudspeaker main resonance, and unless care is exercised it will be found that when the required bass boosting has been obtained, the feedback may be positive, in the vicinity of the resonant frequency of the loudspeaker, so that the damping required for high quality reproduction will be reduced rather than increased.

Negative feedback is used in the circuit of Fig. 35.3 to give distortion reduction, increased speaker damping, bass boosting, treble boosting with sharp cut-off, hum and minimum volume reduction, a decrease in the low and high frequency boosting as the volume control is advanced, and a tone control. The tone control gives treble boosting at one end, a comparatively flat response in the middle and a treble cut at the other end.

It will be seen that feedback is taken from the voice coil of the loudspeaker to the volume control by two separate paths. The simpler path through the 50 ohm resistor R_3 provides a large amount of feedback, independent of frequency within reasonable limits, to the bottom of the volume control. This serves to reduce hum and play-through with the volume control in its minimum position as explained in Sect. 3(iii) of this chapter. Resistors R_3 and R_2 are designed to provide the desired amount of feedback, which must be limited to avoid instability.

The second feedback path is more complicated but can readily be explained in steps. With the variable tone control R_5 set to the position of maximum treble boost (slider connected to ground), R_7 and C_2 form a voltage divider, and the higher the frequency the smaller the voltage that appears across C_2 . It is this voltage which is the main feedback voltage applied to the amplifier, and the decreasing negative feedback as the frequency increases gives increasing output from the amplifier, thus providing treble boost.

The next component in the main feedback path is the resistor R_6 which isolates the treble and bass boosting sections of the network. In the absence of R_6 , C_1 and C_2 would give $0.033 \mu\text{F}$ to earth from the tap on the volume control. R_6 also serves a purpose in the operation of the tone control to be described below.

The next part of the feedback network is another frequency discriminating voltage divider composed of C_1 and R_1 . The effect of this divider is the reverse of the previous one in that the lower the frequency the smaller the voltage appearing across R_1 , owing to the increasing reactance of C_1 , and as feedback is reduced at low frequencies so the overall gain of the amplifier is increased. In this way the bass boost is obtained. However as mentioned earlier there is a limit to the amount of bass boosting which can be used and to prevent the feedback from increasing indefinitely as the frequency is reduced the resistor R_4 is used.

Excessive high frequency response is also undesirable and capacitor C_3 provides a sharp cut-off above the desired range. The reactance of C_3 is so high at mid-frequencies that it has no effect on the response, but as the frequency becomes higher

it provides a progressively lower impedance path between the source of the feedback voltage and the tap on the volume control. Above the useful range of frequencies it becomes the main feedback path.

To prevent instability at very high frequencies where the fraction of the output voltage fed back to the input is very high owing to the small reactance of C_3 , the gain of the amplifier itself is made to decrease rapidly at frequencies above the desired a-f range. This is the purpose of the $33\ \mu\mu\text{F}$ capacitor C_4 , and it has the added advantage of giving a sharper overall cut-off than could be provided by C_3 alone.

The resistor R_1 has been mentioned as one element of the bass boosting voltage divider, but its size is governed by another consideration, the adjusting of the volume at which maximum bass and treble boost are provided. The feedback current flowing into the tap on the volume control returns to ground by two main paths, the volume control and the resistors R_2 and R_3 in parallel providing one, and the volume control, the decoupling resistor R_4 and the diode-cathode path of V_1 being the other. Thus as the slider of the control is turned up from its minimum setting the amount of frequency-compensated feedback applied to the amplifier is increased until the slider reaches the tap and thereafter decreases. With the slider at the tap, the volume should therefore be the lowest normal listening level so that as the volume is increased, the amount of compensation is reduced. The normal type of tapped volume control has its tap at about 50 000 ohms for a 0.5 megohm control and this gives too much volume for maximum compensation, so the value of R_1 is chosen to reduce it to the required level.

The operation of the tone control is comparatively straightforward. With the slider at the earthed end of the resistance element, R_7 and C_2 remove most of the high frequencies from the feedback path to provide a treble boost. However as the slider is turned away from the earthed end the resistance in the capacitive arm of the voltage divider is increased and its frequency discriminating properties are reduced. For example when the resistance between slider and ground is 5000 ohms the amount of feedback used varies only between 10/11 and 11/11 of the total amount as the frequency is increased from zero to infinity. Thus the treble boost is removed over the first part of the rotation.

When the control is set to the other extreme, C_2 is in parallel with R_8 and the sizes of these components are adjusted so that their impedances are the same in the lower mid-frequency range. Under these conditions C_2 offers an increasingly lower impedance path for feedback currents as the frequency increases above say 400 c/s, and the larger amount of feedback results in a falling high frequency response for the amplifier as a whole.

It must be realised that while the foregoing explanation of the feedback circuit is correct as far as it goes, a complete picture of its operation cannot be obtained without a knowledge of the phase shifts introduced by the various coupling elements both in the feedback circuit and in the main amplifier circuit. Feedback which is 180° out of phase with the input at the mid-frequency is no longer negative when a phase shift of 90° has taken place. In Fig. 35.3 at low frequencies the coupling condensers to the grids of V_1 and V_2 , and the primary of the output transformer will each give a maximum phase shift of 90° while capacitors C_2 , C_1 , the screen by-pass of V_1 , the cathode by-pass of V_2 and the decoupling by-pass in the B supply of V_1 will each give a phase shift with a maximum varying between perhaps 20° and 50° , so it is obvious that the phases of the feedback voltages become far more important than their magnitudes. By far the most difficult part of the design of such a circuit is to maintain the feedback negative over the usable a-f range, rather than to obtain the desired frequency response.

Because of the variation in frequency response with the phase of the feedback voltage it is possible to obtain bass and treble boosting without frequency discriminating elements in the feedback path. Such a circuit would be the same as Fig. 35.3 with all feedback components removed except R_2 and R_3 . In such a case circuit elements such as the grid coupling condensers, which would normally be as large as possible to avoid phase shifts in the working range, would be decreased in size to cause phase

shifts and thus develop a bass boost. This is the reverse of what would be expected from such a change in an amplifier without feedback. Similarly a high frequency boost could be obtained by adding a by-pass in the plate circuit of V_1 or elsewhere.

As the amount of negative feedback applied to an amplifier is increased, the peaks of response at low and high frequencies are removed further from the mid-frequency and become greater in amplitude, and with the fewer components available in the simplified circuit it usually becomes necessary to vary the amount of feedback to assist in obtaining the desired response.

(iii) Hum

The a-f gain in a radio receiver is seldom high enough to make hum elimination difficult except in so far as space or economy considerations make it so. Nevertheless economy is such an ever-present need in commercial design that the majority of receivers have hum reduced to a barely acceptable minimum.

The amount of hum permissible at any stage in a receiver can be expressed as the maximum tolerable hum at the output of the receiver divided by the gain at the appropriate frequency between the output and the stage in question. Thus the filtering required by the plate of the output valve is less than that for any other part of the a-f system. Advantage can be taken of this effect in small receivers, in which the plate of the output valve can be fed directly from the capacitor across the rectifier output. Since the output valve plate draws a large proportion of the total B current in a small receiver, the filter used for the supply for the rest of the receiver can be decreased considerably in size, and it may be possible to use a resistive filter instead of a choke without an excessive voltage drop. It should be noted however that since there is gain between the screen of a normal tetrode or pentode and its plate the screen of the output valve in such a case will probably need to be supplied from the filtered source.

Filtering becomes more important when the grid circuit of the output valve and the plate circuit of the a-f amplifier valve are considered. Designs using back-biasing for the output valve normally have the grid of the output valve decoupled for hum reduction, and similarly the plate supply to the first a-f amplifier is often decoupled. It is worth noting that the hum introduced from these two sources is out of phase, and whilst if one decoupling is used as a matter of course, or if the output valve is cathode biased, the other may become essential, yet the results obtained with both omitted are often satisfactory.

Hum introduced between grid and cathode of the a-f amplifier is usually the most difficult to eliminate since the following amplification is high, and the circuit is usually a high impedance one which makes the effects of small capacitive couplings appreciable. The impedance of course is variable, depending upon the volume control setting, and when tracing hum introduced into this stage it is best to turn the volume control to maximum. If noise from the r-f end of the receiver then drowns the hum, the last i-f valve can be removed.

Hum can be introduced into a receiver before the second detector, although under these circumstances (assuming transformer coupling to the detection diode) it can only be troublesome if it modulates the signal. **Modulation hum** can usually be traced to two general sources, firstly amplitude or frequency modulation of the local oscillator in a superheterodyne receiver by hum from the power supply, and secondly amplitude modulation of the signal in a valve working on a non-linear part of its characteristic and with a hum voltage impressed on one electrode.

Modulation hum due to the local oscillator is as a rule only met when the oscillator plate has a separate filter from the rectifier output to eliminate flutter—see Sect. 3(vi) of this chapter. The filter is usually resistive and arranged to give the proper voltages so that an increase in the size of the filter capacitor is the cure.

Modulation hum occurring because of a non-linear characteristic in a r-f or i-f valve is greatest at the point of maximum non-linearity and this as a rule is at some intermediate value of bias, so that the hum may increase up to some particular input and decrease thereafter. This can readily be checked on the a.v.c. characteristic,

plotted as described earlier in this section. A common reason for this type of hum is insufficient filtering for the screen of a r-f amplifier. If the a.v.c. line carries bias generated across a back bias resistor it is also possible for hum from this source to modulate incoming signals in any of the remote cut-off valves to which a.v.c. is applied.

A third source of modulation hum is sometimes met in a.c./d.c. receivers. Owing to insufficient filtering in the mains leads or perhaps to insufficient shielding, the rectifier becomes a part of the circuit in which signal currents circulate. The signal in this path is modulated by the mains frequency since the rectifier is conductive for only half of each mains frequency cycle. A cure for this type of hum is to use a r-f by-pass across the rectifier, a typical capacitor being a $0.001 \mu\text{F}$ mica type.

A receiver with high a-f gain can give trouble with hum due to potentials developed between different soldering lugs on the chassis, and because of this it is usually best to return directly to the cathode of the a-f valve any leads coming from the 'earthy' side of components in the grid circuit of the valve. In addition, the lead between cathode and ground must be separate from the lead earthing one side of the valve's heater. When building the pilot model of a receiver which is likely to give hum trouble it is best to take all possible precautions initially, trying any economy measures one by one after the model is in operation. The alternative of building first for maximum economy may lead to delay, since when several sources of hum are present cancellation usually occurs, and the removal of one source may lead to an increase in total hum.

One aspect of hum which can be put to good use during design is that a hum level which is objectionable at very low listening levels may be satisfactory at higher levels when it is masked by the programme. A circuit which at very small cost reduces hum at the minimum volume setting of the volume control is shown in Fig. 35.5. The connection from the voice coil is in the direction to give negative feedback, and this feedback is a maximum with the volume control turned to zero, decreasing as the volume control is turned up, until at maximum volume the gain of the receiver is reduced only by one or two db. The feedback is also valuable in reducing play-through, and this aspect has a particular application in reflex receivers.

There is a maximum value of feedback which can be used without instability, and in a high gain amplifier use of the full amount of feedback available from the voice coil may give trouble (see Chapter 7 Sect. 3). In addition, the feedback into the bottom of the diode load results in an apparent reduction of the a.c./d.c. impedance ratio.

Fig. 35.5. Negative voltage feedback varied by volume control setting.

The reason for this latter effect can readily be visualized from Fig. 35.5 as follows. Neglecting for the moment the negative feedback, the diode load is the 0.5 megohm resistor R , and an a-f voltage E_a due to the modulation of an incoming carrier produces in the diode load an a-f current I_a of a magnitude given by $I_a = E_a/R$.

Now when feedback is applied, an a-f voltage of magnitude—in a typical case—equal and opposite to E_a with the audio volume control at maximum, is applied to the bottom of the diode load. The a-f voltage across the resistor R is now $2E_a$ and $I_a' = 2E_a/R$

where I_a' = a-f current in diode load with feedback applied.

Thus the a-f current flowing in the diode load has been doubled by the application of feedback for the same demodulated a-f signal E_a . An alternative way of considering this effect is that the a-f voltage E_a is generated across an impedance equal to $R/2$. This is the usual conception of the effect, and the explanation for the statement that the a.c./d.c. ratio is reduced by such a feedback application.

Of course as the volume control is turned down from its maximum setting the feedback voltage applied to the bottom of the volume control is reduced and the a.c./d.c. ratio is improved, even although the amount of a-f gain reduction is increased.

To overcome the trouble of possible instability and increased a.c. loading on the diode load when the full voice coil voltage is used for feedback, the circuit of Fig. 35.6A can be used. Resistors R_1 and R_2 may be of equal size, say 25 ohms each, and the phase of the feedback is such that the feedback at the bottom of the diode load is still negative, so that the feedback into the top of the diode load is positive. The values of the resistors can readily be arranged so that the gain reduction with the volume control at maximum is zero, when the a.c./d.c. ratio is no worse than in the no-feedback condition.

It is quite possible of course to have positive feedback predominating, giving an a.c./d.c. ratio greater than unity, but the reduced detection distortion in this case may be more than offset by increased a-f distortion.

Fig. 35.6A. Combination of positive and negative voltage feedback.

When tracing hum it is essential to be in a location quiet enough for the character of the hum to be recognisable, and a meter reading hum amplitude and an oscilloscope showing hum waveform can each be useful on occasions.

The amount of hum which can be tolerated is very dependent on the frequency of the hum, and pure 50 c/s hum could be of much greater amplitude than say a 150 c/s hum for two reasons. Firstly, the sensitivity of the ear is greatly reduced at 50 c/s, and secondly the sensitivity of the reproducing equipment also decreases rapidly below the resonance of the loudspeaker. Nevertheless a receiver with a small speaker which cannot reproduce 100 c/s satisfactorily can suffer badly from 100 c/s modulation hum, which, although not audible in itself, modulates any other audio frequencies which are present and thus gives a very harsh, broken-up type of reproduction.

Since the effects of hum are to such a large extent subjective it is natural that final approval in a doubtful case must come from a listening test. It is essential that such a test be carried out in a home under the quietest conditions possible, as the masking effects of noise in a normal factory, or even laboratory, make an evaluation of the hum level very difficult.

See also Chapter 31 for a general treatment of hum, Chapter 7 Sect. 2(ix) for hum with feedback, Chapter 12 Sect. 10(vi) for hum in voltage amplifiers, and Chapter 18 Sect. 2(iii) for hum in pre-amplifiers

(iv) Microphony

Microphonic effects in electronic equipment are those in which mechanical movement produces undesired electrical output from the equipment. Many such effects are self-sustaining in that the microphonic noise produced reinforces the original mechanical movement and a continuous output builds up at the frequency of the mechanical vibration.

There are two main sources of microphony in an A-M receiver, the local oscillator and its circuit, and valves. Since all tuned circuits and all valves are microphonic to some extent, the object of a designer when laying out a receiver must be to isolate from the output of the loudspeaker those components which are most likely to give trouble.

Tuning condensers probably give more microphonic trouble than any other component, although frequently this is due to the mounting method used or to the dial drum. Some receivers have the complete tuning unit (condenser, coils, wave-change switch and valves) mounted on a subchassis which is floated on rubber. This precaution, although comparatively expensive, is usually sufficient to remove any microphony, and even the cheaper solution of floating the gang condenser alone will usually give a substantial improvement. A drawback to the use of floating tuning units is that as a rule the dial and tuning knob must float too, or flexible couplings must be provided to them, in which case backlash between the tuning knob and the gang condenser or the dial usually becomes a problem.

The type of gang condenser microphony which can be cured by floating the condenser is usually due to movement of masses of metal such as the complete gang body, or the whole rotor shaft, and an alternative to floating the gang is to make it more rigid. The first step is to stiffen the body by soldering with large fillets of solder the junctions between the cross bracing strips and bars, and the end and dividing plates in the gang. For extreme cases it may be necessary to solder a plate to the back of the body of the oscillator section. An alternative is to mount the gang normally on its feet and then add an additional bracing from the top of the gang to some nearby solid mounting. Such a bracing may be better either rigid or rubber mounted, in the latter case acting more as a vibration damper. A gang condenser with its framework stressed by the mounting is more likely to be microphonic than one which is not stressed. Thus a suitably designed three point mounting may be an improvement on the conventional four point suspension, although in each case care must be taken to see that it is not possible for the condenser to rock.

It does sometimes happen that a complete stator packet vibrates and causes microphony. In such cases it may be possible to reinforce the brackets supporting the stators sufficiently at least to remove the resonance at a frequency at which it will not be troublesome.

Some microphonic effects are due to a large dial drum mounted on the gang spindle. Such a drum may be self resonant if made of metal or it may because of its weight induce flexing effects in the condenser shaft. In other cases its position may give trouble; for instance the drum may be spaced only slightly from the front panel of a mantel model receiver, with the loudspeaker mounted on the same panel. Very considerable acoustical coupling will then exist between the loudspeaker and the gang rotors. Should the drum itself be resonant it may be possible to alter the frequency sufficiently to avoid microphony by punching suitably placed holes in it. Spraying with flock or attaching a piece of felt may damp the resonance adequately.

Another type of gang microphony is due to the vibration of the plates of the condenser. This is more often due to sound waves impinging directly on the plates themselves and acoustical shielding between speaker and gang condenser should be tried as a cure.

Should a valve be causing microphony it can be mounted on a floating socket and shielded as far as possible from the noise from the loudspeaker. Sometimes a rubber sleeve around the glass envelope may effect a cure.

With battery valves, microphony can be affected by circuit design. If the plate current of a remote cut-off valve has been reduced almost to cut-off by a.v.c. action, movement of the filament under the influence of noise from the loudspeaker may cause some sections of the valve which have been completely cut off to conduct again. The resulting change in plate current creates noise in the loudspeaker which maintains the vibration of the filament and the microphony is sustained. An alteration to the circuit which will result in smaller a.v.c. potentials being applied to the valve in question should be tried.

Microphony is also encountered between pickups and loudspeakers, although more recent types of combined gramophone motors, turntables and pickups use very flexible mountings which almost completely remove such troubles.

If the remedies suggested above fail to cure a particular case of microphony there are other methods of attack. The simplest is to mount the loudspeaker on rubber

or felt with no solid connection between loudspeaker and cabinet. Even if this should result in a gap of up to one quarter of an inch between the edge of the loudspeaker frame and the baffle, little change of a-f response need be expected. Such a mounting is, of course, mainly effective in keeping low frequency vibration from the cabinet, and is most likely to cure low frequency microphony.

An alternative method of achieving the same result is to mount the loudspeaker solidly to its baffle, and float loudspeaker and baffle from the cabinet on suitable rubber grommets.

Similar results can be obtained electrically by reducing the bass response of a receiver. If the response is already satisfactory this is undesirable, but it may be found possible to attenuate severely frequencies below say 70 c/s without appreciably affecting the tone, and this could produce the required effect. Alternatively, since microphony is usually much worse on short waves, a bass cut can be switched in with the wave change switch as the receiver is turned to short waves. This possible cure can actually improve short wave reception since fading and noise can be less objectionable with a restricted bass response.

Since some types of microphony are due to a change in receiver output as the oscillator frequency is varied, it follows that the greater the selectivity of a receiver, the more prone it will be to this type of microphony. Receivers with a sharp peak to the selectivity curve are particularly susceptible and this is frequently caused by regeneration in the i-f channel which may be reduced by improved layout or by neutralization—see Chapter 26 Sect. 8(ii).

(v) Instability

This sub-section is confined to instability problems commonly met in A-M receivers. For general information on the subject see Ref. 22.

Probably the most common trouble with new models when wired up for the first time is instability, although the reason can usually be found with little trouble by bypassing possible “hot” points with a large capacitor, say $0.5 \mu\text{F}$, or by placing an earthed piece of metal between stages across which feedback is likely to occur.

More annoying instability problems are those which do not show up in pilot models but which affect production receivers, a typical instance being instability which occurs only at the low frequency end of the broadcast band. The regeneration is due to some of the i-f output being returned to the aerial coil and thus back to the i-f input again. The effect usually becomes evident only towards the low frequency end of the broadcast band where the aerial coil secondary tuning is approaching the intermediate frequency, and in addition the high impedance aerial primary must be resonating at or near the intermediate frequency.

The i-f output is often radiated directly from the second detector valve or from the last i-f transformer, in which case shielding may be needed, or at other times from the loudspeaker leads or frame. Earthing the frame will cure the latter trouble and a r-f bypass in the audio circuit the former.

Since the instability is due to intermediate frequency fed back to the aerial primary, a reduction in impedance of the primary reduces the feedback. A resistor, say 10 000 ohms, across the primary may be sufficient damping, but usually gives a greater loss in gain, selectivity and signal-to-noise ratio than a condenser tuning the primary to a lower frequency than the intermediate frequency. When the latter method is used, additional capacitance due to the aerial can only tune the primary further from the intermediate frequency, but otherwise some critical aerial length may resonate the primary at the intermediate frequency and lead to instability.

Battery receivers are particularly prone to trouble in this respect when operated without an earth, as the aerial capacitance is in series with the capacitance between receiver and ground, so that even a large aerial does not tune the primary much lower in frequency.

A very similar trouble is instability when the receiver is tuned to the second harmonic of the intermediate frequency. In this case the second harmonic is radiated from the second detector circuit—where it has a high amplitude—picked up by the input

circuit and returned to its source. Care in confining the i-f harmonics to appropriate sections of the chassis is sufficient to cure this fault. Sometimes actual instability will not be encountered, but the a-f output of the receiver will decrease as the volume control is turned up over the last few degrees. This is due to rectification by an a-f valve of i-f voltages on its grid, thus increasing the bias on the valve and decreasing its gain. By-passing, or if possible improved layout, will cure this trouble, and it is worth checking with a good oscillograph each new model developed, to see that a-f valves are not handling i-f voltages of the same order of magnitude as the a-f voltages.

A more difficult problem is presented by multistage battery receivers in which coupling occurs in the filament leads. Since some couplings may be regenerative and some degenerative it becomes difficult to determine the true gain. However by filament by-passing and by wiring the valves in a suitable order regeneration can be removed, and if the gain can be spared it is well worth while to introduce degeneration. Under these conditions variations in sensitivity with decreasing battery voltage are minimized.

Battery sets in particular are prone to a type of instability which shows up as a squeal when a strong signal is tuned in rapidly. This is due to interaction between i-f and a-f circuits, and in battery receivers adequate a-f by-passing of the B supply will prevent the trouble from developing when the internal impedance of the battery rises with use. If back biasing is used the resistor may need by-passing for audio frequencies. Filtering of i-f voltages from the a-f end of the receiver is in some cases the only cure necessary for other troubles of this type.

Electrolytic condensers are not always satisfactory r-f by-passes and where more than one i-f stage is returned directly to the B supply an additional paper by-pass is advisable. When two or more circuits have a common by-pass they should be returned to it individually to avoid common impedances.

A tendency to instability at the high frequency end of the short wave band of a receiver is often due to excessive coupling between the signal grid and the oscillator circuit of a receiver and can be cured by coupling from the opposite phase of the oscillator. If a r-f stage is used the trouble may be due to resonance or near resonance in the r-f coil primary and a suitable cure is a small carbon resistor, say 25 ohms, between r-f plate and r-f coil primary.

An indication of the stability of an i-f channel can be obtained from its selectivity curve. While complete symmetry is rarely obtained with the mixture of capacitive and inductive coupling encountered in most receivers, a marked degree of asymmetry at small attenuations can usually be traced to regeneration and it may be difficult to remove the last traces. Apart from coupling due to leads or capacitances inside or outside the amplifying valves—not forgetting capacitances above the chassis where they are apt to be overlooked—magnetic coupling can occur between two transformers either in air, or in the metal of the chassis, the latter trouble being more prevalent with the small spacing occurring with miniature valves.

The two leads from the signal generator should be twisted together when i-f selectivity measurements are made, to keep the loop formed by them as small as possible and so avoid coupling between the first and later stages of the i-f amplifier.

See also Chapter 23 Sect. 7 for instability in r-f amplifiers and Chapter 26 Sect. 8 for instability in i-f amplifiers.

(vi) The local oscillator

(A) Recommended values of **oscillator grid current** are specified for all converter types, and it might be thought that if these values were obtained and the oscillator tuned over the required range, no further design work would be required for the oscillator. However the local oscillator circuit can be responsible in a receiver for flutter, squegging, poor sensitivity with high noise level, unstable short wave tuning, apparently short battery life in battery receivers and other more obscure faults.

(B) The term "**flutter**" covers two different effects, the sound emitted from the loudspeaker being the same in each case. As a strong signal is being tuned in, the voltages in a receiver are varied by the application of a.v.c. to the controlled stages and by the changing plate current of the output valve. If the changes in voltage reach

the oscillator valve the oscillator frequency is altered, and a case could be visualized in which the tuning-in of a station generated voltages sufficient to detune the receiver. The additional voltages would then disappear and the receiver would retune the signal, only to be detuned again. This is actually what happens when a receiver flutters, although the station may not be completely tuned and detuned on each cycle. The time taken for a cycle is dependent on the time constants of the circuits involved, but it is usually low enough for each cycle to be heard separately.

The voltage applied to the oscillator may come from the B supply or from the a.v.c. In each case a receiver is more prone to the trouble when operating on short waves, since a given percentage of detuning is a larger number of cycles per second than on the medium waveband. If the fault originates in the B supply the effect is that as a carrier is being tuned-in the a-f signal causes a large variation in the current drawn from the B supply by the output valve. This variation in current sets up a voltage across the series impedance of the power supply and this voltage is applied to the oscillator plate and detunes the oscillator from the signal.

The time constants concerned are those of the a-f amplifier and of the power supply, and since the a-f amplifier must amplify the flutter frequency, which is very low, a cure is to decrease the bass response of the a-f amplifier. If this leads to excessive bass cutting—although as in the case of microphony it may be necessary only on the short wave band—the alternative of increasing the time constant of the power supply can be tried. This is not so desirable since a larger electrolytic condenser is required at additional expense.

Fig. 35.6B. Reduction of "flutter" by negative feedback.

A cure which has been used successfully is shown in Fig. 35.6B. The condenser C_2 is connected between B+ and the power valve grid circuit and applies negative feedback to any a.c. potentials (due to flutter or hum) appearing across the B+ filter condenser. The usual decoupling condenser C_1 is also necessary unless the hum level on the B supply is very low (complete cancellation of hum across the B supply is not the same as cancellation of hum across the output transformer primary) and values of $0.1 \mu\text{F}$ for C_1 and $0.05 \mu\text{F}$ for C_2 have been used to give appreciable reduction in flutter while leaving the hum level almost unchanged.

To remove the cause of the flutter, rather than curing the symptoms of the trouble, it is necessary to reduce the impedance common to the oscillator and the output valve. A large part of this impedance is the filter in the B supply, and by supplying the oscillator plate directly from the output of the rectifier a big improvement can be effected. A separate filter to remove the hum from the oscillator plate supply will be needed and typical values are a 20 000-ohm resistor from the rectifier cathode and an $8 \mu\text{F}$ electrolytic condenser. The normal oscillator plate resistor, perhaps 30 000 ohms, is connected from the junction of these components to the oscillator plate. A careful check for modulation hum—see Chapter 37 Sect. 1(vi)H—should be made if this circuit is used.

Flutter due to a.v.c. application to converters is confined to short wave bands, and is due to coupling within the valve between the control grid and the oscillator section. Reference should be made to Chapter 25 Sect. 2 for an explanation of this effect. The simplest cure is to use fixed bias on the converter on the short wave band, and this is not unduly detrimental to receiver performance since the maximum signal

input to be expected on short waves is less than on the broadcast band. The a.v.c. curve will not be so flat with one less stage controlled, but this may be an advantage because it is not desirable to hold receiver output too flat when selective fading is experienced as this unduly emphasizes the accompanying distortion. Even when the a.v.c. applied to the converter does not cause flutter, it may make the tuning of strong signals at the high frequency end of the short wave band very difficult, the effect being that no matter how carefully the tuning knob is handled, the receiver tunes just past the station. In addition, the fading of a signal may cause it to be detuned.

(C) **Squegging** of the local oscillator in a receiver is usually confined to the short wave range, but cases have been encountered on the broadcast band when unusual coupling circuits have been used. Squegging is due to high oscillator amplitude in conjunction with a large time constant in the oscillator grid circuit. Oscillation at the desired frequency becomes interrupted at another frequency which is dependent on the time constants in the oscillator circuit. The interruption frequency may be audible or supersonic and depends upon the rate at which the oscillation amplitude at the desired frequency builds up sufficiently to bias the valve to cut-off, and the time required for the charge on the grid condenser to leak away sufficiently for oscillation to start again.

The possible results of a squegging local oscillator are a very high noise level (with or without multiple tuning points and with or without a heterodyne at each point) when the squegging frequency is supersonic, or a continual squeal when the squegging frequency is in the audible range. Such a squeal should not be confused with another which sounds almost identical and which is due to signal grid and oscillator grid circuits being tuned to approximately the same frequency on the short wave band. This second type can be stopped by detuning the signal frequency circuit, but a squeal due to squegging can not.

A third squeal which sometimes occurs at the high frequency end of the broadcast or short-wave band sounds similar but needs a small resistor (say 25 ohms carbon) in series with the control grid of a converter, as close to the grid as possible, for a cure.

The simplest remedy for squegging is to reduce the oscillator grid capacitor and resistor to the lowest values that can be used without reducing unduly the oscillator grid current at the lowest tuning frequency. This may not be sufficient if the same components are used on both the broadcast band and the short wave band (100 $\mu\mu\text{F}$ and 25 000 ohms are about the smallest combination possible if these components are not to affect the oscillator amplitude excessively at frequencies below 600 Kc/s) and a simple alternative is to switch the grid coupling condenser together with the coil as the wave range is changed.

A third possibility is to connect a small carbon resistor in series with the oscillator grid capacitor or oscillator plate lead. This resistor reduces the amplitude of oscillation at and near the high frequency end of the band, where it is a maximum, without noticeably affecting the low frequency end, and thus removes the tendency to squeg.

The varying effect of the resistor can readily be visualized when it is realised that at the high frequency end of the band the total tuning capacitance may be 30 $\mu\mu\text{F}$ and the resistor is in series with the oscillator input which amounts to about 10 $\mu\mu\text{F}$, or one third of the total. At the low frequency end of the range the 10 $\mu\mu\text{F}$ with the resistor in series amounts to only about one fiftieth of the total capacitance.

(D) To produce the required **oscillator grid current** at a specified frequency is usually simple, but to obtain the same grid current over a range of frequencies which is usually greater than three to one can be quite difficult. Fortunately considerable variation in grid current is possible with little change in conversion characteristics and full use is made of this in design.

Battery receivers usually present the most difficult local oscillator problems because of the lower initial slope in the oscillator section of the converter and because of the necessity for the oscillator to operate with A and B batteries reduced to (preferably) 2/3 of their initial voltage. For this reason **battery converter problems** are considered here.

The first trouble to be experienced is usually insufficient grid current at the low frequency end of the short wave band—assuming that preliminary design is such as to allow the required band to be covered. Figure 35.7 shows a simple circuit ("padder feedback") for increasing this grid current without loss of frequency coverage, the only variation from a conventional circuit being that the cold end of the primary coil is connected to the cold end of the secondary. If this circuit is already in use, attention must be given to coil design as discussed in Chapter 11 Sect. 5.

Fig. 35.7. Oscillator circuit with padder feedback.

With valves which do not oscillate readily at high frequencies, it sometimes happens that a frequency range which is impossible when mixing with the oscillator fundamental can be covered with the second harmonic of the oscillator used for mixing. This method of operation also has the advantage of practically eliminating pulling and, in spite of decreased gain at the low frequency end of the short wave band and additional spurious responses arising from unwanted signals bearing with the oscillator fundamental, it is often worth trying.

It is important to remember that it is the voltage across a grid resistor which is the essential requirement. The oscillator grid current published by valve manufacturers is used because it is easier to measure, but it only applies to the published value of grid resistance. If a different value of grid resistance is used, the grid current should be inversely proportional to the ratio of the resistances. For example, if the published grid current is 0.4 mA in 50 000 ohms, then the equivalent value would be 0.8 mA in a 25 000 ohm resistor.

A choice of series feeding or shunt feeding the oscillator plate is often available (see Figs. 24.2B and C for series and shunt feeding of a tuned plate oscillator). An increase in grid current, dependent in size on the value of the resistor used, can be obtained by using series feed as this removes the damping of the resistor from the plate coil.

With series fed oscillator circuits, an increase in coverage can be obtained by connecting the by-pass capacitor in the oscillator plate supply directly to the cold end of the oscillator primary coil, rather than to some other place in the circuit. All oscillator wiring must be kept as short as possible and removed as far as possible from other components and from the chassis if maximum frequency coverage is to be obtained. As the oscillator grid capacitor is in series with the capacitance of the oscillator valve it should be kept as small as possible, and if the capacitor is switched with the oscillator coil, a substantial improvement in frequency coverage can be obtained by the use of the smallest possible value. At the same time the effect of the change in oscillator input capacitance as the valve warms up is reduced, thereby increasing the frequency stability.

It is unfortunate that in battery receivers, in which frequency coverage with sufficient grid current is difficult to obtain, it is also necessary for the oscillator to provide sufficient output for reasonable conversion conductance when the battery voltage is considerably reduced. As a routine test during oscillator coil design for battery receivers, the sensitivity should be checked from time to time with A and B battery voltages simultaneously reduced to two thirds of their initial values, with a converter valve having an oscillator slope as low as is likely to be encountered in production, and under these conditions the oscillator should not only start readily each time the receiver is switched on, but it should also provide enough grid current to give reasonable conversion conductance.

It should be remembered when laying out any receiver that the characteristics of the valves can be seriously affected by the presence of a **magnetic field**. All valves are likely to fall off in performance if placed too close to a loudspeaker, and oscillator grid current can be seriously reduced in this way.

(E) In a.c. receivers it is a simple matter to obtain sufficient oscillator grid current but excessive values should be avoided. On the broadcast band, where so many signals can be tuned, self generated spurious responses must be reduced to a minimum and it is helpful to **reduce the oscillator amplitude** as far as possible. This should be done experimentally as it is found that the reduction can be carried, without undue loss of sensitivity, further than would be expected from a study of published curves of conversion conductance versus oscillator voltage. Signal-to-noise ratio should also be measured when the grid current is reduced as it may even improve with moderately low values of oscillator voltage.

An additional advantage of using the lowest possible oscillator grid current is that radiation from the local oscillator is reduced.

(F) **With most converters it is found that the shortwave sensitivity is affected when the oscillator frequency is changed from one side of the signal frequency to the other.** The reasons for this are set out in Chapter 25 Sect. 2(ii), but it is not always realised that a useful gain in short-wave sensitivity can be obtained with certain types of converters by determining the better method of operation and using it, even if this necessitates an oscillator frequency lower than the signal frequency. Under these conditions the signal frequency circuit (or circuits) is padded and the oscillator circuit is not, but no other changes are necessary, and an increase in sensitivity of two or three times at the high frequency end of the short wave band is sometimes obtainable. In addition image responses are reduced proportionately.

A disadvantage of operating the oscillator on the low frequency side of the signal is that a given ratio of signal frequencies becomes more difficult to cover.

Under all conditions it is advisable to make sure that the converter is not in need of neutralizing on short waves. Neutralization of oscillator voltages in the signal frequency circuit need not require additional components, as an undesired voltage from the oscillator grid circuit can often be offset by a wiring change which increases the capacitance between the oscillator plate and the control grid and vice versa, the wiring to and the capacitances of the wave change switch being very useful for this purpose. **Plate tuned oscillators** develop high oscillator voltages in the plate circuit and need particular care in layout even on the broadcast band.

(vii) Cabinet design

(A) The subject of cabinet design for direct radiator loudspeakers is covered in Chapter 20 Sect. 3. Open-back cabinets have many shortcomings—see Chapter 20 Sect. 3(ii). Completely enclosed cabinets, even with an enclosed volume as small as 2 cubic feet, are capable of giving very much improved low frequency response—see Chapter 20 Sect. 3(iii). Vented baffles give about 3 db additional response over a limited frequency range equivalent to bass boosting—see Chapter 20 Sect. 3(iv).

The cloth used for loudspeaker grilles should be very light and of suitable texture—see Chapter 20 Sect. 1(viii).

Some form of diffuser is highly desirable to increase the angle of radiation at the higher frequencies—see Chapter 20 Sect. 2(vii). One simple form of diffuser is cone shaped and mounted directly in front of the loudspeaker.

Sharp angles (e.g. 90°) on the exterior front of the cabinet should be avoided because of deleterious diffraction effects—see Chapter 20 Sect. 3(vii).

In console and radiogram cabinets improved reproduction can be obtained if the speaker can be directed upwards, particularly if the controls are on the top of the receiver. The high frequencies produced by a loudspeaker are propagated in a beam, and where the speaker is mounted close to the floor the high frequencies do not reach ear level unless the loudspeaker is directed upwards.

When two loudspeakers are used, both reproducing high frequencies, a desirable effect can be obtained by directing the speakers outwards at an angle of about 30°

with respect to each other and upwards if necessary. In this way the high frequency response is spread over a much greater angle.

(B) A small amount of time spent on the **ventilation** of a receiver in a cabinet to which a back is fitted can often materially reduce the operating temperature of the components. Provision must be made for cold air to enter near the bottom of the cabinet and to leave it at the top. The components which affect the frequency of the local oscillator should have a supply of air from outside the receiver passing over them before it passes over any other heat sources. Ventilation should also be provided to permit a copious flow of air to pass over the output and rectifier valves and power transformer.

An efficient ventilation system is essential in the case of small a.c./d.c. receivers. For the power—of the order of 60 watts in a typical case—to be dissipated by radiation alone, the cabinet and the components inside it would rise to excessive temperatures, so that the greatest possible amount of heat should be carried away by convection.

This involves a maximum volume of air passing through the receiver at as high a speed as possible, so that restrictions on the flow must be minimized and the air paths provided should be as direct as possible. At the same time all heat sources within the receiver must be included in the ventilation system.

In the case of wooden cabinets it is essential that some means be employed for preventing hot spots from forming on the timber. Ventilation is the best method where it is possible, but in extreme cases it may be necessary to use asbestos sheeting to protect the wood. Failure to avoid hot spots will sooner or later result in the finish of the cabinet being marred where the heat is excessive, although the seriousness of the blemish will depend on the quality of the veneering and on the type of finish.

When investigating ventilation, it is helpful to allow cigarette smoke to be drawn into the back of the receiver, and to watch its course through, and exit from, the receiver, which should be at operating temperature.

See also Chapter 3 page 81.

(viii) Ratings

Standard laboratory tests in most cases cover the requirement that all components be operated within their ratings. There are some cases however where circumstances arise under which components may be over-run, although the operating conditions under test may be quite satisfactory. A typical case is that of an i-f valve screen by-pass condenser on which the no-signal operating voltage may be 80 volts, rising to perhaps 180 volts when a strong signal is tuned in, and to 380 volts for some 15 or 20 seconds every time the receiver is switched on. The last effect would be due to the use of a directly heated rectifier with a complement of indirectly heated valves and of course a condenser with a working voltage of at least 400 must be used.

Whilst such a case would rarely be overlooked, it should be remembered that even with an indirectly heated rectifier, the same high voltages may be experienced for a shorter time, and electrolytic and other condenser **working** voltages should be specified accordingly.

Other points which have given trouble are

(A) **The screen dissipation of an output valve** should always be checked with a large signal input to, and a large a-f output from, the receiver. A large signal input biases the controlled valves, thus causing the B supply voltage to rise and the bias to decrease if back bias is used, whilst the large a-f output increases the screen dissipation.

The output valve **plate dissipation maximum** will occur with a large r-f signal and no output, since any output is subtracted from the plate dissipation.

(B) If a transformer is to be operated on **frequencies** of 60 c/s and 50 c/s, or 50 c/s and 40 c/s as is the case with transformers in some Australian receivers, the heat run should always be carried out at the lowest rated frequency. The flux density on 40 c/s is 25% higher than on 50 c/s, which will seriously affect the temperature rise.

(C) **The dissipation of the resistors** forming screen circuit voltage dividers changes with applied signal, and the resistor from B supply to screen should be checked under no signal conditions, and the resistor from screen to ground at maximum signal

input. These dissipations should also be checked when the value of each resistor is on the upper or lower tolerance limit, whichever will give the greater dissipation.

(D) **When 1.4 volt valves are operated in series across a 6 volt wet battery**, a large capacitance (500 μ F) electrolytic capacitor is often used to by-pass some of the valves. It frequently happens that every time the receiver is turned on, this capacitor is charged through one or more of the filaments in the string. The resulting flash can readily be seen and can seriously reduce the life of the valve, although the filament voltage may be correct when tested.

Special cases of one sort or another occur in most receivers and emphasize the need to investigate the worst conditions in every case.

(ix) Field testing

Receiver design is, more than anything else, a matter of compromise between various sets of conflicting requirements. The success with which these compromises have been made can only be judged by operation of the receiver over a period of time under normal operating conditions in the field.

Perhaps the most contentious part of a design centres around the frequency response, and final approval can only be given after prolonged listening, so that the widest possible variety of programme material and listening conditions is included. In a receiver in which distortion is kept to a minimum an extension of the a-f response progressively improves such items as a live-artist programme, but also makes progressively more annoying any poor quality recordings. Whether the best fidelity position of the tone control is one which can be consistently used or not is a question which must be decided over a period of time in a home. It may happen too that an extended a-f response sounds pleasant for one item but, probably because of distortion, becomes irritating if left playing for some hours, even on items of good fidelity. A careful check for listener irritation or fatigue after long periods of listening should be made.

Hum may change its apparent volume or character under quiet conditions, and a different level of background noise can also affect the volume control setting at which maximum frequency compensation is needed.

Controls should of course all operate smoothly and it frequently happens that noisy dial drives are heard for the first time in a home, or it may be that non-technical users find a receiver difficult to tune on short waves owing to insufficient drive reduction ratio between tuning and gang spindles.

The number of small points which may be discovered under field testing conditions could be extended indefinitely, but the main point is that no design is complete until it has been used critically and for a period of time in a home and has been found satisfactory.

SECTION 4 : FREQUENCY RANGES

(i) *Medium frequency receivers* (ii) *Dual wave receivers* (iii) *Multiband receivers*
(iv) *Bandsread receivers.*

(i) Medium frequency receivers

A large percentage of commercial A-M receivers have two wave ranges, medium frequency (say 540 to 1600 Kc/s) and short wave (say 5.9 to 18.4 Mc/s). The short wave band is largely ignored in actual use and in most cases a more useful receiver could be made to sell more cheaply if the short wave range were omitted.

The obvious advantage would be that the cost of the extra components (wave change switch, two coils, s.w. padder and knob, as a minimum) could be used to provide, for instance, improved fidelity which would be available to the user at all times.

Another factor is that, particularly in cheaper receivers, the inclusion of a short-wave band restricts the design, to the detriment of the broadcast band performance. For example, microphonic trouble is far more prevalent on the short wave band and the

bass response of a dual wave receiver is frequently reduced for the sole purpose of *avoiding* short wave microphony ; a.v.c. application to the various stages may be a compromise between the broadcast band and short-wave band requirements; and in order to save money on switching, the final circuit may lead to increased overloading or reduced signal-to-noise ratio on the broadcast band ; to reduce costs it is also customary to operate the s.w. and broadcast aerial primary coils in series, thus *avoiding* switching, but somewhat reducing the broadcast aerial coil performance ; if switching is used, the capacitance between the leads to the switch may on the other hand reduce the broadcast band image ratio.

When a receiver is designed only for the broadcast band it is possible to use less i-f amplification owing to the increased aerial coil gain on medium frequencies (average perhaps 8 times) as against that on the short wave band (average not greater than 2 times). This may result in a more pleasant tuning characteristic as a single i-f stage giving maximum gain usually verges on regeneration.

In an extreme case, say in a 3 valve plus rectifier receiver, the inclusion of a short wave band may even make the difference between a reflex and a straight receiver to obtain the required i-f sensitivity for the short wave band. This introduces the problems of a remote cut-off valve used as an a-f amplifier, rectification in the i-f amplifier, and high play-through as discussed in Chapter 28 Sect. 2(i), for the sake of increased amplification which is cancelled by turning down the volume control.

(ii) Dual wave receivers

In Australia many country areas are outside the daylight service range of medium frequency broadcasting stations and dual wave receivers are used in such districts to receive daylight programmes from short wave stations provided especially for this purpose.

The international allocations for the world wide broadcasting bands are given in Chapter 38 Sect. 4(ii), and it will be noticed that a tuning range of 4.2 : 1 would be needed to provide coverage for all short-wave bands on one wave range. Such a tuning range is impossible with standard components and the usual compromise is to omit the two highest frequency bands and to design receivers which tune from about 5.9 to 18.4 Mc/s. The 13 and 11 metre bands give very variable performance, depending upon ionospheric conditions, and although they can provide some of the best short wave entertainment—owing to the absence of static—when conditions are good they are so often unusable that their omission from a dual-wave receiver is not counted a serious disadvantage.

The signal strengths obtainable from international short wave broadcasting stations are of course less than those from a local medium wave station, and more sensitivity is consequently required from the receiver. A minimum sensitivity for 50 mW output for international short-wave listening might be taken as 25 μ V from 18 to 10 Mc/s, falling off to 50 μ V at 6 Mc/s where static drowns the weaker stations. Local conditions and the aerial used will of course considerably affect the required sensitivity.

Selective fading, i.e. fading accompanied by distortion of the signal, is far more prevalent on short waves than on medium frequencies, and has an effect on the preferred type of a.v.c. curve. A curve which is too flat results in the signal being held at the same output level throughout each individual fading cycle, so that the unpleasant effect of the distortion is greatly emphasized. Even in the absence of distortion a flat curve in a sensitive receiver results in the “troughs” of each fading cycle being filled in with noise (receiver or external) which is much less desirable than the silent space in the programme resulting from an a.v.c. curve sloping steeply at low inputs.

To provide the required difference between the broadcast and short wave a.v.c. curves it is often desirable to use a.v.c. on the converter on the broadcast band and not on the higher frequencies. This has the added advantage of improving the oscillator stability on the short wave band.

The frequency of each fading cycle varies from some seconds for each cycle to many cycles a second on the high frequency bands, and in a good receiver a special tone

control position is sometimes fitted to improve short wave intelligibility. Such a control limits the treble response of the a-f section and also reduces considerably the bass response, which removes the "fluttering" effect of rapid fading cycles and some of the more objectionable features of bursts of static and ignition interference from passing cars.

Microphony is an ever-present problem in the design of dual wave receivers, and Sect. 3(iv) of this chapter is devoted to the subject.

A problem peculiar to receivers with more than one wave band is the resonance of unused coils within an operating wave range. It is usually a low frequency coil which, resonated by its own distributed capacitance, interferes with a higher frequency band, and when broadcast and short wave coils are wound on the same former the effect is aggravated. Even in the absence of inductive coupling however, wave change switch wiring often provides enough coupling to give trouble.

A resonance affecting the oscillator coil is easily detected by measuring oscillator grid current. A sharp dip in the grid current (whether to zero or not) is an indication of an unwanted resonance. With an aerial or r-f coil more care is necessary as the resonance will be indicated only by a reduction in sensitivity over a very narrow band. To check for such an effect the receiver must be tuned in step with the signal generator over the whole tuning range using very small increments of frequency.

Whether the resonance is affecting the oscillator, r-f or aerial coil it can be traced by leaving the receiver tuned to the dip (in grid current or sensitivity) and touching with a conductor the "hot" terminals of the disconnected coils. When the resonating coil is touched the grid current (or sensitivity) will return to normal.

The normal cure for such resonances is to use a wave change switch which earths, when necessary, any low frequency coils as the receiver is switched to a higher frequency band.

One type of resonance which is not cured by earthing occurs when a broadcast band coil is wound with two or more pies. Each pie can be self resonant in some other frequency range and as one end, at most, of each pie is available, short circuiting is not possible. It may be possible with a certain value of capacitance to tune such a resonance to some harmless frequency, or it may be necessary to redistribute the turns on the pies, or to remove the coupling between the self resonant coil and the coil in use.

Since the broadcast range of a typical receiver covers 1100 Kc/s and the short wave range 12.5 Mc/s, a movement of the tuning knob sufficient to tune the receiver through 10 Kc/s on the broadcast band will tune more than 100 Kc/s on the short wave band. The difference between the two tuning rates is so great that it is difficult to provide a tuning ratio sufficiently large for the short wave band which does not make the tuning of broadcast stations undesirably slow. One solution is the use of a large ratio and a weighted "flywheel" tuning spindle which will spin when flicked, allowing rapid broadcast tuning.

The requirement for satisfactory tuning seems to be a certain linear movement of the outside of the tuning control for a given frequency change rather than a particular ratio of rotation between tuning spindle and gang spindle. Thus a possible broadcast drive is a very large knob (at least three inches in diameter) mounted directly on to the gang spindle, although this gives quite critical tuning.

For normal knobs of perhaps one inch diameter a twelve to one ratio between tuning and gang spindles is sufficient for the broadcast band but the short wave ratio should be at least eighteen to one for non-technical users of the receiver.

Probably the best mechanical solution is to use a dual ratio tuning control either with concentric knobs or with one knob and the slow speed tuning available for only one revolution of the tuning knob.

(iii) Multi-band receivers

Little expenditure is involved in the provision of additional short-wave bands in a normal dual-wave receiver, and considerable advantages are possible.

Receivers manufactured for export to some tropical countries need to receive frequencies as low as 2.3 Mc/s as well as the normal broadcasting bands and with two

short wave ranges and one broadcast range it is possible to provide continuous coverage from 22 Mc/s to 540 Kc/s with standard components.

However the more usual type of multi-range receiver is one in which the coverage of individual ranges is restricted by reducing the effective change in tuning capacitance. From the view point of ease of tuning it is best in such receivers to give each range an equal coverage in megacycles rather than an equal tuning ratio, as the highest frequency band may otherwise still be quite difficult to tune.

Improved oscillator performance is possible because higher (if necessary) and more constant values of oscillator grid current can be obtained, while r-f and aerial coil performance can be improved because higher values of inductance can be used.

Microphony is reduced because part of the oscillator tuned circuit capacitance is a fixed capacitor. Further advantages of using a number of short wave tuning ranges are brought out in the next subsection.

(iv) Band-spread receivers

Although the short wave tuning range of a dual-wave receiver is usually greater than 12 Mc/s, with consequent difficulties in tuning, the majority of short-wave programmes are to be found within the 16, 19, 25, 31 and 49 metre international broadcasting bands, which have a combined coverage of only 1.65 Mc/s. If the bands could be arranged consecutively on one tuning scale the tuning speed would be quite acceptable. However their separation in the spectrum makes this impossible, and many ingenious methods have been used to spread the short-wave broadcasting bands without spreading equally the whole short-wave spectrum.

When the actual tuning-in of a short wave station has been made easy by mechanical or electrical means, other possible refinements to short wave tuning become obvious. As adjacent short-wave stations are, with band-spreading, separated by a greater mechanical movement of the tuning control it may be possible to give short wave calibrations sufficiently accurate for the identification and relocation of short-wave stations. This is most desirable.

On the other hand any frequency drift which occurs during warming up is made very obvious by the much greater tuning control travel required to correct it, and unless the drift is only of the order of 10 Kc/s, useful calibrations are not possible.

The various general types of bandspreading are shown clearly in Fig. 35.8 (Ref. 14). The mechanical types mentioned are not commonly used in mass production because the accuracy needed to provide the necessary mechanical amplification without undue backlash is not readily achieved. Nevertheless the National H.R.O. dial is one well known example of the precision drive and scale.

A broad distinction is made on the electrical side of the "family tree" shown in Fig. 35.8 between switched inductance and switched capacitance types of band spreading. However it is quite possible for the two types to be used in one receiver, a capacitor being switched in parallel with a coil to tune it to a lower frequency and an inductor to tune it to a higher frequency band. When fixed capacitors are switched for band selection the frequency stability can be at least as good as when inductors are switched, although for draughting convenience this is not indicated in the figure.

Some of the more unusual band-spreading methods include the use of tuning condensers with specially shaped plates to give very rapid tuning between bands, and adequate spreading on the short wave broadcasting bands. Another ingenious system has a normal tuning condenser coupled to an iron core moving continually into and out of the inductor. This increases and decreases the inductance, and the mechanical coupling is arranged so that on the international bands the inductance variation opposes the capacitance variation, giving very slow tuning, while between the bands the two variations are additive, giving very rapid tuning.

The double frequency changing method mentioned on the chart has the advantages of giving the same tuning range on each spread band and of separating the band-spreading and local oscillator circuits. However it is a comparatively expensive system and its use is limited because of this.

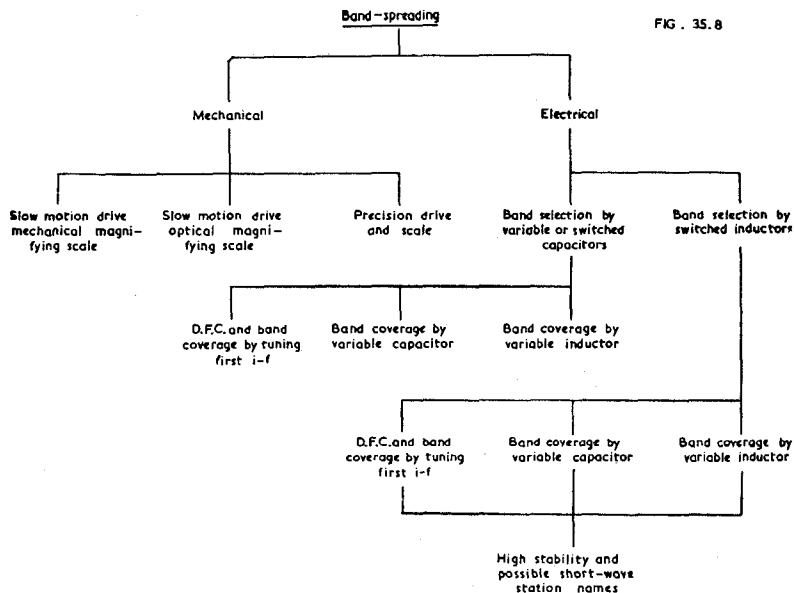

Fig. 35.8. Possible types of bandspreading (from Ref. 14).

Bandspreading by means of moving iron cores has been used in many models, but although this is an electrical type it introduces mechanical problems of core location if the band-spread ranges are calibrated.

The small parallel variable capacitor used for spreading is well known to amateurs but gives a very variable amount of band-spreading, depending upon the capacitance of the main tuning condenser, with which it is in parallel, at different parts of the tuning range. Moreover unless the band-spreading condenser has as many sections as the main tuning condenser the signal frequency circuits become detuned when band-spreading is used. This restricts the proper use of the spreading condenser to the passband of the signal frequency circuits between values of about 6 db loss, and when a r-f stage is used this contains very few broadcasting channels.

A simple method of spreading which avoids the use of an additional tuning condenser is the tapped coil system. When the tuning condenser is tapped down the coil, its effective capacitance is reduced approximately by the square of the tapping ratio. If distributed capacitance across the whole coil is neglected, the coverage at each tapping point will be a constant proportion of the frequency. Distributed capacitance reduces the coverage at the higher frequencies, giving a more nearly equal coverage measured in Kc/s. To restrict the coverage at each tapping point, a capacitor can be connected in parallel (Ref. 20) or in series with the main tuning condenser. Such capacitors can conveniently be brought into circuit by the band-spread switch.

The series capacitor method of bandspreading (Refs. 15, 16) has been widely used. It has the advantage of providing, if desired, continuous coverage of the normal short-wave band (6 to 18 Mc/s) together with tuning on the international broadcasting bands which is comparable with that of the medium wave band. In addition it requires few additional components, all of which are standard types.

Fig. 35.9 shows the essentials of such a band-spreading circuit as applied to an aerial stage. Only two wavebands are shown, but as many as can conveniently be switched can be used. A typical value for the capacitor in series with the gang is $50 \mu\text{F}$ and at the high frequency end of the band, with gang capacitances of the order of $15 \mu\text{F}$ it has only a small effect on the resonant frequency of the tuned circuit. With the gang approaching its maximum setting of $400 \mu\text{F}$ or more, however, C

is the main frequency determining component, as the total capacitance approaches $50\ \mu\mu\text{F}$ asymptotically.

The value of C can be chosen to give continuous short-wave coverage with one international band at the low frequency end of each range, where the maximum band-spreading is obtained. In this case C will have a capacitance of about $57\ \mu\mu\text{F}$ for a typical tuning condenser. Alternatively the requirement might be a tuning rate at least as slow as that at the low frequency end of the broadcast band, in which case C will be $30\ \mu\mu\text{F}$. Padding for the oscillator circuit is obtained by using a smaller series condenser for the oscillator section of the gang, assuming that the oscillator operates at a higher frequency than the signal circuits.

Fig. 35.9. Series-capacitor method of bandspreading.

Fig. 35.10. Bandspread circuit to give linear scale.

The system has the advantage of providing a high L/C ratio, owing to the small maximum tuning capacity, thus giving high gain, and microphony due to the tuning condenser is reduced or eliminated on the spread ranges because capacitance variations in the gang itself are minimized by the series condenser. The main disadvantages are the large number of inductors required—even when full advantage is made of tapped coils—if all short wave bands are to be covered, the unequal spreading within the bands if a large amount of spreading is used, and the small parallel capacitances in the oscillator circuit even on the low frequency ranges, which makes difficult the stabilizing of the oscillator frequency as the valve warms up.

The system just described gives its maximum spreading at the low frequency end of the band. An alternative circuit could be imagined in which no series capacitor was used, but a capacitor in parallel with the gang (say $100\ \mu\mu\text{F}$) gave spreading at the high frequency end of the band. A combination of the two circuits (Fig. 35.10) gives an almost linear spread over the whole tuning range when suitable components are used.

For a case in which one short wave band is to be spread over the whole tuning range, typical values for the components in Fig. 35.10 are

Tuning condenser	12 to $420\ \mu\mu\text{F}$
C_1	$60\ \mu\mu\text{F}$
C_2	$100\ \mu\mu\text{F}$
C_3	$80\ \mu\mu\text{F}$
T	2 to $25\ \mu\mu\text{F}$ trimmer.

These values give a tuning range slightly greater than $400\ \text{Kc/s}$ on the 31 metre band. Although different values of C_3 will obviously affect the tuning range, different bands can be tuned by altering its capacitance and if the oscillator is operated for example on the low frequency side of the $17\ \text{Mc/s}$ band, and on the high frequency side of the adjacent $15\ \text{Mc/s}$ band, the difference in coverage is not serious. Higher frequency bands can be tuned by substituting a smaller inductor, or by connecting another inductor in parallel with the tuned circuit.

The unlimited spreading capabilities of the circuit of Fig. 35.10 allow a short-wave band of $200\ \text{Kc/s}$ to be tuned over the whole dial scale. This is not advisable however, as the tuning becomes too slow, and a suitable minimum tuning range is about $500\ \text{Kc/s}$. A good reason for restricting the tuning range is that a fixed tuned aerial circuit can be used without any serious loss in gain. The gain of an aerial circuit

with an effective Q of 50, tuned to the middle of a band 500 Kc/s wide and including the 15 Mc/s band, falls about 6 db between the centre point and the extremes of the band.

With such a system spreading only the international bands, it may be advisable to provide one short wave band giving continuous coverage from 6 to 18 Mc/s, as many stations of interest are heard outside the bands. This is not a great disadvantage as the components used for continuous coverage can also be used for at least some of the spread ranges.

Apart from the possibility of providing linear spreading up to any reasonable limit (and the consequent need for bandspreading for the oscillator circuit alone in a receiver without a r-f amplifier) the circuit has the advantage of preserving suitable L/C ratios while maintaining at all times a capacitance in parallel with the oscillator input large enough to minimize frequency drift as the valve warms up. Capacitor C_3 can be a temperature compensating condenser to improve the frequency stability.

Microphony from the gang is completely eliminated because, with normal component values, the tuning capacitance is only altered 10% as the gang is turned from maximum to minimum.

An interesting image rejection circuit is given in Ref. 14 (1). Its use is confined to bandspread receivers with a r-f stage and covering one short-wave band only on each band spread range, but image ratios from 35 to 50 db are claimed. Few additional components are required.

SECTION 5 : A.C. OPERATED RECEIVERS

(i) *Four valve receivers* (ii) *Five valve receivers* (iii) *Larger receivers* (iv) *Communication receivers.*

(i) **Four valve receivers***

(A) **T-R-F receivers**

Because it has no local oscillator coil or i-f transformer, the t-r-f receiver is the cheapest to build, but has a performance equivalent to its cost. Using modern valves a sensitivity of a few hundred microvolts can be obtained, or even better if some form of fixed regeneration is used and can be made effective over the whole tuning range, but the selectivity is in general insufficient to separate local stations if they are of high power or situated close to the receiver.

The main application of t-r-f sets is in absolute minimum cost receivers which operate with 3 stages and a rectifier, although using only three or even two actual valve types. In such a case there is a resulting loss in sensitivity, which might then be no better than one millivolt.

Volume controlling is most conveniently carried out by varying the bias of the r-f amplifier, and to ensure low minimum volume on strong local stations the aerial is sometimes wired to the control as in Fig. 35.11 so that it is earthed in the minimum volume position.

(B) **Superheterodyne with a-f amplifier**

An improvement in selectivity can be obtained by using the superheterodyne principle even when no i-f amplifier is used. Such a receiver would have a converter followed by an i-f transformer, a second detector, an a-f amplifier and an output valve. Detection can be by diode (included in an a-f valve), anode bend, or leaky grid detector with possible regeneration in the last case. Since the input to the detector is fixed tuned, pre-set regeneration can provide a constant and appreciable improvement to both sensitivity and selectivity over the whole tuning range without the care which is needed in a t-r-f receiver.

Selectivity is improved since there are three tuned circuits, two of which are fixed tuned and give constant selectivity over the band.

*i.e. three amplifying stages and rectifier.

(C) Superheterodyne with i-f amplifier

The majority of three valve and rectifier receivers are superheterodynes with an i-f amplifier, in which selectivity can be made as good as required. Sensitivity too, while presenting some problems, can usually be made adequate, i.e. less than one hundred microvolts and, in extreme cases, less than fifteen microvolts on the medium wave band.

Three types of second detectors have been used, power grid, anode bend (each carried out by the output valve) and diode, although diodes are now used universally. The power grid detector had the disadvantage of high plate dissipation when no signal was being received, and the anode bend had somewhat higher distortion and needed a very high impedance plate load. The maximum power output when the output valve is detecting is of course seriously reduced. The diodes can be combined with the i-f amplifier or with the output valve, and one receiver has been marketed in which the suppressor grid of the i-f amplifier was used as a diode.

Fig. 35.11. Volume-control circuit used with t-r-f receivers.

Fig. 35.12. A.V.C. circuit suitable for 3/4 valve receiver.

Volume controlling is carried out by manual control of converter and i-f bias or by a.v.c. and an a-f volume control. The design of a.v.c. circuits for low gain receivers without an a-f amplifier presents some problems since they must be cheap, and must give full a-f output with the smallest possible input, which prohibits the use of full, simple a.v.c. as commonly used in cheap receivers with an a-f amplifier. On the other hand the low sensitivity means that the required range of a.v.c. control is less than normal and advantage is taken of this in the usual a.v.c. circuit which is shown in Fig. 35.12.

This circuit needs only one more resistor (R_1) than the simplest possible circuit, and R_1 and R_2 form a voltage divider so that only a fraction of the voltage developed across the diode load is applied to the grids of the controlled stages. The most suitable fraction depends on the initial sensitivity and the valves used, but values of one third to one fifth are common. Two details need care, the negative voltage applied to the diode must be kept to a minimum, to reduce distortion and to prevent the diode from being muted in the absence of a signal and the a.c. shunting on the diode load must be as small as possible. Large values for R_1 and R_2 fulfil both requirements and minimum values can be taken as 1 megohm and 2 megohms respectively. With the normal value of 0.5 megohm diode load the bias on the diode is less than $\frac{1}{2}$ volt, and the shunting reduces the a.c./d.c. ratio to 0.8. Better values to give almost the same ratio would be 2 megohms and 5 megohms (0.2 volt bias on diode; a.c./d.c. ratio = 0.9).

The use of only part of the developed voltage allows the output to rise rapidly with increasing input, which is an advantage for small signals, but there is little flattening of the characteristic with larger inputs.

For a slight increase in cost, delayed a.v.c. can be used and this will give the most rapid rise in output with increasing input, followed by a flat output-input characteristic. A suitable circuit is the "sinking diode" type shown in Fig. 27.38B, and provided that an additional diode is available the increase in cost is slight.

With manual volume control the circuit of Fig. 35.11 is usually employed. However if the B supply voltage is low, the signal handling capabilities of the i-f valve are reduced (owing to the reduced plate-cathode voltage) when a strong signal is tuned in, the volume control is turned back and the cathode voltage of the controlled valves thus increased. This objection can be overcome by using a negative voltage applied to the grids of the controlled stages. One method of obtaining the negative voltage is to connect the power supply filter in the negative lead and use the d.c. voltage generated across it. Some decoupling is necessary, but one stage is sufficient as high value resistors can be used.

A second method of obtaining a suitable negative voltage is to use the volume control resistor as, or in parallel with, the oscillator grid leak (with suitable decoupling). Oscillator grid current must be kept as constant as possible throughout the tuning range when this is done.

Three valve and rectifier receivers with an i-f stage and using i-f transformers with a Q of about 115 and good aerial coils are capable of producing sensitivity figures of the order of $15\ \mu\text{V}$ on the medium wave band when the most suitable commercial valve types are used. This sensitivity is ample for almost any listening conditions providing full volume is not required from very weak signals. In fact, successful dual-wave receivers giving short wave sensitivities not worse than $50\ \mu\text{V}$ have been made with such a circuit.

(D) Superheterodyne with reflexing

Reflexing in a three valve and rectifier superheterodyne receiver provides enough a-f gain to allow full simple a.v.c. to be used, and to allow good short wave performance to be obtained. The additional problems involved are discussed in Chapter 28.

A convenient a.v.c. circuit consists of full a.v.c. voltage applied to both converter and reflexed i-f amplifier, which can give a very flat a.v.c. characteristic. An a.v.c. circuit in which control is applied only to stages before the a.v.c. detector, can never give a completely flat output curve, because some rise is necessary to provide the additional bias needed to reduce the output as the input signal is increased. Such a circuit is a "backward acting" a.v.c. circuit.

A "forward acting" a.v.c. circuit is one in which the developed a.v.c. voltage is applied to a stage after the detector, and with such a circuit the output voltage may even fall with increasing input. The reason is that although the detector output must rise as in the previous case, the gain after the detector will fall, and the net result may be an increase or a decrease or a flat characteristic depending on the constants used.

In a reflex receiver the application of a.v.c. to the reflexed stage controls the mutual conductance of the valve and thus its gain at intermediate and at audio frequencies. As the a-f gain follows the detector the a.v.c. system is a forward acting one.

Alternative a.v.c. designs in a reflex receiver may use full a.v.c. on the converter and a fraction or none on the reflexed stage.

The increased a-f gain makes it possible to use inverse feedback, frequency compensated or otherwise, in the a-f amplifier, and resistive feedback into the bottom of the volume control (see Sect. 3(iii) of this chapter) is useful in reducing minimum volume.

The combination of audio a.v.c. and negative feedback (particularly when frequency compensated) is not always advisable, either in reflex receivers or in larger types in which a.v.c. may be applied to a valve acting only as an a-f amplifier. Since the purpose of the a.v.c. is to vary the gain of the stage, and one of the functions of negative feedback is to minimize any changes within the loop, the two effects oppose each other. This is not undesirable in itself, but the result is that on strong signals, such as local stations, the a-f gain is reduced and the feedback is consequently reduced so that the full effects of distortion reduction are not obtained. When the feedback incorporates frequency compensation the result is that weak stations receive maximum compensation and local stations a reduced amount, which is the reverse of the normal requirement.

Advantage has been taken of this effect in a receiver having one a-f stage with deliberately attenuated high and low frequency response. Audio a.v.c. was applied to this stage so that on strong stations no attenuation resulted—slight high and low frequency boosts were incorporated elsewhere in the a-f circuit—whereas on weak stations considerable treble and bass cutting was automatically introduced, giving a very effective automatic tone control. Suitable treble cutting for such a circuit could be by means of a small capacitor between plate and grid of the controlled stage, and bass cutting could be brought about by a small value of screen by-pass in a pentode.

In conjunction with a pick-up of good sensitivity a reflexed three valve receiver can reproduce gramophone records without added circuit complications.

The most common type of reflexing has the a-f and i-f signals applied to the control grid, with the load for each in the plate circuit. Another type which has been used has the two signals applied to the control grid with the i-f load in the plate circuit and using the screen dropping resistor as the a-f load, with an i-f by-pass from screen to ground. The a-f path to the grid of the output valve is provided by means of a normal grid coupling capacitor.

Since the a-f gain available from a reflex stage is comparatively small if the i-f operation is to be satisfactory, the reduced amplification between control grid and screen grid may be more than offset by the increased a-f load resistor which can be used and by the fact that proper i-f by-passing can be used on the cold side of the i-f transformer in the plate circuit.

(ii) Five valve receivers*

General comparison of types

The three valve receiver using a converter, an i-f amplifier and an output valve can be considered to be the smallest conventional superheterodyne receiver, and a valve can be added to it in three ways, as an a-f amplifier, an i-f amplifier or a r-f amplifier. Three very different types of receivers result, and the comparison serves to show the main ways in which the conventional 4 valve receiver with a-f amplifier can be improved.

The table below lists the order of preference for each type of receiver against a variety of headings.

Additional stage	A-F	I-F	R-F
Cost	1	2	3
Sensitivity	2	1	3
Selectivity	3	1	2
A-F Response	1	2	2
A.V.C.	3	1	2
Stability	2	1	2
Noise	3	2	1
Spurious Responses	2	3	1

The names "a-f receiver," "i-f receiver" or "r-f receiver" are used to identify a receiver with such an additional stage.

Although the performance of the a-f receiver can be improved upon in many ways, its characteristics can be satisfactory, as evidenced by the fact that the great majority of five valve receivers are built in this form. Since most receivers are tuned only to local stations, the advantages of the i-f and r-f types would rarely be displayed, and their additional cost might be more profitably used on a refinement on an a-f receiver such as a tuning indicator, bandsread ranges, or a better loudspeaker, cabinet or a-f system.

*i.e. four amplifying stages and rectifier.

(iii) Larger receivers

The conventional six valve receiver* has r-f, converter, i-f, detector, a-f and output stages, but although the stage usually added to the conventional four valve and rectifier receiver is a r-f one with advantages outlined in the previous section, the customer usually expects improvements in all features of the receiver's performance. To the average listener an improvement in fidelity is more noticeable than, for example, a reduction in image response, and it seems probable that the public would in most cases be better served with a six valve receiver with push-pull output rather than by a single ended receiver with a r-f stage.

Whether or not push-pull is used, some improvement in a-f response is required, for instance an increase in acoustical output, in conjunction with a suitable negative feedback circuit to give a reduction in distortion and a compensated frequency response.

A valve delivering more than four watts into an efficient output transformer and a sensitive loudspeaker can produce a considerable volume of noise but, even without push-pull, impressive reproduction can be obtained from the larger tetrodes and pentodes which draw between 70 and 80 mA of plate current.

The additional selectivity provided by a r-f amplifier with a high Q coil is appreciable and gives even more sideband cutting than is experienced with the usual 4 valve and rectifier receiver, particularly at the low frequency end of the broadcast band. As a result the high frequency response of the larger receiver may be inferior and, in fact, inadequate. The remedy of expanding the selectivity can be quite inexpensive, particularly if a "local broadcast" position is used on the wave change switch, or if one position on a tone control switch is used. Push-button receivers can have one button set aside for expanding the selectivity, which has the additional advantage of minimizing the result of frequency drift of the settings of the other push buttons.

Expanding of the i-f selectivity can be carried out simply and cheaply as described in Chapter 11 Sect. 3(iii), and the wiring is not critical because all leads have a low impedance to ground. It is only necessary to expand the first i-f transformer in a conventional single i-f stage receiver with an untapped second i-f transformer because the heavy damping on the second i-f reduces its selectivity appreciably from that of the less heavily damped first i-f transformer.

After the i-f amplifier has been expanded to give say 6 db attenuation at 8 Kc/s detuning, it may be found that the overall selectivity for small attenuations is still excessive, and the remedy is to expand the r-f stage. The damping of the aerial on the aerial secondary makes it unnecessary to expand the aerial coil: A convenient method of decreasing the r-f coil selectivity is to switch a small resistor (25 ohm carbon) in series with the cold end of the secondary. Gain is not seriously reduced, and the leads involved are low impedance so that they can be taken to the appropriate switch section without giving trouble.

After the high frequency response has been brought up to the required level, the small expense involved in fitting a high frequency diffuser is well repaid. With such a diffuser, the quality of reproduction becomes reasonably independent of the listener's position in front of the receiver, and the usual beam of accentuated high frequency response directly in front of the loudspeaker disappears.

(iv) Communication receivers

(A) Definition

A communication receiver has been defined (Ref. 33) as one which is not designed for limited or specific purposes. In some respects a communication type may be inferior to another receiver (perhaps an interception receiver to operate on a fixed frequency) in a particular application, but in general it has high performance and flexibility. Control of many of the circuits is available to the operator, of whom some technical knowledge is required.

(B) Frequency coverage and calibration

Communication receivers have been designed to provide coverage between 15 Kc/s and 25 Mc/s and between 30 and 300 Mc/s, but many do not tune above

*i.e. five amplifying stages and rectifier.

30 Mc/s or below 540 Kc/s. Provision for reception of F-M broadcasting on 88-108 Mc/s is included in some models.

Owing to the wide range of frequencies covered, the calibration of a communication receiver is important, and increasing emphasis is being placed on the inclusion of facilities for calibration checking and even on the possibility of the receiver being tuned to any given channel in its range without external aids.

An inbuilt crystal oscillator is the usual method of checking calibrations, and when the oscillator operates at 0.5 or 1.0 Mc/s, convenient checking points occur throughout the tuning range. Movable cursors have been used with receivers of this kind to allow corrections to be made to the calibration when found necessary. Figure 35.13 (British patent No. 8706/44) shows a simple circuit to increase the amplitude of the higher harmonics of the oscillator output up to the self-resonant frequency of the choke L . The choke is designed to keep the harmonic output as constant as possible throughout the tuning range of the receiver. Such an inbuilt calibrator can be very useful in the alignment of the receiver. A possible refinement is the modulation of the oscillator output by pulsing with a neon tube, or even by the mains frequency, for ease of identification.

Fig. 35.13. Circuit for increasing amplitude of high-order oscillator harmonics (from Ref. 33).

For the second requirement of setting the receiver accurately to any desired frequency, a crystal oscillator and its harmonics are used as a part of the mixer input, and tuning is provided by a comparatively low frequency oscillator which bridges the spaces between the harmonics of the crystal. The variable oscillator can be designed to operate at a low frequency and to have high stability, any residual fluctuations being a much smaller proportion of the total mixing frequency than of the variable oscillator frequency.

To minimize the possibility of incorrect frequency settings, some receivers have sliding dial scales which expose only the calibration actually in use. Where high setting accuracy is required the frequency may be displayed as the sum of two readings, one in Mc/s and the other in Kc/s.

(C) Bandchanging

Methods of bandchanging can be divided into three main categories, mechanically operated moving coils with stationary contacts, plug-in coils and switched coils. The most common form of moving coil arrangement uses a rotating turret with the coils inside it, but moving platforms which travel along the chassis have also been used. Particularly when high frequencies are tuned, the contacts for the moving coils present a problem as the inductance of the contacts can form a large part of the required inductance—with consequent loss of gain—and the inductance may vary each time a particular band is brought into circuit or when the receiver is subjected to mechanical movement.

Plug-in coils can be efficient as they do away with the need for a wavechange switch—each plug-in unit can even carry its own calibration—but the necessity for grouping the coils adjacent to an opening in the case restricts the layout somewhat. Storage must be provided for the unused coil units close to the receiver.

Switched coils are most commonly used and the main associated problem is the disposing of a number of coils adjacent to each switch. The switches need to be reliable, but modern types using rhodium plating properly applied are satisfactory.

(D) Stability

Many stability problems are automatically eliminated by the use of suitable circuits, e.g. crystal controlled oscillators. Methods of improving electrical stability are outlined in Chapter 24 Sect. 5. However mechanical stability is a first requirement and the tuning units at least should be made as rigid as possible, some receivers even using a cast chassis with this end in view.

(E) Sensitivity and noise

Owing to the number of stages used, the sensitivity is always limited by the noise in the first stages of a receiver. This is taken into account in one method of measurement by defining sensitivity as the lowest intensity of an input r-f carrier modulated at 400 cycles to a depth of 30% such that the total r.m.s. output power (signal and noise) is halved when the modulation is removed from the input carrier. Such a definition of sensitivity gives a good indication of the minimum signal which can be used and figures of the order of one micro-volt and better can be obtained.

Another method of defining the noise ratio is by comparing it with the signal-to-noise ratio of an ideal receiver under the same conditions. The factor by which the noise ratio of an actual receiver is worse than that of an ideal receiver is known as its noise factor. Further details of this method of noise measurement are given in Chapter 37 Sect. 1(vi)G.

(F) Selectivity

The selectivity requirements of a communication receiver are severe and depend on the type of service for which the receiver is being used. For telephony the bandwidth cannot be less than about 5 Kc/s at 10 db attenuation, whereas for telegraphy a bandwidth of a few hundred cycles per second is sufficient while greater bandwidths give increased noise interference.

These requirements can only be met by variable selectivity under the control of the operator, and a good receiver will usually have at least six i-f tuned circuits to provide adequate "skirt" selectivity, with a crystal filter providing varying degrees of "nose" selectivity perhaps together with a variable rejection control for dealing with an interfering station on a nearby frequency. A representative crystal circuit will give an attenuation of 20 db when detuned 200 c/s in its sharpest position and 2000 c/s in its broadest position. With a rejection or "phasing" control in use, an attenuation in excess of 40 db can be obtained within 250 c/s of resonance. The associated i-f amplifier will give an attenuation of 60 db when detuned less than 15 Kc/s. Crystal bandpass filters are becoming increasingly popular and they provide a pass band of say 300 or 3000 c/s with severe symmetrical attenuation on each side. Details on the design of variable selectivity crystal filters are given in Chapter 26 Sect. 6.

An additional means of discriminating between a desired telegraphy signal and an undesired one separated by perhaps only a few hundred cycles per second, is the use of a-f selectivity. A typical selective circuit centred on 1000 c/s gives an attenuation of 15 to 20 db only 100 c/s from resonance and of course much greater reductions with greater separation. Apart from discrimination against undesired signals, such a circuit reduces random noise in the same ratio as it reduces the bandwidth, and the ringing which is experienced with crystals at maximum selectivity when subjected to bursts of noise is eliminated.

Such selective a-f circuits are normally designed with iron-cored inductors because maximum Q is required, but it may be possible to produce equivalent or improved performance with a bridged T negative feedback circuit.

(G) Volume control and a.v.c.

Volume control presents some problems because the range of signal levels which the receiver is expected to use exceeds one million to one, and because different types of control are required for different functions of the receiver. For reception of telegraphy many operators prefer a manual control and some receivers provide separate controls for a-f gain and i-f gain; even separate r-f gain is sometimes provided. A convenient compromise which obtains good results from the receiver and requires no care on the part of the operator is to gang the a-f and r-f controls and delay the

application of bias to the first stage by means of a diode as discussed in Chapter 27 Sect. 3(iii). The r-f control is rendered ineffective when a.v.c. is switched on, and the a.v.c. voltages can be applied to the r-f control circuit.

A.V.C. is frequently used for c.w. reception when a suitable time constant is provided. For telephony a normal time constant is 0.2 second but this needs to be increased to at least 1 second for c.w.

Amplified a.v.c. is used in most large communication receivers to provide maximum control, and results such as a $2\frac{1}{2}$ db increase in output for a 100 db increase in input can be obtained (Ref. 34). Control should begin at the minimum signal level which can be used by the operator.

(H) Beat frequency oscillator

To produce an a-f output from a c.w. signal it is necessary to beat another signal with it. The beat frequency oscillator operates at, or close to, the intermediate frequency and beats with any signal in the i-f channel. The oscillator frequency can usually be varied a small amount ($\pm 2\frac{1}{2}$ Kc/s is typical) by a control on the front panel to allow adjustment of the beat frequency (perhaps to the peak of the a-f response) without detuning the signal from the peak of the i-f circuits.

The required amount and method of B.F.O. injection need some consideration. Sensitivity is lost if the B.F.O. amplitude at the second detector is too small, but when the coupling is increased a large input signal pulls the B.F.O. into zero beat from increasing frequency separations. Pulling into zero beat from a difference frequency of the order of 1000 c/s is not uncommon in bad cases. Another effect of too much B.F.O. injection is that the B.F.O. provides a signal at the second detector large enough to generate appreciable a.v.c. voltages and so reduce the sensitivity of the receiver even without an external signal.

Pulling can be minimized by electron coupling of the B.F.O. into the i-f channel, and with careful control of the amount of beat frequency voltage it is possible to obtain adequate injection without appreciable a.v.c. sensitivity reduction.

(I) Signal strength meter (S meter)

Many receivers use a calibrated meter to indicate the strength of signals tuned. The calibration is usually arbitrary (S1 to S9 for example) because the variation of receiver sensitivity across the various bands, and on different bands, makes an absolute calibration impossible. If this effect, and the varying efficiency of different aerials on different frequencies are borne in mind, the S meter can be a useful reference.

Circuits have been devised (Ref. 34) in which the S meter operates in conjunction with the manual volume control to provide signal strength indications on all types of reception, with or without the beat oscillator.

The usefulness of the meter can be greatly increased by providing a switch which allows appropriate currents and voltages throughout the receiver to be measured.

(J) Aerial input

To allow maximum efficiency to be obtained from different aerial systems, provision is often made for different types of aerial inputs, such as a single wire with separate earth connection, a balanced two wire feeder or a low impedance concentric cable.

An aerial trimmer on the front panel is very desirable when a variety of aerial inputs is provided. Even with a single wire aerial the changes of impedance throughout the short wave ranges allow considerable improvements in sensitivity and signal-to-noise ratio to be obtained by the use of an aerial trimmer, and aerial coil design is not restricted so greatly by the possibilities of mistracking.

An analysis of the effects on signal-to-noise ratio of the ratio of feeder impedance to receiver input impedance with various detuning ratios is given in Ref. 33.

(K) Noise (crash) limiters

These are commonly fitted to communication receivers. Details of the many varieties will be found in Chapter 16 Sect. 7 and Chapter 27 Sect. 5.

(L) Diversity reception

Provision for diversity reception is sometimes incorporated in communication receivers by providing facilities for combining the a.v.c. voltages and outputs of the individual receivers.

Another requirement for diversity receivers is that oscillator reradiation should be kept to a minimum. This can be done by using the lowest possible oscillator grid current, by earthing the whole oscillator circuit at one point and treating other amplifier circuits between oscillator and aerial in the same way, by reducing to a minimum capacitance couplings between primaries and secondaries of signal frequency coils (this includes using high impedance externally wound primaries wherever possible) and by minimizing all couplings other than the coils between the signal frequency and oscillator stages. The tuning condenser rotor shaft is the worst of such couplings and a rotor shaft insulated between sections is very desirable. If this is not possible, low impedance earthing should be provided for the rotor shaft and gang framework between each section.

(M) Cross-modulation

Communication receivers are frequently used close to a transmitter and may be required to receive another station while the transmitter is in operation. Under such conditions the cross-modulation characteristics of a receiver may be of more importance than its signal-to-noise ratio or sensitivity (Ref. 33).

A system known as counter-modulation has been used to allow receivers to operate more satisfactorily in the presence of very strong signals. The cathode resistor of the first valve in the receiver is by-passed to radio, but not to audio, frequencies, so that a-f components due to cross-modulation appear across it. The value of the resistor is adjusted so that the a-f voltages developed are sufficient to remodulate the wanted carrier, with signals approximately equal and opposite in phase to the original cross-modulation. Correct bias for the valve is obtained by applying a suitable voltage to its grid.

Further improvement can be obtained by operating the first valve solely to give minimum cross-modulation and substantial improvements can be obtained for slight reductions in signal-to-noise ratio.

The possibility of cross-modulation occurring in non-linear conductors close to the receiver should not be overlooked (Ref. 3).

SECTION 6 : A.C./D.C. RECEIVERS

(i) *Series-resistor operation* (ii) *Barretter operation* (iii) *Dial lamps* (iv) *Miscellaneous features.*

(i) Series-resistor operation

A receiver for use with d.c. supply cannot use a power transformer with low and high voltage windings, and some of the main problems in designing such a receiver are concerned with providing power for the comparatively low voltage valve heaters.

The problems are partly due to the non-linear relationship between voltage and current in a valve heater (owing to the increased resistance of the wire as the heater warms up) and Fig. 35.14 shows this relationship for a normal 6.3 V 0.3 A heater and for a 21 ohm resistor which draws the same current with 6.3 volts applied to it. It will be seen that with the normal heater a 10% variation in applied voltage gives approximately 6% increase in current.

In a.c./d.c. receivers, power is supplied to the heaters by connecting them in series across the mains, with or without an additional series impedance. When the sum of the required heater voltages is equal to the mains voltage the method is as satisfactory as when a power transformer is used, but when a series resistor is used, a variation of the mains voltage results in a larger percentage variation of the voltage across the heaters.

This effect is illustrated in Fig. 35.15. Curve ABC represents the current voltage characteristic of a string of heaters used in a radio receiver. The rated operating voltage is 108 for a nominal current of 150 mA, and a series resistor of 880 ohms is used to give the required voltage drop with a 240 volt mains supply. The intersection of the line with a slope of 880 ohms, and the current-voltage characteristic of

FIG. 35.14

Fig. 35.14 (A). Voltage-current characteristic of 6.3 volt 0.3 amp. heater ; (B) Voltage-current characteristic of 21 ohm resistor.

FIG. 35.15

Fig. 35.15. Illustration of the effect of mains voltage variation on heater voltage (Method from Ref. 41).

the heaters, is point B, the operating point under normal conditions. Now if the mains voltage is increased 10% to 264 volts the slope of the resistive line is unchanged and it intercepts the curve at point C. A vertical from C cuts the base line at Y, representing a voltage of 123, and an increase of 15 volts, i.e. 14% in the voltage applied to the heaters. Similarly a decrease of 10% in the mains voltage gives more than 10% decrease in the voltage applied to the heaters.

Because of this fact, it is necessary to provide more tappings on a series dropping resistor for various primary voltages than would otherwise be the case. Variations in supply voltages around the nominal value must be taken into account, in conjunction with the manufacturer's tolerance on the valve heaters. For American types this tolerance is usually taken as $\pm 10\%$ of the rated voltage, but other tolerances are also used, and some types have a tolerance on the permissible current variation.

When the dropping resistor is designed for one primary voltage only, it often takes the form of resistance in the power lead. This has the advantage of dissipating the heat outside of the cabinet. However if a receiver was originally designed for 115 volt operation and is converted for 230 volt operation by means of a series resistor, the B+ voltage is liable to be reduced by this method (Ref. 36). The reason is that the value of the series resistor must be adjusted to give the correct average heater voltage (or current) but the rectifier draws its current in pulses and these pulses flowing through the series resistance decrease the applied voltage during the time the rectifier is drawing current. This gives a decrease in the d.c. output of the rectifier, which in a severe case might amount to 30 volts in 110. Methods of providing separate voltage dropping impedances for the heaters and rectifier which are suitable for use on both a.c. and d.c. are given in Ref. 36. Where voltage dropping of this type is required on a.c. only, a series condenser of the correct impedance can be used in series with the power lead (Ref. 42) provided that an adequate voltage rating is specified.

(ii) Barretter operation

A barretter is a device which passes a substantially constant current as the applied voltage varies within the operating range—see Chapter 33 Sect. 1(i) and Fig. 33.1.

The heat dissipation of a barretter is appreciable, and as most of the heat should be carried away by convection, ample ventilation is needed. This is necessary both for the barretter and for the whole receiver, if it is a small one, to prevent the cabinet from becoming unduly hot. The same problem exists, of course, if a series resistor is used.

Apart from eliminating the effects of mains voltage fluctuations on filament current, a barretter does away with the need for changing tappings with different supply voltages over a range covered by the operating characteristics of the barretter. When a receiver is switched on, the initial current surge is limited by the barretter, which has the effect of noticeably increasing the time taken for the receiver to begin playing. The limitation of the surge is of no particular value to the valves themselves but may reduce dial light overloading in some circuits.

Since the barretter contains an iron wire carrying an alternating current it is susceptible to magnetic fields, which cause the filament to vibrate. The vibration leads to mechanical fatigue and breakage and if the barretter cannot be located at some distance from the loudspeaker, a magnetic shield must be used—preferably one which interferes with ventilation as little as possible.

(iii) Dial lamps

The protection of dial lamps from surges when the receiver is first switched on is one of the problems of a.c./d.c. receivers. If a 0.15 A dial lamp were connected in series with an appropriate number of 0.15 A valve heaters across the mains, the high current (several times greater than 0.15 A) drawn by the heaters for some seconds each time the receiver was switched on would drastically reduce the life of the dial lamp. If a series resistor were used the surge would be reduced, but not sufficiently, and even if a barretter replaced the resistor the dial lamp would be overloaded before

the barretter filament reached its operating temperature. The use of a dial lamp of higher current rating than the valve heaters is a possible method of operation. Some manufacturers have produced special lamps for series running. Nevertheless in each of these cases the failure of the dial lamp would remove the voltage from the valve heaters and stop the receiver.

One method of avoiding this trouble is to use a negative coefficient resistor (Thermistor) in series with the valve heaters—see page 190 (n).

A system in which both heater current and high tension supply current are used is given in Fig. 35.17. Special rectifier valves (e.g. 35Z5-GT) have been produced for use in such circuits, and the initial surge is offset by the fact that until the rectifier heater reaches its operating temperature the high tension component of the dial lamp current does not flow. No. 40 or No. 47 dial lamps (0.15 amp) should be used, and when the rectified current exceeds 60 mA a shunting resistor (R_s in Fig. 35.17) is required, its value being 300, 150 and 100 ohms for rectified currents of 70, 80 and 90 mA respectively.

Fig. 35.17. Circuit using 35Z5-GT and dial lamp. The drop across R and all heaters (with panel lamp) should equal 117 volts at 0.15 ampere. R_s = shunting resistor required when d.c. output current exceeds 60 mA.

Other rectifiers making similar provision for a pilot lamp are the miniature 35W4 and the 45Z5-GT.

The trend in small a.c./d.c. receivers is to use a simple dial without a lamp, and thus entirely avoid the use of the troublesome light source.

(iv) Miscellaneous features

(A) Rectifier

Since there is no centre-tapped source of high voltage a.c. in an a.c./d.c. receiver it is not possible to use a normal full wave rectifier. Bridge rectifiers or voltage doublers are possible but half wave rectifiers are most commonly used. They introduce some filtering problems since the frequency of the ripple in the output is one half of that from a full wave rectifier. To give the same electrical attenuation, filter capacitors and inductors would need to be increased in size, but speaker inefficiency and the poorer response of the ear at the lower frequency help in minimizing the effects of higher hum level.

When the receiver is operating on d.c., the rectifier acts only as a series impedance but serves a useful purpose in protecting the electrolytic filter condensers from damage if the mains connection is reversed in polarity, although the receiver will not operate under these conditions.

The high tension voltage is likely to be different with a.c. or d.c. mains of the same rated voltage. The reason is that on a.c. the peak voltage applied to the rectifier is $\sqrt{2}$ times the rated r.m.s. voltage and with small to medium loads and a large input condenser for the rectifier the d.c. output voltage will exceed the r.m.s. value of the a.c. input.

Modulation hum is frequently experienced in a.c./d.c. receivers operating on a.c. due to the presence of r-f signals in the mains, and to the direct connection of the rectifier to the mains. A suitable filter in the mains lead will stop the modulation hum, and any interference coming from the mains, but a satisfactory cure for the hum alone is a small (1000 μF) mica condenser connected between plate and cathode of the rectifier.

(B) Valve order

When the valve heaters are wired in series and connected across the mains the potential between heater and cathode of any valve will be dependent on its position

in the string. Each valve must be placed so that the maximum heater-cathode potential specified by the valve manufacturers is not exceeded, and also so that the potential is not great enough to introduce hum into the receiver output.

The position of a valve in the circuit determines its susceptibility to hum pick-up, and an a-f amplifier is generally the most critical. The usual wiring order, starting from the grounded end is second detector and first a-f amplifier, converter, r-f amplifier, i-f amplifier, output valve, rectifier. The converter is kept as close to ground as possible to avoid modulation hum. It will be found that allowable maximum heater-cathode potentials (90 V max. design centre for American amplifying valves) always allow this order, which is the best for modulation hum, to be used.

(C) Earth connection

Two main types of a.c./d.c. receivers are produced, one with one side of the mains directly connected to the chassis, and the other with mains wiring connected to an earth bus which is by-passed to the chassis proper with a suitable capacitor, perhaps shunted by a high value resistor.

The first type of receiver has fewer design difficulties but does not comply with the safety requirements in some countries, e.g. the Radio Code of the Standards Association of Australia (A.S.S. No. C.69—1937) states: V.7 (f) (ii) "Power units and sets of the transformerless type shall have the live parts of the inner structure isolated from the case or frame by an isolating condenser or other approved means, which shall not be capable of passing a current exceeding 5 milliamperes to case or frame when the full rated voltage is applied in the normal manner of operation."

The main trouble encountered with the other type of a.c./d.c. receiver is instability due to impedance between the earthed bus and the chassis proper, the impedance being made up of the reactance of the by-pass capacitor and the inductance of its leads. This impedance can be reduced to a low value by making up a unit consisting of an inductor wound on the body of the capacitor, the two being connected in series and resonated at the intermediate frequency, at which most amplification occurs.

Many cases of instability need individual treatment and it often becomes necessary to return particular circuits (e.g. the cathode by-pass of the i-f amplifier) to the chassis through a series tuned circuit instead of to the negative bus.

To avoid modulation and other types of hum it may be helpful to use back-bias for amplifying valves so that the cathodes can be directly grounded. This avoids the possibility of hum voltages appearing between cathode and ground.

Where there is any possibility of interconnection of two or more a.c./d.c. units, such as for instance a radio tuner and a separate public address amplifier, it is essential that the mains be isolated from the chassis.

SECTION 7 : BATTERY OPERATED RECEIVERS

(i) *General features* (ii) *Vibrator-operated receivers* (iii) *Characteristics of dry batteries.*

(i) General features

Most battery operated receivers are used in locations where signal strengths are low, and the main requirements are therefore high sensitivity and low noise. The cost of power obtained from batteries is high and every effort is made in the design of battery receivers to keep the current drain to a minimum. This is done by reducing the a-f power output considerably from that available in an a.c. receiver and by using high Q aerial and i-f coils so that high gain can be obtained without operating the valves at their maximum ratings. Many receivers have an economy switch which reduces battery drain by decreasing the screen voltage on the i-f and output valves or by other means. The reduced power output and sensitivity are still adequate for most uses.

The mutual conductance of battery valves is lower than that of corresponding a.c. types to such an extent that although the smallest a.c. receivers in general use have three valves and a rectifier, the smallest battery sets need four amplifying valves to

obtain similar sensitivities. The four types are a converter, an i-f amplifier, an a-f amplifier and an output valve. The i-f output is severely limited by the low plate voltage on the last i-f valve—about 84 volts with fresh batteries in a typical modern receiver—and an a-f amplifier is needed to obtain sufficient a-f voltage to drive the output valve.

The more general type of battery receiver has five valves and uses the additional valve as a r-f or second i-f amplifier. On the broadcast band sensitivities of the order of 1 μ V are readily available in each case, and if a high gain aerial coil is used there is not a great deal of difference in signal-to-noise ratio. On the short-wave band the r-f stage receiver is noticeably quieter but the average sensitivity at 6 Mc/s may be of the order of 25 μ V, against perhaps 10 μ V for the receiver with an additional i-f stage.

Because of the low i-f plate voltage the signal handling capacity of battery operated receivers is limited, and taken in conjunction with the requirement for high initial sensitivity, this means that a normal battery receiver overloads with a comparatively small r-f signal applied. Nevertheless the conditions of use are such that large inputs are not usual, and a receiver which will not distort seriously with an input of 0.1 volt will give satisfactory service in almost all locations.

There is usually only one diode available in a battery receiver, and this severely restricts the a.v.c. design as it makes delayed a.v.c. impossible. The most satisfactory compromise is probably to apply a fraction (say one third) of the developed a.v.c. voltage to the first and last controlled stages (unless the first valve is a r-f amplifier which may take full a.v.c. without increased signal-to-noise ratio) and full a.v.c. to the intermediate one. The small amount of a.v.c. on the input stage minimizes the increased noise from the first valve as a.v.c. is applied and on the last i-f stage it allows larger signals to be handled without overload. The middle stage has no effect on the noise, handles only small signals, and consequently can do most of the gain controlling.

A.V.C. design affects high tension current consumption and if too small a fraction of the developed a.v.c. voltage is used, current will be wasted when a local station is tuned.

Bias for the output valve is usually obtained from a back-bias resistor in dry battery operated receivers. Receivers have been made in which the voltage developed across the oscillator grid leak has been used for this purpose (with suitable decoupling) but if the A battery voltage falls more quickly than that of the B battery, the output valve is operated in an underbiased condition and draws excessive B current.

Separate C batteries have also been used, but the difficulty of discharging the C battery at the proper rate has led to the popularity of back biasing, in which the voltage remains approximately optimum throughout the B battery life.

When a back-bias resistor is used it should be effectively by-passed to audio frequencies, otherwise a-f voltages developed across the resistor are applied to the plate circuits of the i-f and perhaps oscillator valves. This may cause instability as a receiver is being tuned to a station.

Another advantage of back biasing is that if B+ is short circuited to the valve filaments, the bias resistor restricts the current to an amount which will not damage the valves. With a 500 ohm resistor and a 90 volt supply the current is 180 mA, whereas even a four valve receiver normally draws 250 mA from its filament battery.

When a battery receiver is turned off, the B supply voltage does not disappear as in the case of an a.c. operated receiver. The filament voltage being turned off stops the valves from passing current but small leakage currents (for instance, through condensers) have merely to flow through another series leakage—that of the B supply switch. Particularly in humid conditions, the resistance between switch contacts may be only of the order of tens of megohms and the uninterrupted current which flows can lead to electrolysis of fine wires and consequent open circuits.

Unless precautions are taken, the fine wire of the output transformer primary is particularly susceptible to this trouble, leakage occurring between the primary (con-

impedance. An undesirable feature is that the interference may vary each time the switch is operated and may become progressively worse with age as the contact resistance of the switch increases.

If the a-f gain is high, even the common impedance of a fuse may cause trouble and in some cases only the vibrator circuit is fused for this reason.

The electrolytic condensers are also useful in preventing coupling between the filament circuits of the various valves. However high gain receivers usually need additional r-f by-passes on the filament string to prevent regeneration at the intermediate frequency or to keep i-f voltages from the a-f end of the receiver.

One undesirable feature of the circuit of Fig. 35.18 is that if any one of the 1R5, 1S5 or 1T4 valves is removed from its socket, or if one filament becomes open circuited, two other valves will have excessive filament voltage applied. The additional voltage is normally not enough to open circuit the other filaments but if the receiver is left unattended in this condition the valves will deteriorate rapidly.

The resistors R_1 , R_2 and R_3 equalize the filament voltages on the different valves. Since the filament string requires 100 mA and the cathode current of the 3S4 alone is 8.8 mA under typical operating conditions, some adjustment to the voltage across the filaments (in which the cathode currents flow) is necessary. However calculation of the values required for the various valves is not straightforward since the cathode current of each valve has alternative paths of different impedance. For instance in Fig. 35.18 the 1R5 cathode current will flow partly in the negative filament lead and partly in the positive, this latter current splitting into one component which flows through the 1S5 and another which flows through the 3S4. As a result the resistor values are most readily determined experimentally, and with average valves in a receiver and decade boxes connected where shunting resistors are needed, a few minutes' manipulation of the decade boxes will determine the correct values. A.V.C. application will affect plate currents and hence filament voltages, and the resistor values should be decided with an average input signal. By making slight compromises it is often possible to do without one or more resistors, but if this is done conditions should be checked with freshly charged and discharged batteries as well as at the rated battery voltage.

A.V.C. design is complicated in vibrator receivers with series-parallel filament circuits, but satisfactory solutions can usually be obtained by means of a.v.c. voltage dividers returned to different potentials. For instance in Fig. 35.18, which might be the filament circuit of a receiver with two i-f amplifiers, the diode load would be returned to the 1S5 negative filament, i.e. to ground, and a.v.c. would be taken directly to the grid of the 1T4 acting as the first i-f amplifier. This is possible because the filaments are at the same potential. However the 1R5 and second i-f 1T4 have their filaments more positive and would be biased 1.3 volts negative if connected directly to the diode load. A solution would be to connect a two megohm resistor from the top of the diode load to the 1R5 and 1T4 grids, and another two megohm resistor from the grids to the positive side of the 1R5 filament. This would remove the bias from the 1R5 and 1T4 and reduce the amount of a.v.c. to these valves which would be desirable—see subsection (i) of this section.

The elimination of hash from a vibrator operated receiver usually involves work on the power unit (Chapter 32) but some precautions in the receiver may be necessary. A frequent source of interference which is difficult to trace is hash picked up by the converter valve. A very small amount of interference in the B supply may modulate the oscillator and be fed into the i-f amplifier with the local oscillator injection, or interference on the converter filament may be troublesome. In each case the interference receives the total receiver amplification. A separate r-f choke is often used for the converter filament to eliminate this trouble.

When tracing hash, a convenient method is to connect a shielded wire, with one end bared, to the receiver's aerial terminal through a capacitor. The bared end of the wire is used as a probe and when in contact with various points in the receiver circuit indicates whether interference is present. The first points to check, of course,

are the incoming leads from the vibrator unit to the receiver and in general these should be filtered until they are quite "cold".

To be sure of trouble-free production runs it is advisable to work on hash elimination until, with an aerial wrapped around the battery leads and battery, no interference can be heard at any frequency with the receiver operated at maximum gain in a screened room.

Mechanical noise and vibration from the vibrator also present a problem. The high frequency noise components can readily be minimized by felt or other sound-absorbing material, and even the metal shielding box in which vibrators are often used may be sufficient. However noise at the fundamental frequency of the vibrator is more difficult to cure and much trouble can be avoided by using a very flexibly mounted vibrator socket. Each new receiver usually presents different problems in this respect.

(iii) Characteristics of dry batteries*

A knowledge of dry battery characteristics is essential in designing receivers which are to use the batteries to the best advantage. It is also helpful in obtaining maximum battery life with a particular receiver.

The decrease in battery life caused by a receiver design which gives unsatisfactory performance—or none—when the battery voltage falls below certain levels is best illustrated in Fig. 35.19. If the average B current of a receiver is taken as 15 mA it will be seen that the useful life of the battery is increased from 1.16 to 1.49 ampere hours, an increase of 28%, by designing the receiver so that it will operate satisfactorily when the output of the 90 volt B battery has fallen to 60 volts, instead of becoming unusable when the output is 68 volts.

It will be noticed that as the current drain in Fig. 35.19 is reduced, the output rises to a maximum and then falls. This is due to the fact that the batteries were discharged for 2 hours each day so that with a 10 mA drain for instance the test lasted for 175 days. Tests with smaller drains take longer and the effects of shelf life become more important than the decreased drain.

Fig. 35.19. Ampere-hour output versus discharge current for various end-point voltages (Ref. 25).

*Information taken from Ref. 25.

Fig. 35.20 shows the importance of reducing battery drain to a minimum or alternatively of specifying batteries of as great a capacity as possible. As the drain is reduced a progressively greater amount of the battery output is made available at a high voltage, and as an extreme example, a 2.9 mA drain on the cell will give 83% of the battery's output (assuming that the cell can be used until discharged to 0.8 volt) at a voltage greater than 1.3, whereas a 187 mA drain gives only 16% of the battery's output at 1.3 volts or more. The curves of Fig. 35.20 were taken on continuous discharge, and with operation of say 4 hours a day the effects of shelf life would modify the figures obtained.

Fig. 35.20. Working voltage of No. 6 size cells during discharge through various resistances (Ref. 25).

The main interest of Fig. 35.21 is to the user of the receiver, as it shows the effects of heavy battery usage in decreasing battery output. For a B drain of 15 mA and 8 hours of use each day, each cell will give 1.13 ampere-hours output, but with 2 hours daily usage the output rises to 1.48 ampere-hours. Thus the batteries will last for about 50 days with 2 hours of use, but less than 10 days with 8 hours of use. The effects of shelf life in Fig. 35.21 are clearly indicated at low current drain and with decreasing hours of discharge per day.

An aspect of dry battery performance which is of particular importance to receiver designers is the increase of internal resistance of each cell as it becomes discharged. The resistance of a new cell can be ignored for radio purposes, as it varies from about one third of an ohm for small B battery cells, to one fiftieth of an ohm for large A battery cells. However as the battery ages, an impedance of the order of 20 ohms per cell may develop and for a 90 volt battery this represents a series impedance of 1200 ohms.

Such impedances cause coupling between circuits, and in the case of an A battery may cause instability due to coupling between different i-f stages or between i-f and a-f stages. The remedy is an adequate by-pass ($0.5 \mu\text{F}$ may be necessary) across the filament circuit, and the necessity for this should be tested with a discharged battery during design. Impedance in the B supply circuit can cause trouble between almost any pair of stages (including the oscillator) in the receiver. An electrolytic condenser in parallel with a r-f by-pass ($0.1 \mu\text{F}$) is commonly used to avoid this trouble.

The only completely satisfactory method of testing a receiver for performance with discharged batteries is to use a set of batteries which has been used normally until the voltage has fallen to the required level. Accelerated rates of discharge do not

Fig. 35.21. Ampere-hours output versus discharge current for various operating cycles (Ref. 25).

produce such a high internal resistance. Noise will sometimes be encountered with a discharged battery unless a large by-pass is connected in parallel with it.

The effect of temperature on dry cells is very marked. At high temperatures the deterioration of unused cells is rapid and tests have shown that batteries stored for one year at 104°F. have deteriorated more than similar batteries stored for five years at 48°F. Small cells have a shorter shelf life than large ones stored under the same conditions.

The reasons for the increased rate of deterioration at high temperatures are increased moisture loss from the electrolyte, and increased chemical activity in the battery. This latter effect is beneficial when the battery is actually in use and a battery discharged in a comparatively short time at 100°F. has been found to give 140% of the output of a similar battery at 70°F. At 40°F. the output fell to 48% of the output at 70°F.

When testing batteries it is important to realise that there is no relationship between the current delivered by a dry cell on a short circuit amperage test and the service capacity of the cell. On the other hand the working voltage of a dry cell does decline progressively as the cell becomes exhausted, so that a voltage test under normal load is a good indication of a battery's condition. The voltmeter used should have a resistance of not less than 100 ohms per volt for single cells or 1000 ohms per volt for B batteries. The current drawn by lower sensitivity meters may lead to a lower voltage indication than actually occurs in use.

In some types of portable receivers which can be used with dry batteries or an a.c. power supply the dry batteries can be charged during a.c. operation or while the receiver is not in use. This is claimed to increase the service obtainable from the dry batteries although the degree of improvement depends on the conditions of use. It is important that the charging current should not be excessive. Further information is available in Refs. 56, 57, 69, 70, 71.

SECTION 8 : CAR RADIO

(i) *Interference suppression* (ii) *Circuit considerations* (iii) *Valve operating conditions.*

(i) Interference suppression

The main problem in car-radio design is the suppression of interference from the car and from the power supply of the receiver. Ignition interference is the more troublesome, and while there are methods of suppression which apply in all cases any particular installation is liable to present problems of its own.

One theory as to the mechanism by which interference is produced is that each spark causes oscillatory currents in the ignition leads covering a wide band of frequencies. The spectrum is propagated from the ignition lead which acts as an aerial, and the receiver amplifies those frequencies to which it is tuned. See Ref. 10 for a comprehensive survey of reports on the nature, measurements and suppression of ignition interference.

Another possible mechanism has been described in Ref. 1, although objections to it are brought forward in Ref. 10C. This conception of interference generation is that the radiated field is an impulse which is short compared with the period of the carrier frequency up to frequencies of hundreds of megacycles. Each burst of interference heard is thus the impulse response of the receiver and its aerial, so that the interference is more dependent on the bandwidth of a receiver than on the frequency to which it is tuned, although of course the signal received will vary in amplitude with large variations in frequency.

In addition to ignition noise, interference is caused by the brushes on the generator but this is readily removed by by-passing. Special suppression capacitors are available of 0.5 μ F capacitance, 200 volt working, encased in a metal can to which one side of the capacitor is connected.

Methods of dealing with the majority of straightforward interference suppression problems are given below (Ref. 60).

(a) Cut the high tension lead connecting the ignition coil to the centre of the distributor head as close as possible to the distributor head and screw the two ends of the leads into a resistor suppressor. Suitable suppressors consisting of a carbon resistor of 15 000 ohms with facilities for attaching the two leads are available commercially.

(b) Connect a suppression capacitor to the point where the receiver low tension cable is connected to the car's low tension system, with the metal case clamped to the chassis.

(c) Clamp the metal case of another suppression capacitor to the generator housing and connect the lead to the generator armature-terminal. The capacitor must not be connected to the generator field-terminal. In American cars the correct terminal is usually the larger one.

In most English cars the armature terminal is not accessible on the generator and the suppression capacitor should be connected in such cases to the "D" terminal on the voltage distribution channel.

If trouble is still experienced the following points should be investigated.

(d) See that the distributor contacts and spark plug points are clean, in good condition and correctly adjusted. Replacements may be needed.

(e) If the engine is rubber mounted a bond may be necessary between the engine block and the chassis. This bond should be a piece of flexible copper braid not less than $\frac{1}{8}$ in. wide and as short as possible, although allowing for engine movement.

(f) See that the low tension leads do not come close to any of the high tension wiring. In some cars it may be necessary to remove the low tension wires from channels provided for the spark plug leads.

(g) Make sure that there is a good connection between the ignition coil can and the engine block.

(h) Bond all oil pipes, bowden cables, etc., to the bulkhead as they pass through to the driving compartment.

(i) Try the effect of bonding various parts of the bodywork to the bulkhead or engine block with $\frac{1}{8}$ in. copper braid. It sometimes happens that a large section of metal, for example a mudguard, is insulated by rubber or fabric beading, or even by paint, from the rest of the body. Bonding of such sections may eliminate interference.

(i) By-pass separately the various electrical components of the car, such as the horn, ignition switch, windscreen wiper motor, petrol pump, head lights, dome light, parking lights, petrol gauge, electric clock, etc.

In fitting the various units of the radio itself it is necessary to remove some paint from the metal to make sure that the unit is electrically earthed.

Occasionally trouble is experienced from wheel and tyre static. Graphite grease in the wheel bearings, may be sufficient to effect a cure, but in some cases spring contacts bearing on the wheel hub have been used.

(ii) Circuit considerations

The main requirements for a car radio are high sensitivity, high signal-to-noise ratio, good a.v.c., high a-f output, compactness, the ability to withstand vibration, and mechanical flexibility for installation purposes.

The first four items have almost standardized the design into the form of a receiver with r-f, converter, i-f, a-f and output stages. Such a combination allows the receiver sensitivity to be limited only by the noise in the first stage—which is desirable.

The high over-all sensitivity ($1 \mu\text{V}$ input for 0.5 watt output is not uncommon) causes high a.v.c. voltages to be developed with comparatively small inputs so that strong a.v.c. action is available even when signals fade to very low levels. The a.v.c. diode load is often returned to a source of bias for the r-f and i-f amplifiers so that a delay of two or three volts is obtained and this flattens the a.v.c. characteristic even more, after the delay has been overcome. The a-f sensitivity is adequate to allow full output.

When full a.v.c. is applied to the r-f stage a check should be made from Scroggie's curves—Sect. 3(i) of this chapter—to see that the noise from the first valve does not become comparable in size with that from the input circuit and so affect the signal-to-noise ratio.

FIG. 35.22

Fig. 35.22. Car-radio aerial input circuit.

The design of the aerial input circuit is very important in a car radio, because of the small effective height and physical size of the aerial itself. Different aerials may be used with the receiver, but telescopic types with a capacitance of about $50 \mu\mu\text{F}$ are commonly assumed. One of the most popular circuits is shown in Fig. 35.22. L_1 is a choke consisting of a few spaced turns of thick wire, resonant at about 40 Mc/s. It is used to minimize incoming ignition interference without seriously affecting the desired signals. L_2 is the aerial coil primary, which is arranged to resonate with the aerial and the rest of the circuit outside the low frequency end of the required band. However the resonance is kept as close to the band as possible without introducing too much mistracking between the aerial and r-f circuits, in order to obtain the maximum possible gain at the low frequency end of the band.

The capacitor C_1 is from 50 to $100 \mu\mu\text{F}$ in a typical case, and provides capacitance coupling to improve the gain at the high frequency end of the band. L_3 is tapped at from one quarter to one third of the total number of turns from the cold end. Coup-

ling between L_2 and L_3 usually approaches 20%. The Q of L_3 must be as high as possible and iron cores are commonly used. Q values in air as high as 250 at the maximum point in the band have been used, and a gain of from 8 to 10 is obtainable over the band with such a coil mounted in the chassis. Gain is measured with the output of the signal generator connected through a 50 $\mu\mu\text{F}$ capacitor to the aerial end of the shielded input cable. Noise figures obtainable are of the order of equal noise and power output when the input signal is from 0.3 to 1.0 μV , 30% modulated.

A series trimming condenser (say 50-350 $\mu\mu\text{F}$) is sometimes used between the spark coil and the aerial primary so that the aerial coil can still be tracked with the r-f coil even when a high capacitance aerial is connected to the receiver.

Power supplies for car radios are vibrator operated, using either synchronous or non-synchronous types. The non-synchronous system has the advantage of keeping a constant output polarity when the input polarity is reversed, so that the lack of uniformity between car manufacturers as to positive or negative grounding of the battery becomes unimportant. Non-synchronous systems also have fewer troubles from vibrator hash in the receiver and are generally assumed to be more reliable in operation but of course they are more expensive, since a rectifier must be provided, and consume more current if a hot cathode type of rectifier is used.

In the elimination of interference either from the vibrator or from ignition noise in a car radio, "spark plates" are often used. These are by-pass capacitors using the chassis as one plate, a thin sheet of insulating material, preferably mica, as the dielectric and tin-plate or brass as the other plate, the assembly being eyeletted together with suitable insulating washers. Because components are soldered directly to the top plate and the bottom plate is the chassis, the series inductance of such a capacitor is very small. It has been recommended that incoming leads should be soldered to one end of a spark plate and outgoing leads to the other end. Capacitances between 10 and 200 $\mu\mu\text{F}$ are commonly made up in this way.

Because of the intense ignition interference field it is often necessary to filter all leads coming into the receiver. Tone control leads and even loud speaker leads may need by-passes or series chokes to eliminate interference.

The effects of vibration must be considered in car radio design. Reliable air dielectric trimmers are more stable than compression mica types, but need to be sealed after alignment. Large paper capacitors need to be held by means other than their own leads, and smaller components must be mounted so that they cannot vibrate on their leads. Older types of valves, such as G types and others of similar size can give trouble through falling out of their sockets under the influence of vibration, particularly when mounted horizontally. For this reason and for the extreme compactness which they allow, miniature valves are well suited for car radio designs.

(iii) Valve operating conditions

Valves in car radios are subjected to heater voltages outside both the top and bottom limits specified by valve manufacturers. Extremes of perhaps 8.0 and 4.5 volts may be encountered with the battery on charge and fully charged, and off charge and discharged.

Excessively high heater voltages reduce valve life by evaporating the coating from the cathode, and care should be taken to see that plate or screen dissipations do not exceed valve manufacturers' ratings under any anticipated working condition, particularly as the ambient temperature inside the car radio is likely to be very high at times.

When heaters are operated at excessively high voltages it is possible for control grids to rise to a temperature at which grid emission takes place. To reduce the effects of this grid emission current, it is advisable to use the lowest convenient values for output valve grid leaks and a.v.c. series resistors in car radios.

When the supply voltage is very low, the receiver loses sensitivity and power output but remains usable so long as the oscillator operates. To guard against oscillator stoppage a new design of receiver should be checked with a large number of valves including some with low oscillator grid current under normal operating conditions.

Since valves are only tested by manufacturers to the recommended voltage limits, there is no guarantee of uniformity of operation between valves at voltages outside those limits

SECTION 9 : MISCELLANEOUS FEATURES

(i) *Spurious responses* (ii) *Reduction of interference* (iii) *Contact potential biasing*
(iv) *Fuses* (v) *Tropic proofing* (vi) *Parasitic oscillations* (vii) *Printed circuits*
(viii) *Other miscellaneous features.*

(i) Spurious responses

With a superheterodyne receiver, several types of signal can be received which do not originate in stations broadcasting on the frequency to which the receiver is tuned. The signals are not necessarily objectionable of themselves, but owing to the congested condition of the broadcasting band, almost any spurious signal will interfere with a true signal. These spurious responses are due to several causes which are listed below.

- (a) Harmonics of a station operating at a lower frequency.
- (b) Two stations broadcasting on frequencies separated by the intermediate frequency of the receiver.
- (c) A station broadcasting on the image frequency of a desired station.
- (d) A combination of local oscillator harmonics with other signals or harmonics.
- (e) Feedback of intermediate frequency harmonics.
- (f) A station broadcasting on the intermediate frequency of the receiver.

Interference of type (a) will be received by any receiver of sufficient sensitivity and cannot be minimized in the design of a receiver.

When type (b) interference is experienced, the two stations will be heard together over two bands of frequencies centred on the frequencies of each of the stations. The interference continues even when the local oscillator is stopped. Since it is necessary for the two signals to be present at the grid of the frequency changer for the interference to be troublesome, selectivity before this point is required to eliminate it. Alternatively the intermediate frequency of the receiver can be altered to a frequency at least 10 Kc/s removed from the difference frequency.

Type (c) interference can be cured by adequate signal frequency selectivity, and is the main reason for this selectivity. Particularly in the short-wave range of dual wave receivers is trouble experienced (although not always recognised) from this source, and it is so prevalent that the signal frequency selectivity of a receiver is always expressed as its image ratio.

Methods of calculating image ratio are given in Chapter 23 Sect. 4(ii) for coils without capacitance coupling. To obtain the full calculated rejection, particularly at the high frequency end of a band, it is necessary to reduce to a minimum all couplings other than that by mutual inductance. Separation of circuits and earthing at one point for each circuit will be found beneficial when high gain is used. Capacitance coupling must be particularly avoided. Ref. 21 (pp. 225-237) gives circuits which increase image rejection.

There are many possibilities of type (d) interference but it is not a major problem in most receiver installations. Nevertheless it is advisable to restrict oscillator grid current to a minimum, consistent with other requirements, to minimize this source of interference.

Feedback of intermediate frequency harmonics can occur through B supply, a.v.c. or other wiring, or by means of voltages induced into the converter input circuit from the second detector, or any part of the a-f amplifier. The feedback may be sufficient to cause actual instability or merely an annoying heterodyne on stations adjacent in frequency to the harmonics of the i-f. Shielding and perhaps decoupling or an r-f by-pass in the a-f circuit readily remove the trouble.

Interference from a signal on or near the intermediate frequency continues when the local oscillator is stopped and becomes progressively worse as the receiver tuning approaches the intermediate frequency. It is seldom encountered in superheterodynes with a tuned r-f amplifier, but receivers with an untuned r-f amplifier or with none usually have very poor i-f rejection at frequencies lower than 600 Kc/s.

A method of plotting interference signals is given in Ref. 21, Part 1, page 201. An example of the estimation of the interference to be expected in a given set of conditions will be found in Ref. 53.

(ii) Reduction of interference

There are two main methods of minimizing the effects of external noise on radio reception. The first is by the use of noise limiters in the receiver (Chapter 16 Sect. 7 and Chapter 27 Sect. 5) and this method is equally applicable whether the noise is of man-made or natural origin. The second method consists of using filters and noise-reducing aerials and is only applicable to noise from man-made sources.

Most mains operated receivers receive appreciable r-f inputs from the supply lines, and when noise is troublesome the ratio of signal to noise is often much lower in the mains than in an aerial. This occurs when the source of interference is connected to the power supply and induces interference into the mains wiring. In such a case filtering of the mains leads can give a substantial improvement in signal-to-noise ratio.

An electrostatic shield between primary and secondary windings of the power transformer is the most common method of treatment. Methods of incorporating such a shield in the power transformer are described in Chapter 5 page 233. The alternative method (b) of winding the earthed low voltage filament between primary and secondary, due to its inductance, is probably less effective than the normal shield (a).

Fig. 35.23. Interference from power-supply induces noise into input circuit of receiver.

FIG. 35.23

By-passing of the incoming mains leads to the chassis, with or without series inductors, is often used to reduce interference. Fig. 35.23 shows that this method is of limited use, depending on the impedance between the receiver chassis and ground. Noise currents represented by arrows flow from mains to chassis and from chassis to ground, thus setting up a noise voltage on the chassis relative to ground. This voltage causes another noise current to flow through the primary of the aerial coil and the capacitance of the aerial to ground, and thus a noise voltage is induced in the aerial coil secondary and applied to the first valve of the receiver.

The fact that interference stops when the aerial is removed from the receiver is not proof that the noise is picked up by the aerial. If the aerial were removed in Fig. 35.23 the interference would stop because the path to ground through the aerial primary would be removed, but the noise source is the supply mains.

Figure 35.23 indicates how improvements in noise reduction can be made. Firstly, if the earth lead for the mains by-passes is separated from the receiver earth, the noise potential between chassis and ground is eliminated. The separation needs to be more than electrical, as if two wires were close to each other the noise currents in the filter earth would induce noise currents in the receiver earth.

Secondly the incoming noise currents can be considerably reduced by using a r-f choke in series with the mains leads before the first by-pass to increase the impedance of the path. This will reduce the noise voltage between chassis and ground, but

increase the noise voltage between mains leads and ground, and the capacitance between mains and aerial leads may lead to increased noise from this source.

A third possibility is the use of a balanced aerial coil primary connected to the ends of a symmetrical lead-in from the aerial. When the two ends of the primary are balanced with respect to capacitance to chassis (a small trimmer can be used on either side of the primary if found necessary to give the greatest noise reduction) then noise currents flowing from receiver chassis to ground through the aerial capacitance do not give rise to noise voltages in the aerial coil secondary or the remainder of the receiver. An electrostatic shield can be used between primary and secondary as an added precaution against electrostatic asymmetry between primary and secondary windings.

The symmetrical lead-in can be terminated at the aerial end in another transformer coupling it to the aerial, in a dipole, or aerial and counterpoise or the lead-in may be merely a two wire feeder with one end extended to form the aerial. In any of these cases additional noise reduction can be expected from the fact that the aerial proper can be placed at some distance from the power supply mains or any other known source of interference, e.g., it can be removed as far as possible from, and placed at right angles to, tram lines.

Before proceeding with elaborate noise reduction methods it is advisable of course to make sure that the receiver itself is not picking up noise directly. In strong fields large voltages are induced into grid leads and under-chassis wiring, and complete shielding of the receiver proper may reduce interference without other assistance, or it may be essential if the full benefit of more elaborate methods is to be obtained.

In-built aerials on mains operated receivers usually work on the principle of providing an earth return for signals coming from the mains, in some cases as shown in Fig. 35.23, and in other cases with a capacitance between mains and aerial terminal, and the receiver chassis providing, through capacitance or direct connection, the return to ground. In the first case the requirement for the "aerial" is merely the largest possible capacitance to ground, and a ground connection to the chassis should reduce the signal input. In the second case an earth connection should improve signal strength as the current through the coil will be increased.

Even when a mains-operated receiver is equipped with an in-built loop aerial, some of the signal input is due to the capacitance effect of the loop as a whole. A mains filter may improve the signal-to-noise ratio in such a case, but with the other two types of in-built aerial a mains filter will reduce the signal and noise by the same amount leaving the ratio unchanged.

(iii) Contact potential biasing

Electrochemical activity between the electrodes of a valve produces potential differences without the application of external e.m.f's. The effect is most noticeable on grids and diode plates since their "contact potential" may be of the same order as potentials applied from other sources. The effective bias depends on the surfaces of the two electrodes and the impedance connected between the respective valve pins. The control grid contact potential will vary with different types of valves, with different valves of the same type and with age in a particular valve.

In practice, control grid and diode contact potentials are found in indirectly-heated valves to vary between -0.1 and -1.1 volts with different types of valves, and the contact potential of a particular valve may vary as much as 0.4 volt during life. Because of this, the contact potential of valves has a restricted application as a source of bias, but it can be satisfactory if its limitations are borne in mind.

The two types of contact potential bias are "grid leak bias" of a-f amplifiers and "diode bias" of i-f and other amplifiers. Some valve types which are likely to be used with grid leak bias e.g. Radiotron types, 6B6-G, 6SQ7-GT, and 6AV6, are given a 100% production test for grid leak bias by Amalgamated Wireless Valve Co., under conditions sufficiently severe to ensure that any change of characteristics during valve life will not affect their performance. These types can be recommended

for this type of service provided that the plate current is restricted to a maximum of 1 mA, the grid leak is 5 megohms or larger (2 megohms can be used with a small signal input but distortion should be checked) and the output required is not greater than 25 V r.m.s. Under these conditions less distortion can be expected from grid leak bias than from cathode bias (Ref. 43).

Pentode valves have more critical bias requirements when used as low distortion resistance coupled a-f amplifiers and because of this are not so suitable for grid leak biasing. However when used with a series screen resistor of high value and comparatively small a-f inputs they can be satisfactory, and remove some of the hum problems from fairly low-level a-f amplifiers since there is no bias supply to be filtered, and the cathode is at ground potential so that heater-cathode conductance is not troublesome.

Diode biasing finds its main application in minimum cost 5 valve (4 valve plus rectifier) receivers. A.V.C. is applied to the i-f and converter valves directly from the diode plate of the second detector, the diode load and the cathode of the i-f amplifier being returned to ground. Under these conditions the contact potential of the diode is the only bias applied to the i-f amplifier, and its screen voltage is adjusted to keep plate and screen dissipations within tolerances. The converter may need additional bias, obtained from a cathode resistor and by-pass, depending on the type used.

A trouble which occasionally occurs with this circuit is that the diode bias is too small, the i-f valve draws grid current, and its reduced input impedance damps the i-f transformer sufficiently to cause a serious drop in sensitivity with small inputs. As the input is increased, the additional i-f bias from the a.v.c. line restores the sensitivity to normal so that over a small range of input signals the receiver output increases much more rapidly than the input. A receiver with this defect may show poor sensitivity for 50 mW output, but normal sensitivity for the larger signal required to give 0.5 watt output as recommended by the I.R.E. "Standards on Radio Receivers, 1948."

Additional methods of using contact potential for bias are given in Ref. 44.

(iv) Fuses

Commercial A-M receivers rarely incorporate a fuse owing to the difficulties involved in providing a satisfactory one. The peak current in the primary of the power transformer when a receiver is switched on may be twenty times the average current for a time not exceeding 0.01 sec. This occurs during normal operation, but on the other hand a fault resulting in twice the normal primary current over a period of time may lead to transformer breakdown.

Since a normal cartridge fuse will blow within 0.01 sec. with five to ten times its rated current applied, a fuse of four times the rated current of a receiver would be the smallest value which could be used. Such a fuse would probably not fail immediately, even with a complete short circuit on the whole high tension winding of a receiver, and would be almost useless.

Two types of fuse which can be used satisfactorily under such conditions have been described (Ref. 30). The first consists of the normal glass cartridge and ends, containing in series a small spring soldered under tension to a fine manganin resistance wire by means of a blob of low temperature solder (e.g. Wood's metal). A prolonged overload produces enough heat in the resistance wire to melt the solder and allow the fuse to clear, but the thermal inertia of the mass of solder protects the fuse against short duration surges. With a severe overload the resistance wire clears almost instantaneously. An advantage of this type of fuse is the low temperature required for operation—of the order of 100°C compared with perhaps 900°C for a normal type of fuse.

Another fuse has been made consisting of a high melting point nickel wire with blobs of magnesium powder in a binding varnish supported on it. Once again the thermal inertia of the blob allows short duration surges to occur without damage, but

a prolonged overload raises the magnesium powder to ignition point (about 500°C) and the fuse clears.

A different type of protection has been used in other types of receivers. This consists of an insulated strip of metal with high heat conductivity which is included in the power transformer during winding. One end of the strip projects outside the winding and to this a small stirrup is soldered with very low melting point solder. A spring engages in the stirrup under tension and the primary current to the whole receiver passes through the assembly. Any overheating of the power transformer melts the solder and the spring disconnects one side of the mains from the receiver. Such a device might not protect a low impedance rectifier from damage if the input condenser were to break down, but it could save the power transformer and would certainly prevent a fire.

A heat-operated overload cut-out is described in Ref. 65.

See also Chapter 38 Sect. 12 for general information on fuses, and Table 55.

(v) Tropic proofing

Tropic proofing has been the subject of a large amount of investigation (Ref. 40). However many treatments described are not applicable to commercial A-M receivers—even if only because of expense—and in any case are not required for equipment which, although in the tropics, is to operate inside a home.

For “commercial tropic proofing” the following points might be taken as a minimum requirement:—

(a) Good quality resistors, derated to dissipate no more than two thirds of the manufacturer's rating.

(b) Good quality paper capacitors, preferably sealed in glass, but at least moulded in some non-hygroscopic composition, with particular care (non-cracking wax or varnish sealing for instance) against ingress of moisture along leads. Voltage rating to be at least twice that experienced under working conditions. Mica capacitors to be used in positions critical to leakage e.g. a-f coupling capacitors, or a.v.c. by-pass capacitors.

(c) Mica capacitors in tuned circuits to be of silvered mica type, flash-dipped in non-hygroscopic wax or varnish.

(d) Trimmers to have air dielectric.

(e) Power transformer to be moisture proofed, preferably by baking and vacuum impregnation with bitumen, or with a varnish which can be made to set satisfactorily right through the winding (this must be checked). Failing vacuum impregnation, pitch sealing can be used providing good penetration is obtained. Penetration is assisted by baking the transformers, standing them on edge with the top of the winding just above the surface of the pitch immediately after baking for perhaps half an hour, and then lowering the whole transformer below the surface in the same position and leaving for another quarter hour. The transformers can then be drained.

(f) A-F transformers and chokes to be vacuum impregnated and to have the core connected to the winding, the whole assembly being isolated from the chassis.

(g) Coils to be wound on moulded or ceramic formers and baked, impregnated (preferably under vacuum) and flash dipped in non-hygroscopic wax.

(h) Very fine wire to be avoided; 36 A.W.G. is a suitable minimum size.

(i) Hook-up wire to be covered only with good quality rubber of low sulphur content, or P.V.C.

(j) All corrodible metals to be suitably treated, e.g. steel to be well and heavily plated (and lacquered where possible), aluminium to be anodised if possible or chromate dipped in such places as gang plates, brass to be plated. Die castings and readily corrodible metals, such as zinc, to be avoided.

(k) Plywood to be urea-bonded.

(l) Good quality micarta to be used for lug strips, wavechange switch wafers, etc. Micarta to be baked and vacuum impregnated in non-hygroscopic compound where possible.

(m) All fungus-supporting media such as cloth and other organic materials to be avoided as far as possible and fungus and moisture proofed if used.

(n) Wiring to be arranged as far as possible to minimize the effects of leakage e.g. B+ and a.v.c. not to be wired to adjacent lugs on a lug strip, etc.

(o) All-glass valve types to be used to avoid losses in moulded insulating material, together with high quality valve sockets.

(p) Ceramic insulation to be used in the tuning gang if possible. Micarta—if used—must be baked, vacuum impregnated in varnish and rebaked.

Additional improvements which can be incorporated include the use of ceramic instead of micarta for such items as lug strips, wavechange switch, and valve sockets, hermetic sealing for individual components (particularly transformers), hermetic sealing for the complete equipment with silica gel used for dehydration, and the avoiding of contact potentials in excess of a small fraction of a volt between contacting metals. Platings of appropriate metals can be used to minimize potential differences between adjacent metal surfaces.

See also Chapter 11 Sect. 7 for tropic proofing of coils.

(vi) Parasitic oscillations

The high slope of modern valves makes them particularly liable to generate parasitic oscillations unless suitable precautions are taken. In a radio receiver, a power output stage employing a high slope valve is the most probable cause of trouble, which may show up as a continuous “frying” noise, as an irritating “buzz” perhaps only on loud passages, or merely as reduced output with distortion.

Parasitic oscillations often occur at frequencies of the order of 100 Mc/s with leads from valve sockets forming resonant circuits and with a feedback path provided by a few micromicrofarads of capacitance between plate and grid circuits. In such a case a suitable remedy is a non-inductive resistor (say 50 000 ohms, $\frac{1}{2}$ watt, carbon) wired directly to the grid pin. This increases the losses in the high frequency circuit to such an extent that oscillation is not possible.

Because the placing of wires is liable to vary between receivers, oscillation may occur only in some receivers of a production run, but it is normal practice to provide a grid stopper in each set to avoid rejects. In extreme cases it may also be necessary to use stoppers in screen grid or plate circuits, but the values must be much smaller to avoid excessive d.c. voltage drop.

Valves other than high slope output valves can be troublesome, and in one instance some of a production run of receivers having i-f amplifiers with bare tinned-copper leads a few inches in length connecting the grid and plate pins to the i-f transformers were found to be oscillating at a frequency in excess of 200 Mc/s. The trouble showed up as poor i-f sensitivity with high noise level, and was cured by wiring the hot side of the i-f trimmer directly to the valve socket, thereby including the inductance of the lead to the transformer in the i-f tuned circuit.

The best test for parasitic oscillation in an a-f amplifier is to examine with an oscilloscope the output waveform with the amplifier driven from zero input to overload at various frequencies. Oscillation may be shown as a thickening of the trace over part or all of the cycle or by a higher frequency superimposed on the correct trace. In the absence of an oscilloscope, unusual or varying plate current in an output valve may be taken as an indication of oscillation particularly if the plate current can be varied by moving the hand near the valve.

Additional details on parasitic oscillations are given in Ref. 52.

(vii) Printed circuits*

Printed electronic circuits are no longer in the experimental stage. Introduced into mass production early in 1945 in the tiny radio proximity fuze for mortar shells developed by the National Bureau of Standards, printed circuits are now the subject of intense interest on the part of manufacturers and research laboratories in this country and abroad.

Circuits are defined as being “printed” when they are produced on an insulated surface by any process. The methods of printing circuits fall into six main classifications. (1) Painting. Conductor and resistor paints are applied separately by means of a brush or a stencil bearing the electronic pattern. After drying, tiny capacitors

*Reprinted by permission of The Institute of Radio Engineers from Ref. 38.

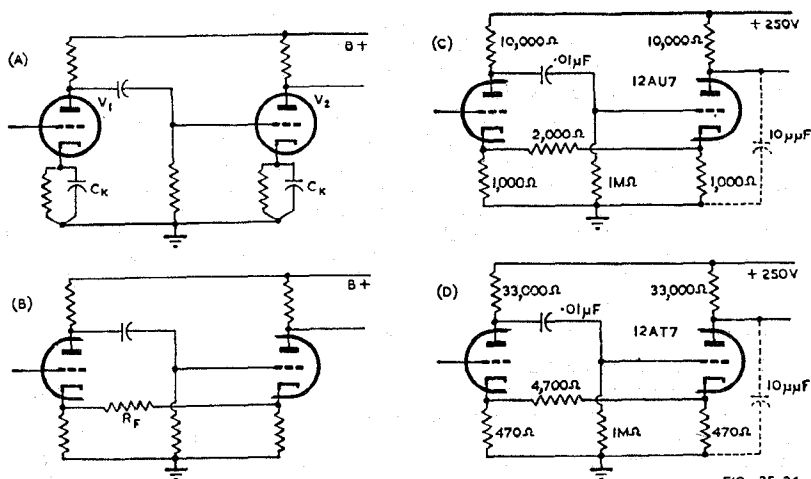

FIG. 35.24

Fig. 35.24. Positive feedback circuits for eliminating cathode bypass capacitors (Ref. 51).

and subminiature tubes are added to complete the unit. (2) Spraying. Molten metal or paint is sprayed on to form the circuit conductors. Resistance paints may also be sprayed. Included in this classification are an abrasive spraying process and a die-casting method. (3) Chemical deposition. Chemical solutions are poured onto a surface originally covered with a stencil. A thin metallic film is precipitated on the surface on the form of the desired electronic circuit. For conductors the film is electroplated to increase its conductance. (4) Vacuum processes. Metallic conductors and resistors are distilled onto the surface through a suitable stencil. (5) Die-stamping. Conductors are punched out of metal foil by either hot or cold dies and attached to an insulated panel. Resistors may also be stamped out of a specially coated plastic film. (6) Dusting. Conducting powders are dusted onto a surface through a stencil and fired. Powders are held on either with a binder or by an electrostatic method.

Methods employed have been painting, spraying, and die-stamping. Principal advantages of printed circuits are uniformity of production, and the reduction of size, assembly and inspection time and cost, line rejects, and purchasing and stocking problems.

See Ref. 37 for a description of the production of complete radio receivers by printing techniques. See also Refs. 38, 39, 46, 47, 61, 62, 63, 64.

There are components which it is not practicable to produce by printing, e.g., electrolytic and other high value capacitors. In Ref. 51 details are given of circuit techniques to eliminate such components without seriously affecting performance.

Fig. 35.24A shows a conventional two-stage triode amplifier and Fig. 35.24B a circuit with similar gain which does not use electrolytic capacitors. In Fig. 35.24B the removal of the cathode by-passes decreases gain and results in an a-f voltage appearing across each of the two cathode resistors. These voltages are in opposite phase and by adjusting the positive feedback through R_F from the cathode circuit of the second valve to the cathode circuit of the first valve the gain of the amplifier can be restored to the original level.

Fig. 35.24C shows a practical amplifier with a voltage gain of 80 and a bandwidth (3 db down) of 250 Kc/s. Fig. 35.24D gives a single valve amplifier with a gain of 1000 and a bandwidth of 100 Kc/s. Two such valves can be used in a four stage amplifier with a gain of one million and a volume of six cubic inches.

Fig. 35.25A shows a method of eliminating screen by-passes by using positive feedback from the plate of a following valve, while Fig. 35.25B demonstrates a screen regeneration circuit similar to the cathode regeneration circuit of Fig. 35.24B.

Circuits for high frequency compensation by means of positive feedback used in place of compensating inductors are also given in Ref. 51.

An analysis of a-f circuits with "cathode neutralization" will be found in Ref. 54

Fig. 35.25. Positive feedback circuits for eliminating screen bypass capacitors (Ref. 51).

(viii) Other miscellaneous features

Synthetic bass is described in Chapter 14 Sect. 3(viii) and its application in receivers in Chapter 15 Sect. 12(ii).

Tone control is covered in Chapter 16.

Whistle filters are covered in Chapter 16 Sect. 11.

SECTION 1 : F-M RECEIVERS

(i) *Comparison with A-M* (ii) *Aerial and r-f design* (iii) *Local oscillator design*
(iv) *I-F amplifier* (v) *F-M detection and A-M rejection.*

(i) Comparison with A-M

Many of the problems encountered in F-M receiver design are new, but the majority are similar to those in A-M receivers and yield to similar treatment to that described in Chapter 35.

The advantages conferred by F-M are not so great that an obviously improved service will necessarily be available to the F-M listener unless suitable programme material is broadcast, and unless the receiver design makes full use of the increased dynamic range, frequency response and noise reduction which are possible with F-M.

To obtain the advantages of the noise reducing properties of frequency modulation it is necessary to design the F-M receiver with considerable care. If this is not done the receiver can destroy much of the improvement obtainable. In many applications F-M does offer undeniable advantages over A-M but this is not true in every case. It should not be assumed that F-M offers a cure-all for every type of noise problem, and for some communication systems A-M may be superior to F-M (see Refs. 9 and 24).

The main differences between A-M and F-M receivers are due to the higher frequencies used for the signal, local oscillator and intermediate frequencies, the need for greater i-f bandwidth, the different type of detection required and the necessity for some form of amplitude rejection. New techniques required for the higher F-M signal frequency would be equally necessary for an A-M system operating on the same frequency.

(ii) Aerial and r-f design

See also Chapter 22 (Aerials) and Chapter 23 (R-F Amplifiers).

(A) The inductance of a straight non-magnetic wire with a length much greater than its diameter can be obtained (Ref. 1) from the approximate formula

$$L = 0.005 l [2.3 \log_{10} (4 l/d - 0.75)] \quad (1)$$

where L = inductance in microhenrys,

l = length of wire in inches,

and d = diameter of wire in inches.

The inductance of one inch of 22 A.W.G. wire is thus $0.025 \mu\text{H}$, and its reactance at 100 Mc/s is 16 ohms, so that when laying out circuits for use at v-h-f every lead used must be considered as an inductance. This factor, and the reduced input admittance of valves at v-h-f, are responsible for most of the problems in F-M receiver front-end design.

(B) Since at 100 Mc/s one quarter wavelength is only about 30 inches, it is quite possible to provide a **tuned aerial system** with F-M receivers. A type commonly used with console receivers is made from 300 ohm ribbon type transmission line. The usual arrangement is approximately half a wavelength long with the two wires connected together at the ends and one side cut to take the feeder. The aerial is tacked around the cabinet, on the back or inside, or it may be placed under floor coverings.

Such aerials operate quite satisfactorily at distances up to fifteen or twenty miles from a transmitter in favourable circumstances, but they are too big for mantel models. However a "**mains aerial**" (or "line antenna") consisting of a small capacitor between one side of the mains and the hot end of an unbalanced aerial primary can be used with comparable results.

For improved results in difficult locations an **outside aerial** should be erected as a matter of course, and in all cases it is advisable to investigate the effect of slight changes in position or orientation of the aerial since they may make a large difference to the signal strength. This is due to the fact that the dimensions of the waves are comparable with those of houses, rooms and even people, so that reflections occur, and standing waves exist which vary in amplitude with small changes in location. When a receiver is operated with an inbuilt aerial on low-level signals this is strikingly illustrated by signal strength variations being caused by reflection from people moving in the vicinity of the receiver.

(C) Aerial coil design is greatly influenced by the input conductance of the first valve, but in all cases it is necessary for the layout of the stage to be such as to include as much as possible of the required tuned circuit inductance in the coil. This prohibits the use of switching within the tuned circuit, and since a typical aerial coil secondary inductance might be $0.06 \mu\text{H}$ (less than the inductance of two inches of 22 A.W.G. wire) a good system is to mount the secondary coil across the tuning condenser (if one is used) when no a.v.c. is applied to the input stage. If a.v.c. is used an assembly can be made of the tuning condenser, tuning coil and a.v.c. by-pass. In the usual case in which a 300 ohm transmission line is used, the main function of the aerial coil is impedance matching and no appreciable voltage gain is obtained. In some cases there may even be a slight loss. See Ref. 14 for calculation of aerial coil constants, although in the example a 75 ohm transmission line is used.

(D) **The valve used in the first stage** has a considerable effect upon the signal-to-noise ratio of a receiver. Although the impedance* between the grid of the input valve and ground might be as low as say 800 ohms in a typical case, reference to Chapter 23 Sect. 6 shows that the equivalent noise resistance of the valve (probably of the order of some few thousands of ohms) is effectively in series with the input circuit and can thus be the most important source of noise in the first stage.

Also the input impedance of the first valve controls the Q (and thus the gain and selectivity) of the aerial coil. It is possible to increase this input impedance—or even make it negative—by using an unbypassed cathode resistor in the r-f stage, but inductance in the cathode circuit and inter-electrode and electrode-to-ground capacitances, which are not accurately known, make it difficult to calculate the value of resistor required. A convenient experimental procedure is to couple a signal generator to the aerial primary and to measure the voltage on the grid of the r-f valve with the heater open-circuited. When power is applied to the heater, the voltage on the grid of the valve will fall owing to its reduced (hot-cathode) input impedance. A suitable value of unbypassed cathode resistor will reduce this drop to negligible proportions.

The effect of the resistor on changes in input capacitance with changing a.v.c. voltage (see Chapter 26 Sect. 7(ii) also Figs. 23.15 and 23.16) should be checked before the value of the resistor is finalized.

(E) The main problem with r-f stages is **instability**, and apart from the causes experienced at lower frequencies, impedances common to the input and output of the

*See Chapter 2 Sect. 8 for valve admittances.

stage become particularly important. These impedances are usually inductances and at 100 Mc/s the inductance of the rotor shaft of the gang condenser becomes sufficiently important in some cases to determine the maximum gain that can be obtained from a r-f stage. This is one reason for the use of permeability-tuned signal frequency circuits, or of loaded resonant lines with a movable short-circuiting bar (Ref. 2). Other couplings can be avoided to a large extent by returning all leads from the input circuit to one point and leads from the output circuit to a different point. If two cathode leads are available in the r-f valve they should be used for this purpose.

Coupling from output to input of the r-f amplifier can be caused by inadequate internal shielding due to an impedance between the screen grid and the cathode. This is usually due to the inductance of the leads in the screen by-pass capacitor, but this inductance can be put to good effect by series tuning it to the operating frequency. By using a small (100-500 $\mu\mu\text{F}$) mica capacitor with leads as short as possible, perhaps $\frac{1}{2}$ in. in all, much better by-passing is obtained than with larger capacitors. The actual frequency of series resonance is not particularly critical. In the case of pentagrid converters of the 6BE6 type satisfactory by-passing is particularly important to prevent undesired impedances from appearing in the oscillator circuit.

Owing to the impedance at signal frequencies of the B+ and filament leads it may happen that more than one B+ by-pass is necessary. Hot spots may occur in the tuning range, and self-resonant by-passes (100-500 $\mu\mu\text{F}$ mica) should be tried at various points in B+, a.v.c. and heater wiring.

A stage gain of 10 can usually be obtained from a r-f stage without undue trouble, and higher gain (at least up to 15) is possible, particularly when there is no coupling between grid and plate circuits in the rotor shaft of a gang condenser.

(iii) Local oscillator design

See also Chapter 24.

Local oscillator stability is important in a F-M receiver because much of the noise-reducing ability of the receiver depends on the centring of the signal on the discriminator characteristic. Detuning in excess of about 25 Kc/s can noticeably affect noise reduction and audio distortion (Ref. 11). On the other hand even a technical user of a F-M receiver can make tuning errors of this order. It is necessary therefore for the local oscillator stability to be of the order of 25 Kc/s in 100 Mc/s, i.e. $2\frac{1}{2}$ parts in 10 000, if the receiver performance is to be unaffected.

This requirement is not easy to meet and an average figure for an uncompensated oscillator is more like 8 parts in 10 000. By keeping heat sources away from the oscillator circuit and introducing compensation after all possible precautions have been taken, a long and short term stability of 2 parts in 10 000 is possible.

Additional oscillator stability can be obtained by using automatic frequency control if the local oscillator is a separate valve, and if suitable control voltages can be obtained from the detector circuit (Refs. 10 and 21). Improvements in oscillator stability of five to ten times are possible, but care must be taken to see that the a.f.c. will allow the receiver to tune from a strong local station to a weak one in an adjacent channel.

Some designs have used permeability-tuned-oscillator circuits to eliminate the temperature instability of a tuning condenser (Ref. 11). Harmonic operation has also been used and gives a reduction in frequency shift due to capacitance variations when a larger tuning capacitor is used to tune to the lower oscillator frequency.

Harmonic operation has the added advantage of greatly increasing the separation between the oscillator and signal frequencies and it thus improves oscillator frequency stability in cases where pulling is experienced between oscillator and signal frequency circuits.

For other methods of frequency stabilization see Chapter 24 Sect. 5.

Grid-tuned and plate-tuned oscillators are not commonly used in the F-M band because the feedback winding becomes comparable in size with the tuned winding.

This leads to tracking troubles and the possibility of an oscillator changing from grid tuning to plate tuning or vice versa in a particular band.

Both Colpitts and Hartley circuits are used, the Hartley (Fig. 24.4B) probably because it is widely used on the broadcast band with 6SA7 type converters. However unless the receiver has only one waveband, switching of the cathode lead is necessary which introduces undesirable impedance between the cathode and the tap on the coil and may lead to parasitic oscillation. Added to this the Hartley circuit is in any case more prone to parasitic oscillation than the Colpitts, and is also liable to change over to a Colpitts type using valve interelectrode capacitances to give a tapping point in the oscillator circuit.

FIG. 36.1

Fig. 36.1. Simplified switching from Colpitts high frequency oscillator to Hartley medium wave oscillator.

Because of this, the Colpitts oscillator is popular in F-M receivers, and a convenient arrangement for a two band receiver is shown in Fig. 36.1 (from Ref. 16). The inductance of the choke L_1 is small enough to be negligible on the broadcast band so that it is only necessary to switch one connection to the oscillator circuit to change from the F-M to the broadcast band. The ratio of internal capacitances between screen grid and cathode and between oscillator grid and cathode determines the amount of feedback, and, if desired, external capacitances can be added to modify the feedback and increase the grid current, as shown (C_1 and C_2) dotted on the circuit. However, these capacitors also have an effect on the signal frequency circuit and sensitivity and signal-to-noise ratio should be checked at the same time as the oscillator grid current. It may be necessary to compromise between maximum sensitivity, maximum signal-to-noise ratio and maximum oscillator grid current.

The chokes L_2 and L_3 comprise the two remaining sections of a trifilar choke made by twisting together three lengths of enamelled 28 A.W.G. copper wire and then winding 15 turns, closely-spaced, on a $9/32$ in. former, $\frac{1}{2}$ in. long. The sections L_2 and L_3 introduce impedance between the heater of the oscillator valve and ground so that variations in heater-cathode capacitance do not appear across a part of the tuned circuit. This is a recommended precaution against microphony and may improve frequency stability during the heating period (about five minutes) of the mixer.

Care is needed in the local oscillator design to avoid microphony and modulation hum since any a-f variation in oscillator frequency results in an equivalent output from the frequency discriminator. A check on modulation hum produced by the local oscillator can be obtained by comparing the hum in the receiver output when intermediate frequency and signal frequency inputs are fed into the converter grid.

(iv) I-F amplifier

See also Chapter 26.

When the maximum Q allowable by bandwidth considerations is used in a F-M transformer the gain obtained with the types of valves currently used approaches the maximum gain possible without an undesirable amount of regeneration. Usually there are three valves amplifying at the intermediate frequency and the over-all gain is greater than 10 000 times, so that regeneration problems are common.

A convenient method of tracing regeneration is described in Ref. 1. It consists of feeding the i-f signal to the hot side of the plate circuit of the second last i-f amplifier by means of a very small capacitor ($3 \mu\mu\text{F}$ or less), retrimming the circuit, and converting the detector to an A-M type by open-circuiting one diode and replacing it with an appropriate capacitor to keep the circuit aligned. When A-M signals are fed into the amplifier the output will be due to the generator and to any regenerative effects from earlier stages which may be present. If the receiver output is decreased

by short-circuiting the input of the second last i-f amplifier regeneration exists and various parts of the receiver can be short-circuited to trace it.

The method has the advantage of making it possible to deal with regenerative signals alone in the first stage instead of regenerative plus desired signals as when tracing regeneration by more conventional means. In addition the A-M signal generator can be set to various frequencies in the passband of the i-f amplifier to trace regeneration which may be more severe at some frequency other than the centre of the pass-band.

When regeneration occurs due to plate-to-grid capacitance in a single valve the circuit of Fig. 36.2A (Ref. 5) provides economical neutralization as illustrated in Fig. 35.2B. Phase shifts and stray inductances complicate the circuit sufficiently to make the calculation of C_n difficult but an average value is about $3000 \mu\mu\text{F}$ and correct neutralizing is obtained when, using the tracing method just outlined, no change in output occurs as the input transformer is tuned through resonance by C_2 .

Fig. 36.2. Circuit for i-f amplifier neutralization (A) Actual circuit (B) Capacitance rearranged to show bridge (Ref. 5).

Series resonance can be obtained in i-f by-passes by allowing half-inch leads with typical $0.01 \mu\text{F}$ paper capacitors. Larger values may give less by-passing and once the self-resonant frequency is passed the effective series impedance increases more rapidly than the frequency at which the by-pass is used.

The i-f amplifier design can be responsible for poor noise rejection on the part of the receiver unless adequate stability is provided against the effects of time, temperature, moisture and varying signal strength. The detuning of one or more i-f tuned circuits from the centre point of the discriminator characteristic will result in decreased noise rejection whether or not a limiter is used (Ref. 3).

Stability versus time characteristics are usually satisfactory when good trimmers are used, but compression type mica trimmers may give trouble, particularly when the effects of vibration in transit between factory and the user's home are considered.

The effects of temperature and humidity can be offset by suitable impregnation methods for coils and the use of low temperature coefficient condensers to tune the transformers. Silvered-mica types are satisfactory as are most air-dielectric trimmers.

Frequency instability with varying signal inputs applies to individual circuits rather than to the i-f amplifier as a whole and can be caused by a decrease in regeneration as gain is reduced by a.v.c. application or by valve input capacitance changes due to a.v.c. applied to i-f amplifiers or to sudden changes in the amplitude of the applied signal in the case of limiters. One method of overcoming the latter trouble is to use resistance coupling between the last i-f amplifier and the limiter (Ref. 21), although this can only be done at the expense of gain and selectivity.

When impulse noise is present the detuning with each pulse may result in phase distortion of the signal which will no longer be centred on a symmetrical pass-band. The noise itself will also be heard and under extreme conditions the effect of a limiter can be to increase noise, as the increase due to mistuning more than offsets any other effect of the limiter (Ref. 3).

In the absence of noise, detuning due to a.v.c. application decreases the amplitude rejection of the receiver and may increase phase distortion.

On the other hand, some detuning due to a.v.c. might be preferable to the amount of detuning caused by overloading in the grid circuits on strong signals. Resistance-capacitance networks having suitable time constants are often used to provide additional self bias when the signal strength is high. This system is usually preferred to normal a.v.c. application.

To minimize detuning effects the i-f amplifier must be non-regenerative and the capacitors on the secondary—at least—of limiter input i-f transformers should be increased as much as the consequent reduction in gain will allow. If the primary can conveniently be wound with a different number of turns from the secondary the primary inductance may be increased when the secondary inductance is reduced and gain will be unchanged if $\sqrt{L_p L_s Q_p Q_s}$ remains constant. This should not be carried to the point where detuning of the primary circuit becomes noticeable either when valves are changed or due to differences in wiring capacitances between different chassis.

In addition, an undue increase in L_s can cause the grid-to-plate gain to become excessive, resulting in instability.

The same precautions can be taken with the input circuits of stages to which a.v.c. is applied and in addition an unbypassed cathode resistor can be used to reduce input capacitance changes. Figures 23.15 and 23.16 show the effect of varying values of unbypassed cathode resistors on the change in input capacitance of type 6AC7 and 6AB7 valves. For type 6BA6 a common value of resistor is 68 ohms.

(v) F-M detection and A-M rejection

There are three main methods of performing the functions of F-M detection and A-M rejection in commercial F-M receivers, the limiter-discriminator combination, the ratio detector and the locked oscillator. See Chapter 27 Sect. 2 for design details and Ref. 8 (from which some of the following information is taken) for a consideration of the capabilities of each. The effect of the type of detector used on over-all receiver performance can be summarized as follows.

(a) Assuming reasonably high a-f sensitivity, the use of a **ratio detector** can save one valve from the number required for a receiver using a limiter and discriminator or a locked oscillator.

(b) The downward A-M handling capability of the ratio detector is less than that of the other two types. For the ratio detector an average figure is about 60% for medium and large inputs whereas the other types rapidly approach 100% once their threshold input is passed. Serious distortion occurs in a ratio detector if the downward amplitude modulation is excessive since this stops the diodes from conducting (see Chapter 27 Sect. 2).

(c) The ratio detector gives some A-M rejection at very small inputs whereas the limiter discriminator combination has a threshold (the beginning of limiting) below which there is no A-M rejection. The locked oscillator also has a threshold—the input required to lock the oscillator. As a result, interstation noise levels on a receiver using a ratio detector are noticeably low for a given sensitivity.

For medium and high inputs all three types reduce amplitude modulation to a small percentage of the original, with the proviso in the case of the ratio detector that the downward amplitude modulation must not exceed about 60%.

An amplitude modulated signal tuned to the mid-point of a balanced discriminator will not give any a-f output, and in such a case the A-M rejection of the discriminator alone is 100%. However, if the signal is not centred on the discriminator characteristic there will be some a-f output.

Even 100% A-M rejection will not remove noise from a F-M carrier. If the carrier is considered as a rotating vector and at a particular instant a noise carrier of twice the amplitude and with a 180° phase difference is added to it, the resulting carrier will be unchanged in amplitude but rotated through 180° by the noise. Thus, phase modulation (and so equivalent frequency modulation) of the desired carrier has occurred and noise must appear in the output of the detector. Since the amplitude is unchanged there will be no limiting. In practice, both amplitude and frequency modulation of a desired carrier occur, and although the receiver may have 100% A-M rejection the effect of the frequency modulation cannot be eliminated.

(d) The output of a ratio detector is proportional to the average amplitude of its input so that some form of a.v.c. is desirable. With the other two types output is almost independent of input above the threshold level, although some form of a.v.c. is often used to prevent overloading of i-f stages and the consequent detuning.

(e) With each type there is a side tuning response when the signal is tuned to the skirt of the i-f selectivity curve. However in the case of the ratio detector this is at a much lower level than the main response and tuning is not a great deal more difficult than with an A-M receiver.

The limiter discriminator circuit gives distorted side responses at a level at least equal to the correct tuning position and tuning is not easy for non-technical users, unless a suitable tuning indicator is incorporated in the receiver.

The locked oscillator circuit may produce severe distortion as the signal crosses the locking threshold in the side tuning positions, or stations may tune with a definite "plop" as the oscillator locks.

If a.f.c. is used it is possible to arrange for the receiver to be pulled rapidly through the side responses by the a.f.c., thus minimizing their effect.

In general, the saving of a valve and the desirable tuning characteristic of the ratio detector make it attractive. However more care is needed in design to obtain correct balance between the two diode circuits for maximum noise rejection, and the limited downward modulation handling capability means that the selectivity of the i-f amplifier must be closely controlled in production. If this is not done, excessive selectivity due to decreased coupling may introduce more amplitude modulation than can be handled by the ratio detector (even without the possible addition of noise) resulting in severe distortion.

The standard de-emphasis characteristic required has a falling characteristic with increasing frequency and is equivalent to that provided by a simple circuit having a time constant of 75 microseconds. The components used to filter i-f voltages from the detector circuit are given suitable values to provide this de-emphasis. Fig. 15.1 gives the standard curve.

Valves designed especially for limiting and F-M detection are available, namely the gated beam discriminator type 6BN6 and the Philips " ϕ -detector" type EQ80.

In the 6BN6 two grids are operated in a quadrature phase relationship at centre frequency and the phase of one grid voltage is caused to vary with respect to the other about the quadrature point as the frequency is varied. The quadrature voltage is developed by space charge coupling to a special grid to which a parallel tuned circuit is connected. Limiting is obtained by controlling the current of an electron beam by an apertured slot located in the beam in a region of high current density.

Typical performance of the 6BN6 (Refs. 25, 26) is that with a F-M intermediate frequency of 10.7 Mc/s the output voltage for 75 Kc/s deviation is about 4.5 volts r.m.s. Maximum A-M rejection with 30% A-M and 30% F-M modulation applied simultaneously is about 35 db. The A-M rejection with respect to signal input varies but at least 20 db of A-M rejection is obtained with 1 volt input and from 15 to 30 db at signals above 1.25 volt r.m.s. An a-f output of 3.7 volts with less than 1% distortion can be obtained using accelerator and plate supply voltages of 60 and 80 volts. Higher voltages and correspondingly higher plate loads will give an a-f output up to 15 volts r.m.s. for 75 Kc/s deviation which is sufficient to drive the output valve directly.

The EQ80 (Ref. 27, from which the following information is taken) contains seven grids of which the second, fourth and sixth grids are screen grids and the seventh is a suppressor grid. To each of the control grids a voltage of at least 8 V r.m.s. is applied from an i-f transformer. The mean value of the anode current is a function of the phase shift between the two control voltages whilst the phase shift is a function of the frequency deviation. Both functions are approximately linear when the phase shift has a sweep between 60° and 120°.

The amplitude of the anode current is not dependent upon the magnitude of the control voltages (provided they are greater than 8 V) so that the valve also acts as a limiter. The ϕ -detector gives an a-f output of about 20 to 25 volts. The first grid can be arranged to cut off the cathode current if the control voltages are not large enough, so that interstation noise is suppressed.

SECTION 2 : F-M/A-M RECEIVERS

(i) R-F section (ii) I-F amplifier (iii) General considerations.

(i) R-F section

The valve complement and other major features of a combination F-M/A-M receiver are determined by the F-M requirements almost exclusively, and the A-M receiver operates with a suitable selection of the parts already in use.

There are of course some additions, and the A-M tuning device is one. The two tuning systems may use separate gang condensers or separate permeability tuning arrangements or a combination of the two. There are two well-known systems of tuning the two bands with one control, one using a tuning condenser with A-M and F-M sections on the same rotor shaft, and the other with a cam on the rotor shaft of a normal A-M type gang, the cam operating slugs in the F-M coils.

On the F-M band, tuning should be accurate within about 20 Kc/s in a band of 20 Mc/s—one part in one thousand—which is comparable with a required A-M setting accuracy of about 1 Kc/s in a band of about 1000 Kc/s. Thus a tuning rate which is satisfactory for the A-M broadcast band should be suitable for the F-M band.

Much of the ingenuity in combined F-M/A-M design is directed towards the elimination of switching, particularly in hot circuits. This is not so much to save the cost of the switching but to avoid the losses in leads to switch contacts and in the additional stray capacitances which are introduced.

One example of this can be seen in Fig. 36.1 where one switch section is saved by converting the oscillator from a Hartley on A-M to a Colpitts on the F-M band. Fig. 36.3 (taken from Ref. 10) shows a system of combining short wave A-M input with F-M band input without switching and without undue loading of one circuit by the other.

Untuned r-f amplification also saves switching, and choke coupling can conveniently be used or a mixture of choke feed for the r-f amplifier on the F-M band and resistance feed on the A-M band. In this case there is of course a considerable loss in image rejection compared with that obtainable with tuned r-f amplification.

Other systems which have been used include a circuit in which the r-f stage is used only on the F-M band with an A-M loop switched to the converter grid for A-M reception, and a more complicated one (Ref. 4) in which the F-M signal is converted by a 12BE6 to the 10.7 Mc/s intermediate frequency and is then amplified by a second 12BE6 operating as an i-f amplifier. On A-M the second 12BE6 becomes the converter by comparatively simple switching, and an A-M loop is connected to its grid while the F-M second i-f amplifier becomes the single A-M i-f amplifier. The first 12BE6 is not used in A-M reception.

(ii) I-F amplifier

As in the r-f section of the receiver, it is important to avoid switching hot circuits in the i-f amplifier, and the fixed tuning and large frequency difference between 10.7 Mc/s and 455 Kc/s fortunately makes a simple series connection of the two i-f's quite satisfactory (see Chapter 26 Sect. 3).

One trouble experienced with this system is that when operating on A-M, spurious responses (e.g. oscillator harmonics) can set up large signals across the 10.7 Mc/s tuned circuits and may overload later i-f amplifiers, interfere with a.v.c. arrangements

FIG. 36.3

Fig. 36.3. Combined F-M band and A-M short wave band input circuit (Ref. 10).

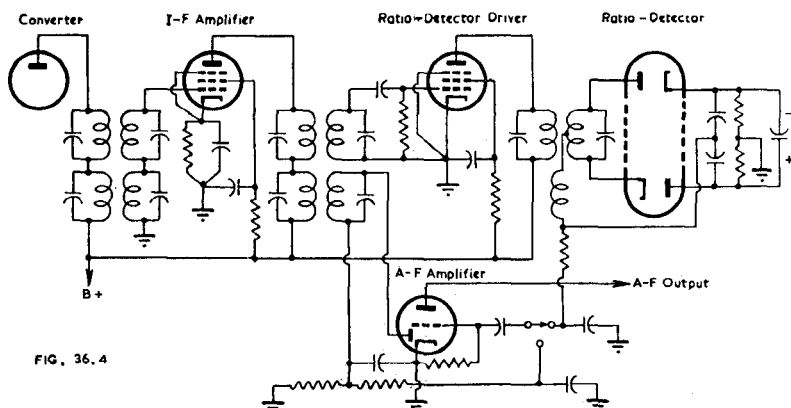

Fig. 36.4. Combined F-M A-M i-f channel using one A-M i-f amplifier and two F-M i-f amplifiers.

or cause other trouble depending on the circuit of the subsequent sections of the receiver. To minimize this trouble it is common practice to switch the converter output to the appropriate (10.7 Mc/s or 455 Kc/s) winding. In such a case the secondary and all other i-f windings (except the output windings) would be series connected. Separate converters, each connected only to its own i-f, have also been used. This eliminates the spurious response trouble, allows very simple switching between bands (only the converter B supply need be switched) and allows more flexibility in the F-M oscillator design.

When using a ratio detector, two i-f amplifiers are needed, and with a limiter-discriminator combination an extra valve is required. As against this the i-f amplifier for an A-M receiver needs only one valve, particularly if of the high slope type commonly used as F-M i-f amplifiers.

One method of obtaining an extra F-M i-f amplifier was mentioned in sub-section (i) the case in which the A-M converter was switched to carry out this function. However, the more usual arrangement is shown in Fig. 36.4 for the case of ratio detector F-M receiver. A combined detector of the triple-diode-triode type could be used to save one valve, but the main point is that the last A-M i-f is not connected in series with the F-M winding, to avoid the necessity for switching a high level i-f circuit.

F-M detection can be carried out by tuning the F-M signal to the skirt of the i-f response and applying the resultant amplitude and frequency modulated wave to a diode. The amount of A-M introduced can be high (see Fig. 26.6) so that a few times greater detection sensitivity is available than from a conventional discriminator. This is obtained at the expense of distortion, the degree of which is dependent on the degree of non-linearity of the i-f skirt characteristic, and the circuit also gives two tuning points. Tuning must be for minimum distortion which is not necessarily obtained at the same tuning point as maximum volume or maximum signal-to-noise ratio. An additional disadvantage is that the circuit has no inherent amplitude rejection properties, as has a discriminator, although a limiter could be used.

(iii) General considerations

The problem of providing comparable a-f output on F-M and A-M has different aspects depending on the type of detection used in each case

With a ratio detector the a-f output is approximately proportional to the r-f input so that some form of a.v.c. is needed, as with an A-M diode detector. The direct voltage generated by the detector provides an excessive amount of control when applied to the grid of the i-f amplifier unless high a-f gain is provided or unless delay is used. The circuit of Fig. 27.38B can be used for delay if a diode is available.

However "partial limiting" as discussed in Chapter 27 Sect. 2(iv)C provides a satisfactory a.v.c. characteristic and at the same time removes the need for any other means of A-M detection since if suitable constants are used this is carried out satisfactorily in the control grid circuit of the driver of the ratio detector. The direct voltage available from this circuit can also be used as an a.v.c. voltage for previous stages (on A-M or F-M).

If about one third of the a-f voltage developed in the "partial limiter" grid circuit is used on A-M, and the full ratio detector output on F-M, similar a-f output will be obtained from the receiver over a range of input signals with each system.

A small discriminator bandwidth (some commercial designs have a width of only 200 Kc/s) will increase the a-f output, which would allow a larger fraction of the A-M output to be used, and increase the output available from small signals with each system.

In the case of a limiter-discriminator combination having A-M taken from the input to the limiter stage, the a-f output is high and almost constant on F-M but is much less with small inputs on A-M. A poor A-M a.v.c. characteristic which allows the a-f output to increase rapidly can provide approximately equal F-M and A-M output when reasonably large A-M signals are received.

SECTION 1 : A-M RECEIVERS

(i) *Introduction* (ii) *Definitions* (iii) *Equipment required* (iv) *Measurements and operating conditions* (v) *Measurements* (vi) *Performance tests.*

(i) Introduction

Few of the results of measurements made on radio receivers can be expressed as the difference between an ideal receiver and the receiver under test. For this reason it is desirable to adopt standard methods of measuring the performance characteristics of receivers and of presenting the results of those measurements. When this is done direct comparisons between receivers are possible, whereas if for instance one manufacturer expresses noise as the percentage of output voltage remaining when the 400 c/s 30% modulation is removed from the modulated carrier required to give standard output, and another follows the English R.M.A.* recommendation and expresses it as the unmodulated r-f input carrier for which the output is equal to the output given by a 10% modulation of that carrier at 1500 c/s, then it is not easy to form any opinion of the relative merits of receivers measured under the two systems.

Unfortunately there is no standard international method of measuring receiver performance and the two series of tests due to the American I.R.E. (Ref. 1) and the English R.M.A.* (Ref. 2) differ in important details. The main requirements of the two testing specifications are given in this chapter.

(ii) Definitions

(A) **Standard input voltages** (I.R.E.) "Four standard input voltages are specified for the purpose of certain tests, as follows :

(1) A "distant-signal voltage" is taken as 86 decibels below one volt, or 50 microvolts.

(2) A "mean-signal voltage" is taken as 46 decibels below one volt, or 5000 microvolts.

(3) A "local-signal voltage" is taken as 20 decibels below one volt, or 100 000 microvolts.

(4) A "strong-signal voltage" is taken as one volt.

(B) **Antenna sensitivity-test input** (I.R.E.) "The sensitivity input is the least signal-input voltage of a specified carrier frequency, modulated 30 per cent at 400 cycles and applied to the receiver through a standard dummy antenna, which results

*This standard is now obsolete and it is understood that a new R.I.C. standard is in course of preparation. References to the old standard have been included where it appears that they convey useful information or follow current practice.

in normal test output when all controls are adjusted for greatest sensitivity. It is expressed in decibels below 1 volt, or in microvolts."

(C) Normal test output (I.R.E.) "For receivers capable of delivering at least 1 watt maximum undistorted output, the normal test output is an audio-frequency power of 0.5 watt delivered to a standard dummy load.

For receivers capable of delivering 0.1 but less than 1 watt maximum undistorted output, the normal test output is 0.05 watt audio-frequency power delivered to a standard dummy load. When this value is used, it should be so specified. Otherwise, the 0.5-watt value is assumed.

For receivers capable of delivering less than 0.1 watt maximum undistorted output, the normal test output is 0.005 watt audio-frequency power delivered to a standard dummy load. When this value is used, it should be so specified.

For automobile receivers, normal test output is 1.0 watt audio-frequency power delivered to a standard dummy load."

The English R.M.A. recommends a standard output of 50 milliwatts measured across a non-inductive resistance connected in place of the speaker voice-coil and with an impedance equal to the modulus of the voice-coil impedance at 400 c/s.

A level of 1 mW has been suggested (Ref. 3) for communication receivers intended for phone operation or for connection to a land line. An alternative of 0.1 mW is suggested in Ref. 4 for special conditions.

The use of 500 mW for large receivers has the advantage of decreasing the effects of hum and noise on the standard output, but when simple a.v.c. is used the sensitivity may be affected by the a.v.c. before the standard output is reached, so that sensitivity and the a.v.c. characteristic both affect the results obtained.

(D) Maximum undistorted output (I.R.E.) "The so-called maximum undistorted output is arbitrarily taken as the least power output which contains, under given operating conditions, a total power at harmonic frequencies equal to 1 per cent of the apparent power at the fundamental frequency. This corresponds to a root-sum-square total voltage at harmonic frequencies equal to 10 per cent of the root-sum-square voltage at the fundamental frequency, if measured across a pure resistance. (The root-sum-square voltage of a complex wave is the square root of the sum of the squares of the component voltages.)"

(E) Bandwidth (I.R.E.) "As applied to the selectivity of a radio receiver, the bandwidth is the width of a selectivity graph at a specified level on the scale of ordinates."

(F) Standard antenna (I.R.E.) "A standard antenna is taken as an open single-wire antenna (including the lead-in wire) having an effective height of 4 meters."

(iii) Equipment required

(A) Standard signal generator (English R.M.A.) "Signal generators shall give readings of microvolts to $\pm 10\%$ up to 10 megacycles per sec. and to $\pm 25\%$ above 10 megacycles. Their frequency calibration shall be within 1% or within 10 kc, whichever is the greater and incremental frequencies shall be within 0.5 kc; the modulation shall be accurate to within 1/10 of the nominal percentage."

I.R.E. recommendations include the following three points:—

(1) At broadcast frequencies an output voltage indication accuracy within 10% is usually adequate. At higher frequencies an accuracy of indication within 25% is satisfactory.

(2) A frequency indication accuracy of 1% is generally sufficient, but for selectivity or interfering-signal tests the radio frequency should be adjustable in small increments about the desired frequencies and adjustment and indication to within 0.1 per cent of the carrier frequency are desirable.

(3) Frequency modulation should be kept as low as possible. The maximum permissible frequency modulation in cycles is given by $(50 f_c + 100)m$, in which f_c is the carrier frequency expressed in megacycles and m is the modulation factor.

Built-in 400 c/s modulation facilities are usually provided, at least for 30% modulation and sometimes for varying depths. The 400 c/s source should have low distortion (not greater than 1%). It is desirable for modulation depths between 0 and

90% to be available and modulation distortion should be small. There should be provision for the connection of an external a-f generator so that the modulation frequency can be varied between the limits of 30 and 10 000 c/s.

The r-f output should be variable at least between one microvolt and one volt, but a maximum output of two volts is useful.

A smooth, backlash-free drive is necessary, with a movement slow enough and scale large enough for small increments of frequency to be accurately recorded when selectivity curves are being taken.

Fig. 37.1. *Standard dummy antenna and method of connection (from Ref. 1).*

FIG. 37.1

(B) Standard dummy antenna (I.R.E.) "The elements of the standard dummy antenna are capacitors (C_1 and C_2) of 200 and 400 micromicrofarads, respectively, an inductor L of 20 microhenrys, and a resistor R of 400 ohms, connected as shown in Fig. 37.1. The effective values of R , L , and C should be within 10% of the nominal values. The stray capacitance between any two points must be so small as to be negligible at operating frequencies, and the dummy antenna must be so devised as to avoid coupling to other equipment. If the output impedance of the attenuator of the signal generator is not negligible with respect to that of the dummy antenna, this impedance should be deducted from the respective constants thereof.

The leads used in connecting the standard-signal generator through the dummy antenna to the receiver should be so short as to introduce negligible voltage drop. They should be shielded to reduce external fields."

(C) Output-power-measuring device (I.R.E.) "The standard dummy load is a pure resistance which should be of sufficient power capacity to carry the maximum power output of the receiver without change in its resistance. If provided with taps, these should be sufficiently numerous to allow adjustment to within 10% of the proper value. The precise value of the resistance of each step should be known.

Dry-rectifier-type voltmeters, vacuum-tube voltmeters, or thermocouple-type ammeters are suitable for measuring the power delivered to the standard dummy load. They may read root-sum-square values and be calibrated in current, voltage, power, or directly in decibels, the former units being more commonly used. While dry-rectifier-type voltmeters are subject to temperature and frequency errors these are usually not of sufficient magnitude to affect the measurements seriously, so long as distortion is not high."

(D) Audio-frequency generator The output of the a-f generator should be sufficient to modulate the r-f signal generator to 100% from 30 to 10 000 c/s, and to drive the output valve of the receiver to full output when connected to its grid circuit. The maximum harmonic distortion should not exceed 1%.

(E) Audio-frequency attenuator An attenuator is desirable which gives known a-f output voltages continuously variable between 1 V and 1 mV when supplied with a 1 V (or larger) input. Commercial types are available with an output range of 1 V to 1 μ V. The calibration should be accurate (or the correction known) over the range of frequencies to be used.

(F) Wave analyser A wave analyser is required to measure the relative magnitudes of harmonics and inter-modulation products. The I.R.E. requirements for such an instrument are "the accuracy of measurement of each frequency should be within 5% of the indicated harmonic amplitude, and sufficient selectivity should be available to prevent adjacent harmonics at any measured frequency from influencing the results. In this type of analysis it is, of course, necessary that the signal-generator harmonics be small in comparison with the harmonic distortion being measured."

A **distortion-factor meter** can be used to measure total distortion* i.e. the receiver output at all frequencies except the fundamental of the signal source. It is worth noting that the English R.M.A. definition of "distortion factor" is

$$\frac{1}{2} \sqrt{\frac{\sum_{n=2}^{\infty} n^2 V_n^2}{\sum_{n=1}^{\infty} V_n^2}}$$

where n represents the order of an individual harmonic. This expression† loads the higher harmonics in proportion to their order.

An I.R.E. recommendation is "If an instrument is used which makes a lumped measurement of all distortion, by elimination of the fundamental, a high-pass filter should be used, in order to eliminate hum and similar low-frequency noise from the result."

(G) **Meters.** Meters are required to cover the range of voltages and currents to be measured. Valve voltmeters are useful for measuring small a.c. voltages and currents and for making measurements in which a minimum of circuit loading is necessary (e.g. a.v.c. bias voltages).

(H) **Equipment for acoustical tests** A number of I.R.E. and English R.M.A. tests are of an acoustical nature. For information on the equipment required and the testing conditions, Refs. 1 and 2 should be consulted.

(iv) Measurements and operating conditions

(A) **Output measurements** The I.R.E. requirement is that output measurements are to be made in terms of the power delivered to a standard dummy load, which is a pure resistance of a value equal to the 400 c/s impedance of the loudspeaker to be used with the receiver. Where an output transformer is connected between the radio receiver and the loudspeaker, the output transformer is to be treated as part of the radio receiver.

There are special requirements when power output is to be measured in the presence of background noise. If the background noise power is smaller than the output power being measured, the incremental reading of output power may be used. With a thermocouple output meter the incremental output power is equal to the observed total power minus the observed noise power. If another type of output meter is used, a calibration should be made in terms of incremental power.

If the background noise is greater than the output power being measured, it is desirable to use a band-pass filter tuned to the test audio frequency to remove the background noise wholly or partially from the output meter. This filter should be connected between the load and the output meter.

Alternatively an electro-dynamometer with its field synchronously excited from the original source of modulation can be used.

(B) **Summary of additional I.R.E. requirements** "The operating voltage applied to a radio receiver should be held constant at the specified value during measurements of receiver characteristics. Certain receiver characteristics may be desired at other than normal test voltage, or over a range of operating voltages, in which case a statement of the voltages used should be included in the test data. In any case, tests should be made to check whether the receiver operates satisfactorily over the full range of operating voltage that is liable to be encountered in practice.

A.C., A.C./D.C., or D.C. receivers should be tested with 117 volts r.m.s. A.C. or 117 volts D.C. applied, unless some other operating voltage is stated.

Automobile receivers should be tested with 6.6 volts at the receiver-battery terminals. The voltage should be obtained from a battery being charged at the required rate and not by the use of a dropping resistor. 32-volt farm-lighting-plant receivers are tested with 36 volts.

*Total harmonic distortion, see Chapter 14 Sect. 2 (iv) p. 609.

†This is the same as the Weighted Distortion Factor described in Chapter 14 Sect. 2(v) p. 610.

Other battery-operated receivers are tested with batteries of the type and voltage specified. The batteries used should not have abnormally high internal resistance. The valves used should be selected to have the rated values of those characteristics which most affect the performance of the receiver."

(C) Summary of English R.M.A. requirements The receiver is to operate in its cabinet for at least half an hour before tests begin.

All batteries are to be at their normal operating voltages. The internal resistance of the H.T. battery is to be increased by adding, in the H.T. negative lead, a resistance equal to 1 ohm per cell. Care should be taken to see that the added resistance does not affect the grid bias.

Where the receiver carries a mains tapping device and a number of marked ranges, the applied voltage should fall in the middle of one of these ranges, the midpoint being calculated as a geometric mean.

(v) Measurements

Tests are applied to receivers for various reasons ; as an aid to design, to compare different designs, to compare a mass-produced receiver with a laboratory prototype and as a preliminary to repairs. Appropriate tests should be selected from the following sections to suit the required object, or perhaps the available equipment. An arbitrary distinction has been drawn between measurements (carried out with voltmeters and ammeters) and tests, which in general need more equipment.

For normal **voltage and current measurements** receivers and amplifiers should be operated without input or output, and bias-controlling volume controls should be turned to maximum.

If all voltages are to be checked it is necessary to use a high impedance meter (20 000 ohm/volt or more) but most important checks can be made with 1000 ohm/volt meters. In any case allowance must be made for meter resistance in all high impedance circuits and it is useful to know the actual value of resistance for any particular range in use.

Measurements of grid bias should normally be made either across the cathode bias resistor (if any), or between the cathode and the earthy end of the grid resistor. This will give the grid-cathode voltage unless current is flowing in the grid resistor. The latter may be checked by short-circuiting the grid resistor with a suitable current meter in the plate circuit, and noting any change in reading.

There are two methods which can be used to determine plate and screen voltages when high values of series resistors are used. The first is the direct method, noting the reading on a high impedance voltmeter and making allowance for the meter resistance. If a suitable two range voltmeter is available, the method described by Lafferty may be used to determine the correct voltage—see Chapter 4 Sect. 7(iii) pages 163-164, and eqns. (10) and (11). Alternatively, the series resistor in the voltmeter may be shunted by an external resistor of equal value, with a switch to remove the shunt when required. This gives a scale ratio of 2, and enables eqn. (11) on page 164 to be used. The shunt resistor may well take the form of a decade box, accurately adjusted to the internal voltmeter resistance. Other methods of making allowance for meter resistance may introduce serious errors.

The second method of measuring plate and screen voltages, which may be called the indirect method, is to measure the voltage from B+ to cathode and also the current to the electrode. The value of the series resistor should then be measured, and the voltage drop across it may be calculated by Ohm's Law.

An example of the error which may be introduced by other methods is given below. Suppose that a 20 000 ohm/volt meter on the 25 volt range is used to measure the bias voltage (from grid to cathode) on an output valve which has back bias and a 0.5 megohm grid resistor.

Although the meter resistance is equal to the resistance of the grid leak so that half of the bias voltage appears across the meter, only one half of the generated bias voltage is applied to the grid of the valve, its plate current is increased, and a larger voltage is developed across the back-biasing resistor. The indicated bias voltage is thus more than half the working bias voltage.

When voltages and currents are being measured to check valve electrode dissipation or component ratings it may be necessary to modify receiver operating conditions to obtain the worst conditions for the component in question. For example tuning a strong signal with a back-biased receiver will decrease the bias on the output valve and may cause the plate dissipation to exceed the limit. The effect of component tolerances must also be taken into account.

A measurement of, say, oscillator grid current at low voltages as part of a type test in a battery receiver at low voltages would not be considered finished until many valves had been measured to determine the average and minimum values, or unless valves with bogie and limit characteristics were available.

The maximum **temperature rise** allowed in radio power transformers by R.M.A. specification M4-541 is 65°C (core or windings whichever is greater) when operated continuously with the specified load, at the specified frequency, under standard conditions and at a voltage 10% above that of the standard line voltage.

The standard conditions are set out in M4-546 and require a specially constructed asbestos box. The core temperature is measured with an all-glass mercury bulb thermometer brought into good contact with the surface of the core by means of glazier's putty.

The temperature of the primary and secondary windings are determined by the resistance method using the following formula : (A.I.E.E. Rule 13-207)

t = reference temperature of winding

T = temperature of winding to be calculated

r = resistance at reference temperature t

R = observed resistance at temperature T

$$T = \frac{R}{r} (234.5 + t) - 234.5.$$

The observed resistance R is to be measured within one minute from the completion of the test run, that of the highest voltage secondary winding being measured first and that of the primary winding being measured second.

The temperature rise of the transformer is determined by subtracting the temperature of the ambient air within the enclosure at the end of the test from the temperature of the core or windings (whichever is highest) at the end of the tests.

In determining the ultimate temperature of the core and windings, the operation of the transformer is continued until temperatures within the enclosure show constancy for three successive readings at intervals of at least 15 minutes.

An ambient temperature of 40°C is maintained within the enclosure throughout the test.

(vi) Performance tests

(A) Sensitivity

All measurements, including sensitivity, which are made with the signal generator output applied to the aerial terminal of a receiver require a standard dummy antenna to be connected between the two, except that in the case of a receiver designed for use with a special aerial, a dummy aerial is required with constants giving an impedance characteristic similar to the special aerial. The sensitivity is expressed as the input required to give standard output from the receiver. The input referred to is the open circuit voltage from the signal generator, modulated 30% at 400 c/s.

For purposes of recording results sensitivity is usually measured at or near the three tracking points on each wave range, but when curves are to be drawn additional points are required.

With sensitive receivers noise forms a large part (or all) of the output in sensitivity measurements, and alternative methods of measurement which specify the input required to give a minimum signal-to-noise ratio are becoming increasingly popular. One method is to specify the input required to give equal signal and noise outputs i.e. when the modulation is switched off the output power is halved. A signal-to-noise ratio of 15 db is more commonly used for communication work in England, this ratio being taken as providing satisfactory intelligibility.

When the signal-to-noise ratio method of measurement is used for all types of receivers it is necessary to make provision for insensitive receivers by defining sensitivity as the input required to give a certain signal-to-noise ratio, or the input required to give standard output, whichever is the greater.

Sensitivity measurements on telegraphy receivers are carried out by adjusting the beat note to the peak of the a-f response.

To check the gain of individual stages in a receiver, a measurement is made of the input to successive grids required to give standard output from the receiver. The generator is coupled to the receiver by means of a large capacitor (say $0.1 \mu\text{F}$) and the normal connections to the grid are not disturbed.

Measurements made in this way are liable to errors at high frequencies and when regeneration is present. At high frequencies the inductance of the generator output leads and the input capacitance of the stage being measured may seriously affect the results.

During measurement, regenerative effects may be eliminated by the low impedance of the signal generator connected between grid and ground but when the gain from the previous grid is measured the regeneration will re-appear so that the apparent gain of the earlier stage is its true gain multiplied by the gain due to regeneration in the subsequent stage.

The regeneration may be from causes such as feedback due to the plate-grid capacitance of an i-f amplifier, or in the case of a converter it may be due to oscillator voltages on the signal grid. For the latter reason, measurements of conversion gain and r-f gain (or aerial coil gain if no r-f stage is used), particularly at high frequencies, should be treated with reserve unless it is known that these effects were not present.

(B) Selectivity

Selectivity measurements are made with the object of determining the frequency separation necessary to eliminate interference between a desired signal and a stronger undesired signal.

It is not possible to specify one selectivity test the results of which will be a measure of the interference to be expected, because there are several ways in which interference can occur.

These are :—

(1) Because of inadequate selectivity the two modulated carriers may both be present at the second detector, and although no noticeable interaction occurs between the signals, they are both heard.

(2) The desired carrier may be modulated by the modulating frequencies of the undesired carrier (cross-modulation).

(3) A reduction of the a-f output from the desired carrier may be caused by a.v.c. voltages developed by the undesired carrier, or by demodulation by the undesired carrier.

(4) When the frequency separation between adjacent carriers is an audible frequency a continuous heterodyne is heard. This effect is very noticeable in receivers with a good high frequency response as they are capable of reproducing frequencies of 9 or 10 Kc/s by which medium wave broadcasting stations are separated.

(5) Intermodulation may occur between two stations of which the frequency difference or frequency sum is the same (or nearly the same) as the frequency of a desired station. An intermodulation product can then interfere with a desired signal.

(6) Distortion in the receiver may produce harmonics of an undesired signal which interfere with a desired signal.

(7) "Monkey chatter" may occur due to the sidebands of the undesired carrier being detected, with frequency inversion, as sidebands of the desired carrier. For example, if the desired carrier is separated by 20 Kc/s from the undesired carrier, which is lower in frequency and which is modulated by frequencies of 7 and 12 Kc/s, the higher sidebands of the undesired carrier become respectively 13 and 8 Kc/s lower sidebands of the desired signal.

Sturley (Ref. 3) points out a less commonly recognised extension of this effect. The presence of small percentages of a-f harmonics may greatly extend the carrier

frequency separation across which monkey chatter may occur. For example, suppose a strong local station on 1000 Kc/s induces 1 volt 50% modulated at 7 Kc/s in the aerial of a receiver tuned to 1030 Kc/s. If there is a fourth harmonic sideband percentage of 0.1% the amplitude of the upper frequency harmonic sideband (1024 Kc/s) is 500 μ V. A station on 1030 Kc/s would thus have added to it a 6 Kc/s sideband of ample power to cause over-modulation at low signal levels.

An investigation into the poor agreement between selectivity as measured by the one or two signal generator methods and actual performance on the air is detailed in Ref. 13.

The I.R.E. recommendation for a single signal selectivity test is that the receiver be tuned to the test frequency as in the sensitivity test. The signal generator is then detuned each side of resonance, the radio-frequency input voltage which results in normal test output is observed, and its ratio to the sensitivity-test input is computed. If this test is made at only one frequency in superheterodyne receivers it is recommended that this be 1000 Kc/s.

When the selectivity of the a.v.c. circuit is the same as that of the signal circuit no special precautions are necessary. However if there is any appreciable difference between the two selectivities it is recommended that the a.v.c. voltage be maintained at the value obtained at centre frequency. This method provides an indication of the circuit selectivity rather than of discrimination against interference.

Errors may occur in very selective receivers because the receiver output is the result of applying a band of frequencies (carrier and upper and lower sidebands) to a sloping characteristic. To avoid this effect an unmodulated carrier can be used and diode current in the second detector circuit taken as the output indication.

Another point which may give trouble is that with very sensitive receivers the majority of the standard output at full sensitivity is noise. A different signal-to-noise ratio at standard output will be experienced when tuning towards a strong carrier and a faulty reading will be obtained. To overcome this a reference input is often selected to give a good signal-to-noise ratio while still leaving the a.v.c. inoperative—10 μ V is a suitable input in many cases.

Two-signal tests are specified by the I.R.E. for cross-talk, whistle and blocking interference. The signal generators are preferably connected in series but parallel connection is possible with special dummy aerials. The radio receiver is tuned to the desired signal at one of the standard test frequencies and at one of the standard input voltages. The receiver volume control is adjusted to give normal test output when the signal is modulated 30% at 400 c/s, after which the modulation is switched off.

An interfering-signal input voltage is applied to the receiver, in addition to the desired signal which remains unchanged. The interfering signal is modulated 30% at 400 c/s. The interfering signal is tuned through a wide frequency range and the interference-test input voltage which gives interference-test output at 400 c/s (30 db below standard output) is observed wherever its value is less than one volt. Readings are not taken for carrier spacings so close that beat note interference is more severe than cross-talk interference.

Such a test is the only type of selectivity test which shows correctly the selectivity curve, at reduced sensitivity, of a receiver having a.v.c. It is also the only method by which the selectivity of a receiver having automatic selectivity control can be tested directly.

The interfering signal may also reduce the desired-signal output by a.v.c. action or overloading. Blocking interference tests can be carried out for this effect (as specified by the I.R.E.) by modulating the desired signal and measuring the change in output with varying signal strength and frequency of the unmodulated signal. The results of blocking signal tests can be plotted on the same sheet as the results of the two-signal cross-talk tests.

The two-signal whistle interference test specified by the I.R.E. indicates the greatest interference input permitted without the output exceeding the equivalent of approximately 1% modulation of the desired signal. If the desired signal is modulated 30%, the permitted interference output power is 0.001 of the desired-modulation output power.

The signals are the same as for the cross-talk test, except that the interfering signal is unmodulated. The interfering signal is tuned through a wide frequency range, and the interference-test input voltage, which gives interference-test output at 400 c/s, is observed wherever its value is less than one volt. No reading is made with the desired and undesired signals separated by 400 c/s.

The English R.M.A. selectivity test is similar to the I.R.E. cross-talk interference test but a 400 c/s bandpass filter is used between receiver and output meter to eliminate the effect of the heterodyne between carriers. The desired signal is 1 mV, 30% modulated at 400 c/s and the receiver volume control is adjusted to give one quarter of the rated maximum output. Modulation is removed from the desired signal and the input required to give an output 40 db below the previous output is noted for various off-tune frequencies of the 400 c/s 30% modulated undesired carrier.

In Ref. 40 a test for r-f intermodulation is given. A "wanted" signal 30 db above 1 μ V is applied to a receiver, the sensitivity control is adjusted for standard output (a.v.c. switched off) and the signal is then removed.

Two interfering signals are then applied to the receiver with a frequency difference or frequency sum equal to the frequency of the wanted signal. The interfering signals are each 110 db above 1 μ V and neither is of such a frequency as to give an appreciable output when applied alone. Under these conditions the receiver is not to produce an output exceeding the standard output.

When this test is used care should be taken to see that intermodulation does not occur outside the receiver, for instance in measuring diode circuits of signal generators.

A test for r-f harmonic generation in the receiver is also given in Ref. 40. Standard output is obtained from a wanted signal as above, and then the wanted signal is replaced by an unwanted signal of half the frequency and at a level of 116 db above 1 μ V. The output from the receiver should not exceed the standard output. The effect of signal generator harmonics must not be overlooked when this test is being performed.

Sturley (Ref. 3) gives additional tests whereby the effects of heterodyne whistles, monkey chatter and a receiver whistle filter can all be shown on a set of curves.

(C) Electric fidelity (frequency response)

The electric fidelity test specified by the I.R.E. shows the manner in which the electric output of a receiver depends on the frequency of the a-f modulation. The radiation characteristics of the loud speaker are not taken into consideration and this minimizes the value of the test.

30% modulation of a 1000 Kc/s 5000 μ V signal is used, and the receiver is tuned to it in the following manner. Firstly the receiver is tuned to the carrier with 400 c/s modulation, and then the modulating frequency is increased until the receiver output has fallen to one fifth. The receiver tuning is then readjusted slightly for **minimum** output.

The receiver output is measured in terms of current or voltage in a standard dummy load, or in terms of the voltage across or of the current in the voice coil of the loud speaker. In the latter case, the loud speaker should be located in its baffle or cabinet, with the receiver chassis in place. The data should include a statement of which load is used. The receiver volume control is adjusted to give normal test output. The modulation frequency is then varied continuously from 30 to 10 000 cycles while maintaining 30% modulation and the output variation is observed.

If the electric-fidelity curve has decided peaks, there is abnormal tendency towards overloading, and the observations may have to be repeated with less output.

It is frequently unnecessary to make or plot these observations below -20 db, but further observations may be desirable, particularly if a large amount of negative feedback is used.

Suitable precautions must be taken to prevent hum or noise, if present, from affecting the accuracy of the results.

If electric-fidelity varies appreciably with the signal frequency, the input level, the volume or tone control settings or any other parameter, additional tests should be made to show the effect of these changes.

(D) Harmonic distortion (I.R.E.)

This test is intended to evaluate the spurious a-f harmonics which appear in the electric output of the radio receiver during normal operation. Care should be taken to avoid appreciable harmonic distortion occurring in any part of the signal-generating equipment, or in the output-measuring circuit. The required harmonic-measuring equipment in the output circuit should not appreciably affect the output load conditions. This equipment may measure each harmonic individually or may measure all harmonics collectively. The proper tuning of the receiver is important in making distortion tests.

No one complete set of conditions can be prescribed for this test, because harmonic distortion depends on so many details of radio receiver design and operating conditions. Harmonic distortion is caused by overloading and many other phenomena, and is present under various operating conditions, especially at high degrees of modulation. The following series of tests is intended to show the effect of operating parameters on distortion.

Variation of output. The receiver is tuned to 1000 kilocycles and a "mean-signal" input, modulated 30% at 400 cycles, is applied. The distortion is noted as the output of the receiver is varied by means of the volume control.

Variation of modulation. With a "mean-signal" 1000-kilocycle, 400-cycle-modulated input, the modulation is varied from 10 to 100% and the distortion observed. The output is maintained at normal test output by the volume control for this test, or as near this value as possible.

Variation of input signal level. With a 1000-kilocycle signal, modulated at 400 cycles, the distortion at normal test output is noted as the input signal voltage is varied. This test is to be performed at both 30% and 80% modulation. It is usually sufficient to take distortion at the standard input levels which fall within the limits of the receiver. When a standard-signal level exceeds the limit of the receiver, a measurement should be made at that limit.

Variation of modulation frequency. To disclose the effect of the modulation frequency on distortion, tests on variation of output and variation of modulation should be repeated at several modulation frequencies throughout the a-f range. The maximum modulation frequency at which harmonic distortion can be measured is one-half the maximum frequency which can produce any appreciable output.

The harmonic distortion is measured across a standard dummy load and may be measured as either root-sum-square total harmonic distortion or each harmonic may be measured separately. It is expressed as the ratio of the harmonic voltage to the fundamental voltage either in per cent or decibels.

Intermodulation measurements. Owing to the lack of signal generators suitable for r-f intermodulation work, these measurements are normally carried out only on the a-f end of radio receivers. See Sect. 3(ii)A of this chapter for details.

(E) Maximum undistorted output (I.R.E.)

"This test is intended to indicate the maximum power output which the receiver will deliver under given conditions, before appreciable overloading or other forms of distortion occur. The maximum undistorted output may be determined under given conditions by observing the total harmonic distortion, and continuously increasing the output from zero up to the least value which contains a total harmonic distortion of 10% (root-sum-square voltage). This value is designated the maximum undistorted output under the given conditions.

The data should include a statement of the operating conditions, including which condition was varied in order to increase the output during this test. It is suggested that the volume control of the radio receiver be varied, the other conditions being unchanged during a single test and being chosen as suggested for the harmonic-distortion test. Freedom from distortion depends on the r-f input voltage and on the frequency and percentage of modulation.

It is understood that there is no sharp dividing line between appreciable and negligible distortion. The figure of 10% has been chosen somewhat arbitrarily as a reasonable basis for the definition of maximum undistorted output as affected by all operations in the receiver."

(F) Automatic volume control

The I.R.E. recommendation is to tune the receiver to a mean-signal input voltage 400 c/s 30% modulated at 1000 Kc/s and to adjust the volume control so that with one volt input to the receiver the output is one half of the maximum power output. The output is then read as the input is varied from one microvolt to one volt.

A disadvantage of this method is that the output readings for low inputs, from which much valuable information can be obtained, are carried out at very low levels (perhaps below 1 mW) and hum in the receiver output may be troublesome.

Scroggie (Ref. 6) suggests beginning the a.v.c. curve with the volume control set at maximum and with the minimum input. Output readings are taken with increasing input until the output reaches one quarter of the maximum. It is then reduced to one tenth of this value by means of the volume control and the input is further increased. This procedure is repeated until the maximum input is applied to the receiver. The sections of the curve are made continuous by the use of appropriate multiplying factors. This method has many advantages—Chapter 27 Sect. 3(xiv).

Useful information can also be obtained from a noise curve plotted on the same sheet. The same procedure is adopted as for drawing the a.v.c. curve but the input carrier is unmodulated.

Other information sometimes added to a.v.c. curves includes graphs of distortion, a.v.c. bias voltage and electrode current and dissipation for the controlled valves vs. input voltage, and it may be useful to draw a horizontal line across the a.v.c. curve (when drawn by Scroggie's method) at a level representing the nominal output of the receiver. Alternatively the maximum output of the receiver may be plotted.

When the converter valve has a.v.c. applied to it, detuning of the signal may occur as the signal input is varied. This should be remedied by retuning the receiver with each input level change if necessary.

(G) Noise

The I.R.E. recommendation is that noise should be expressed as the equivalent-noise-sideband-input (ensi). An unmodulated input carrier of suitable strength, E_s , is applied to the receiver, and the noise output power P_n is measured on a R.M.S.-reading instrument. A 400 c/s bandpass filter is connected between receiver and output meter, the carrier is 30% modulated at 400 c/s and the signal power output P_s is measured. Then

$$\text{ensi} = 0.3 E_s \sqrt{P_n/P_s}.$$

E_s should be at least three times and preferably ten times greater than the computed noise voltage.

Excessive low frequency hum components may usually be filtered out by the use of a 300 cycle high-pass filter without materially affecting the random-noise output.

An alternative method of specifying noise is by comparing the signal-to-noise ratio of a particular receiver with that of an ideal receiver, the difference being called the noise factor of the receiver in question. Ignoring any noise external to the receiving system, the only source of noise which is inseparable from an incoming signal is the thermal agitation noise due to the radiation resistance of the antenna. Thus a signal-to-noise ratio has its highest possible value when the noise due to the antenna radiation resistance is the only noise source in a receiving system.

Where a signal voltage e_{ant} is induced into an antenna of radiation resistance R_{ant} , maximum signal power is delivered to a receiver with an input resistance of R_{ant} . This maximum power available from the antenna is

$$\left(\frac{e_{ant}}{2}\right)^2 \times \frac{1}{R_{ant}} = \frac{e_{ant}^2}{4R_{ant}}.$$

Similarly the noise from the antenna available to the receiver is

$$\left(\frac{e_{noise}}{2}\right)^2 \times \frac{1}{R_{ant}} = \frac{4KT\Delta FR_{ant}}{4R_{ant}} = KT\Delta F,$$

where K = Boltzmann's constant = 1.38×10^{-23} joule/degree Kelvin

T = absolute temperature in degrees Kelvin

F = bandwidth of system in cycles per second,

and the signal to noise power ratio of an ideal system is

$$\frac{e_{s,ant}^2}{4KT\Delta FR_{ant}}$$

The noise factor of an ideal receiver can thus be defined as the number of times by which the available signal power from the aerial must exceed $KT\Delta F$ in order to give unity ratio of available signal to noise power.

The noise requirement for such an ideal receiver is that it must contain no internal sources of noise. It must also present an infinite impedance to the antenna so that there will be no loss of signal voltage. If for instance the input impedance of the receiver were to match the antenna impedance the voltage available to the receiver would be one half of the signal voltage induced into the antenna and this would be developed across one half of the antenna impedance due to the parallel connection of the antenna and the matching input circuit. Substitution of these factors in the expression above shows that in such a case the maximum noise factor obtainable is 2, i.e. 3 db.

Since the requirement for maximum power transfer is that the input impedance of the receiver should be equal to the antenna impedance, it is evident that the conditions for maximum gain are in general different from those for minimum noise. The best noise figure in practical receivers is obtained when the input impedance is intermediate between an open circuit and an impedance match with the antenna system.

When noise calculations are being made the value $T = 290^\circ\text{K}$ is commonly used as this gives KT the convenient value of 4×10^{-21} . However, the effective temperature of the radiation resistance is subject to wide variations, and is affected by the surroundings with which the antenna can exchange energy by radiation. For instance, the noise temperature of a highly directional micro-wave radar antenna pointed at the depths of space may be only slightly above absolute zero. On the other hand a directional 7 metre antenna pointed at parts of the Milky Way may have an effective temperature much higher than ambient.

The noise factor of a receiver can be obtained by using a signal generator or a noise diode (see below). With a signal generator, difficulty is experienced in that the characteristic of the detector in the receiver may affect the ratio of signal power to noise power. If the detector is a true power sensitive device such as a thermocouple no error occurs, but with normal detectors error is introduced to a degree dependent on the variation between the assumed and the actual detection characteristic.

On the other hand, if the signal generator is replaced by a noise diode, detector distortion can be ignored since the noise from the diode has the same spectrum as the noise from the antenna.

The signal generator method is to apply the generator output to the receiver through a resistor R_{ant} and to adjust the output until the indication at the receiver detector is twice that from noise alone. The noise factor is then obtained by calculation from the formula

$$\text{noise factor } F = \frac{e_{s,o.}^2}{4KT\Delta FR_{ant}}$$

where $e_{s,o.}$ = voltage output of signal generator.

Alternatively the anode current of a temperature limited diode (noise diode) can be used as a noise source. The diode is connected with suitable d.c. isolation across the receiver input, which is also shunted by a resistor equal in value to R_{ant} . The d.c. anode current of the diode is then increased until the noise output of the receiver alone is doubled, and under these conditions the noise factor of the receiver is

$$\text{noise factor } F = \frac{2eI_b\Delta FR_{ant}^2}{4KT\Delta FR_{ant}}$$

where e = charge on an electron = 1.59×10^{-19} coulombs

and I_b = diode plate current in amperes.
therefore noise factor $F = 20 I_b R_{ant}$ at 290°K.

A comparison of the two noise factor formulae shows a second advantage of the noise diode method, viz. : the receiver bandwidth need not be known.

Additional information on noise factors will be found in Refs. 7, 8 and 9.

(H) Hum

Hum is a low pitched composite tone which may include a component at any integral multiple of the a-c power supply frequency. It may be due to the loud-speaker itself, to the a-f stages or to the r-f stages.

When the field winding of a speaker is used for filtering, hum may appear in the voice coil even although some neutralizing is accomplished by connecting a hum-bucking coil in series with the voice coil. The I.R.E. recommendation is that this type of hum "should be measured in terms of the hum current through the loud-speaker voice coil itself, rather than in terms of the voltage across the loudspeaker, and the total hum calculated using this current and the loudspeaker voice coil impedance. The loudspeaker is connected in the normal manner to the radio receiver when the observations are made. The current measuring equipment should introduce into the voice coil an impedance which is negligible as compared with the voice coil impedance. In the case of a loudspeaker having a field coil carrying hum current, this procedure evaluates the combined effect of hum originating in the radio receiver itself and hum induced in the voice coil from the field coil, with due regard to their phase relations."

"Hum from the a-f stage of the receiver should be measured

- (a) with the volume control at minimum,
- (b) with the volume control left at that setting which would produce normal test output with mean-signal input, but with the intermediate-frequency-amplifier circuits inactivated, as by-passing the last i-f plate to ground,
- (c) with the volume control at full volume and the i-f system inactivated.

"In the case of phonograph combinations, a-f hum should also be measured with the phonograph pick-up connected to the a-f amplifier under the following conditions :

- (a) with the phonograph motor de-energized, the pick-up on the rest, and the volume control at minimum
- (b) same as (a) but with the volume control at maximum
- (c) with the volume control adjusted, while reproducing the outside 1000 cycle band on R.M.A. Frequency Test Record No. 1 to give normal test output, the needle then lifted not more than $\frac{1}{4}$ inch above the record, with the motor still running."

"Hum modulation is produced by hum sources which modulate a carrier being received, and its intensity generally increases with increasing carrier voltage.

The hum-modulation test is intended to evaluate the hum components introduced in a radio receiver by hum disturbances modulating the received carrier. In order to measure hum modulation, as distinguished from a-f hum, the former is accentuated by the adjustments of the receiver. The receiver is tuned in the normal manner to each of the four standard input voltages at 1000 kilocycles. If the receiver has a tone control, it should be set in the "high" position. The volume control is first adjusted to give the normal test output with the given signal voltage modulated 30% at 400 cycles and the modulation is then reduced to zero. The hum is measured with the load and output-measuring equipment connected as in the electric-fidelity test, and is expressed in terms of reduction in decibels below standard test output."

Hum distortion can also occur. It is identified as sidebands of frequencies differing from the audio frequency of modulation by an amount equal to the frequency of the hum disturbance causing the distortion.

A typical design likely to introduce hum distortion is one in which the plate of the output valve is fed directly from the rectifier output (assuming a condenser-input filter). No specific test procedure for measuring this effect is given by the I.R.E. or R.M.A. but owing to its unpleasant effects it should be eliminated if this is possible.

Acoustical measurement of hum output is desirable but difficult by available methods. The results of the electric measurement must be interpreted with reference to electric- and acoustical-fidelity curves and the characteristics of audition.

(I) Frequency shift (I.R.E.)

"This test is intended to show the variation in the frequency of the oscillator of a superheterodyne receiver. The tests are normally performed with the receiver tuned to a frequency in the middle of each tuning range of the receiver. If observations under the worst conditions are desired, the receiver should be tuned to the highest frequency of each range.

"The variation of frequency is observed with the aid of a beat note obtained between the oscillator under test and another oscillator of constant frequency. For example, the frequency of the beat note may be observed by comparison with a calibrated a-f oscillator.

"(a) The frequency varies with time during the warming-up period of the receiver The time is measured from switching on the receiver but observations are ordinarily started one minute later.

"(b) The frequency varies with power-supply voltage in a manner that depends on the rate of variation of this voltage. The major change occurs almost instantly following a change of the power voltage. Therefore the test is performed as quickly as possible to minimize other effects. In the case of operation from a 115-volt power line, the line voltage is varied at least between 105 and 130 volts and the resultant frequency shift is observed. The amount of frequency shift is expressed in cycles per 1 per cent change of power voltage, as an average value over the specified range of power-line voltage.

"(c) If the receiver has automatic gain control, the variation of signal-input voltage affects the oscillator frequency indirectly by way of the control circuit. The frequency shift with variation of signal-input voltage is observed after the receiver has been in operation a sufficient length of time to reach temperature stability."

(J) Spurious response (I.R.E.)

"With the radio receiver tuned to each of the test frequencies, the signal generator should be continuously varied over a wide frequency range to discover if the receiver is simultaneously resonant at frequencies other than the test frequency. These other resonant frequencies are called spurious-response frequencies and are most often found in superheterodyne receivers. Each spurious-response frequency is noted and the spurious-response sensitivity-test input is measured as in the sensitivity test, provided it is smaller than 1 volt. Its ratio to the desired-signal sensitivity-test input may be computed, and is called the spurious-response ratio."

"Care should be taken that the harmonic output of the signal generator is attenuated sufficiently not to affect the observation of the spurious response of the receiver."

Image response. "A superheterodyne receiver is generally responsive to two frequencies whose difference from the local-oscillator frequency is equal to the intermediate frequency. One of these (usually the lower) is the desired-signal frequency, and the other is called the image frequency. This is a special case of spurious-response frequency, and is tested as such. Its observed characteristics are referred to as 'image-sensitivity test input' and 'image ratio.'"

Intermediate-frequency response. "Another special case of a spurious-response frequency in a superheterodyne receiver is that due to the sensitivity to an intermediate-frequency signal input. The test procedure is the same as for other spurious responses, and the observed characteristics are referred to as the intermediate-frequency-response sensitivity and the intermediate-frequency-response ratio."

(K) Noise audibility (I.R.E.)

"The actual audibility of random noise, hum, and miscellaneous noise is best determined by a listening test. Such observations are not capable of precision, but are fundamentally sound, as distinguished from less direct electrical observations. The completely assembled and operating radio receiver is placed in a quiet room, and an experienced observer with normal hearing notes the greatest distance at which the noise is audible under stated conditions. The distance is used to express the audibility of the noise. The room is preferably large, or treated to minimize rever-

beration. This method takes into account noise produced both by loudspeaker radiation and by mechanical vibration of parts. A brief description of the sound heard is useful, in addition to the audibility observation. Obviously, this method is suited only for observing a small amount of noise, audible for only a short distance.

The noise-audibility test is intended to evaluate collectively random noise and hum under operating conditions. The radio receiver is tuned in the normal manner to each of the four standard input voltages at 1000 kilocycles. If the receiver has a tone control, it is set in the 'high' position. The volume control is adjusted to give normal test output with the signal modulated 30% at 400 cycles, and then the modulation is reduced to zero. The audibility of the remaining noise is then observed. The residual noise audibility is likewise observed, with no signal and with the volume control set at minimum."

(L) Radiation from local oscillator (I.R.E.)

"A local oscillator, such as is employed in a superheterodyne receiver, may radiate sufficient power to cause interference in other radio receivers operating in the same neighbourhood. Such radiation may be caused by coupling to the antenna, power line, or other external leads, or by incomplete shielding of the oscillator and the circuits coupled thereto.

The receiver is connected to its proper antenna, and the electric- and magnetic-field intensity in the neighbourhood is observed by any of the known methods. There is no simple form for expressing the results. (The recommendation for local oscillator radiation in F-M receivers is that results are to be expressed in field intensity as a function of distance from the receiver under test. Observations are made at least at the middle frequency of each tuning band, and preferably at the extreme frequencies of each band."

(M) Microphony

Microphony troubles are of two main types, audio frequency only and those involving radio frequencies. A convenient test to apply for the first type—which might be due to feedback between the speaker and a pick-up mounted in the same cabinet for instance—is to feed the receiver into a dummy load with an output meter across it, and excite the speaker, mounted in its normal position by means of a variable a-f oscillator.

The pick-up is allowed to stand on a stationary record and a tendency to microphony is indicated by appreciable output across the dummy load at any particular frequency. When the voltage across the dummy load equals the voltage across the speaker, microphony would occur (assuming equal speaker and dummy load impedance at the frequency concerned). Another speaker can be used instead of a dummy load if desired, so long as no sound from this speaker reaches the receiver.

This test has the advantage of indicating the margin available in a particular model before sustained microphony will be experienced. It can also be used for types of microphony involving radio frequencies, but owing to the increased number of possible variables it loses some of its advantages. Tests outlined in (O) 1 below may be used for r-f microphony.

(N) Phonograph combinations (I.R.E.)

"In addition to the above tests on radio receivers, there are several special tests which reveal useful information on the operation of the phonograph portion of combination receivers . . . In addition to hum, the following characteristics should be measured :

- (1) Electric fidelity
- (2) Rumble
- (3) Maximum output
- (4) "Wow" or flutter.

Definitions of these characteristics, with methods of measurements, are given below.

(1) **Fidelity.** The fidelity of a phonograph reproducer corresponds to the a-f fidelity described in Sect. 1(vi)C of this chapter except that RMA Frequency Test Record No. 1 is used instead of a modulated carrier. This RMA Frequency Test Record No. 1 contains, on side A, a gliding frequency from 10 000 to 30 cycles for

usual nominal level testing. Side B contains five 1000-cycle bands, recorded at 0, 2, 4, 6 and 8 decibels above the 1000-cycle reference on side A, and a gliding frequency 6 to 8 decibels above side A in the range between 3000 and 30 cycles for checking pickup tracking at various levels.

In making the fidelity test, side A is used, and the output is first set at standard output using the outside 1000-cycle band. Readings of output are then made at all announced frequencies, including the 1000-cycle bands at start and finish.

Suitable correction usually must be made for noise resulting from needle scratch to provide accurate data above 1000 cycles.

(2) **Rumble.** Rumble is a low-frequency tone or series of random pulses generated at the phonograph pickup as a result of vibrations of the record player. It is generally a maximum when the needle is near the outside of a 12-inch record.

Rumble is measured with the load and output-measuring equipment connected as in the electric-fidelity test, except that a low-pass filter is used with a sharp cutoff at 300 cycles. The measuring equipment should have low wave-form error.

Side A of the test record is also used in this test. The volume control is adjusted to give normal test output while reproducing the outside 1000-cycle band and with the low-pass filter disconnected. The filter is then reconnected and measurements made of rumble components while the needle is in the region between the 1000-cycle tone and the 10 000-cycle tone.

In some cases, a particular rumble frequency may predominate, resulting from motor vibration or pickup-arm resonance. Measurements of such a frequency may be accomplished by means of a tuned filter or harmonic analyzer.

(3) **Maximum output.** The maximum audio output on phonograph may be less than that obtained on radio, because of the absence of automatic-gain-control voltage which normally causes a rise in plate and screen voltages in the audio amplifier.

The test is made by reproducing the 1000-cycle tone on side A of the test record and adjusting the volume control to produce maximum output. The measuring equipment used must give an accurate indication of root-sum-square independent of wave form.

(4) **'Wow' or flutter.** 'Wow' or flutter is caused by minute imperfections in the motor and/or transmission means used to drive the phonograph turntable; and, if present to an appreciable extent, may noticeably impair the quality of reproduction. It is usually evident when a steady note is being reproduced, such as the 1000-cycle band, and evidences itself as a cyclic variation in pitch; hence the name 'wow.' While there is no great distinction between 'wow' and flutter, the former is usually applied to very low cyclic variation, the latter to the more rapid type.

'Wow' or flutter is measured as a percentage of root-mean-square deviation in frequency of a tone to the average frequency. Special equipment is required to make such a measurement, this equipment being capable of responding uniformly to all flutter rates up to 200 cycles, and of measuring to a precision of 0.02% flutter.

Care should be exercised to insure that the method of measurement permits normal conditions to exist as when playing a commercial pressing."

(O) Miscellaneous

(1) Tuning tests

Some receivers which perform well when tuned to a station exhibit undesirable characteristics while being tuned. A test which shows up most of these effects is to tune in unmodulated signals of varying strengths up to the maximum liable to be encountered in service, moving the tuning control slowly and also as rapidly as possible. The volume control should be at its maximum setting, and the test should be repeated at the high and low frequency end of each wave range, and also with modulated signals.

Faults which are liable to be discovered are squeaks as the receiver is tuned rapidly through the sidebands of a signal, flutter on short-waves (and sometimes medium-waves) with slow tuning, microphony, or a rapid variation in the tuning rate near the carrier frequency on short waves due to varying electrode potentials or capacitances affecting the oscillator frequency. This should not be taken as a complete list of possible faults and any unusual effect should be investigated.

Other tests should be made with different aerial lengths (including very short aeriels, and none) and signals tuned in all sections of the tuning range. Regeneration at the low frequency end of the broadcast band, particularly when a short aerial is placed as closely as possible to the second detector, and oscillation on the short-wave band with no aerial are possibilities in this case.

(2) Dry battery receiver tests

A set of batteries which has been discharged by normal use to a required low voltage should be used to test battery receivers at least for sensitivity, power output, stability and oscillator grid current (using a valve on the low limit of oscillator mutual conductance).

The requirement that the batteries should be discharged by normal use is necessary since rapid discharge gives a lower value of internal resistance. To simulate a discharged battery by means of added resistance, fresh heavy duty batteries can be tapped and the following table (Ref. 21) used.

Resistance Required to Simulate Discharged Radio "B" Batteries.

Volts per 22½ volt section	Resistance per 22½ volt section	
	Farm type batteries	Portable type batteries
22½	0 ohms	45 ohms
20	10 ohms	60 ohms
17	50 ohms	110 ohms
15	110 ohms	175 ohms
12	250 ohms	330 ohms

The following points are important. First, only fresh heavy-duty batteries should be used, their resistance being negligible. Second, if intermediate voltage taps are used the added resistance must be distributed between the taps in proportion to their respective voltages. Third, voltage readings should be taken only under load and across the battery cable terminals to include the voltage drop of the load current through the added resistances.

Battery end-of-life tests can be carried out in accordance with R.M.A. (U.S.A.) specifications M4-431 and M4-432 at 1.1 volts per cell for the A battery and 17, 15 and 12 volts per 22½ volt section for the B battery.

The lowest filament voltages used for testing battery valves by valve manufacturers are 1.1 volts for 1.4 volt valves and 1.7 volts for 2 volt valves. Below these voltages, performance may not be consistent.

(3) Interference tests

A suitable test for vibrator operation is to wrap a short lead around the battery cable and battery, connect one end of the lead to the aerial terminal of the receiver and check for interference throughout the tuning range of the receiver at maximum sensitivity. In a well designed receiver no interference will be heard.

Car-radio interference tests can be arranged using appropriate parts from the ignition system of a car, but such tests give no guarantee of interference-free reception from the receiver installed in a car.

The R.M.A. Standard REC-11 reads as follows :—

Chassis Pickup of Vehicular Receivers.

Vehicular receivers shall be considered as complying with the principles of good engineering practice if, when installed according to the manufacturers' instructions and using materials supplied by the manufacturer, there is no perceptible chassis pick-up with any setting of the user controls.

"Chassis pick-up" is defined as the interference arriving in the vehicular receiver other than through the antenna.

"Perceptible" is defined as the difference in the noise output of the receiver with the engine running and with it stopped.

Testing for chassis pickup shall be done by replacing the antenna of the installed receiver by an antenna equivalent, adequately shielded and grounded ; the antenna trimmer of the receiver shall be tuned for resonance at the normal aligning frequencies ; and observation made of any perceptible noise output.

(4) Distortion

Causes of distortion may be present in a receiver and remain undetected in spite of reasonably thorough testing with instruments. One such type of distortion occurs with insufficient capacitance by-passing a.v.c. lines, which results in low frequency intermodulation or perhaps hum modulation in a back-biased receiver. Another may be due to simultaneous high modulation levels and high signal strengths, and another may be the hum distortion mentioned in (H) above which is easily missed. Because of this, testing is not completed until critical listening to broadcasting stations over a period of time has shown that such faults are not present.

(P) Acoustical tests

Refs. 1, 2 and 5 should be consulted.

SECTION 2 : F-M RECEIVERS

(i) *Definitions* (ii) *Testing apparatus* (iii) *Test procedures and operating conditions* (iv) *Receiver adjustments* (v) *Performance tests.*

(i) Definitions

The information presented in this section, except where otherwise stated, is taken from the "Methods of Testing Frequency-Modulation Broadcast Receivers, 1947," Standard on Radio Receivers (Ref. 12), published by the Institute of Radio Engineers. Additional F-M information is available from the "Standards of Good Engineering Practice Concerning FM Broadcast Stations" published by the Federal Communications Commission in 1945.

(A) The three **standard test frequencies** are 88, 98 and 108 Mc/s. When only one frequency is used for testing it should be 98 Mc/s.

(B) The five **standard input values** may be expressed in terms of available power or of input voltage. The available power is that delivered by a generator to a matched load and is equal to $E^2/4R$ where E is the equivalent open-circuit voltage of the generator and R is the internal resistance of the generator (including the dummy-antenna resistance).

Five standard input values are specified, the voltage and power figures being equivalent when the receiver has an input impedance of 300 ohms and R is 300 ohms.

(a) Standard Input Powers

- (1) 130 decibels below 1 watt
- (2) 110 decibels below 1 watt
- (3) 90 decibels below 1 watt
- (4) 50 decibels below 1 watt
- (5) 30 decibels below 1 watt

(b) Standard Input Voltages

- (1) 11 microvolts
- (2) 110 microvolts
- (3) 1100 microvolts
- (4) 110 000 microvolts
- (5) 1.1 volts.

(c) The standard mean-signal input is either 90 decibels below 1 watt, or 1100 microvolts.

(C) The **standard test modulation** is a deviation at 400 c/s of $22\frac{1}{2}$ Kc/s (30% of maximum deviation).

(D) The **standard test output** is as set out from the I.R.E. Standards for A-M Receivers in Sect. 1(ii)C of this chapter.

(E) The **maximum undistorted output** is as set out from the I.R.E. Standards for A-M Receivers in Sect. 1(ii)D of this chapter.

(F) The **standard 300-ohm antenna** comprises a pair of resistors, one connected in series with each terminal of the signal generator, of such value that the total impedance between terminals, including the signal generator, is 300 ohms (Fig. 37.2).

Fig. 37.2. *Standard v-h-f dummy antenna and method of connection (from Ref. 12).*

FIG. 37.2

(G) The **standard pre-emphasis characteristic** has a rising response with modulating frequency, equivalent to that provided by a single circuit in the modulating source having a time constant of 75 microseconds. The characteristic may be obtained by taking the voltage across an inductor and a resistor connected in series and fed with constant current. The inductance in henries is 0.000 075 times the resistance in ohms.

(H) The **standard de-emphasis characteristic** has a falling response with modulation frequency, the inverse of the standard pre-emphasis characteristic, equivalent to that provided by a simple circuit having a time constant of 75 microseconds. The characteristic may be obtained by taking the voltage across a capacitor and a resistor connected in parallel and fed with constant current. The capacitance in farads is equal to 13 333 divided by the resistance in ohms. The standard de-emphasis characteristic is usually incorporated in the audio circuits of the receiver.

(ii) Testing apparatus

(A) "A **frequency-modulated signal generator** is required for testing frequency-modulation radio receivers.

The signal generator should cover at least the carrier-frequency range from 88 to 108 megacycles. It preferably also covers the intermediate-frequency range and frequency ranges required for spurious-response tests.

The generator output should be controlled by a calibrated attenuator, and the output should be adjustable over a range of at least 1 microvolt to 100 000 microvolts, and preferably from 0.1 microvolt to 1.1 volts. Balanced output terminals should be provided for the radio-frequency ranges, and single-sided output terminals for the intermediate-frequency range. It may be desirable to provide single-sided output terminals for the radio-frequency range also. All of these terminals should be provided at the end of a flexible cable.

The output meter of the signal generator should indicate the open-circuit voltage at the terminals, and the internal impedance should be stated.

The generator should be capable of being frequency-modulated at rates from 30 to at least 15 000 cycles per second, and at deviations from zero to at least rated system deviation and preferably to twice that value. It should be provided with a deviation indicator reading from not more than 5 kilocycles up to the maximum deviation.

The modulation circuit of the generator should be provided with a standard pre-emphasis network. A switch should be provided for cutting this pre-emphasis network in or out of the generator circuit at will.

The generator should provide a frequency-modulated signal at 400 cycles up to maximum rated system deviation with less than 2%, and preferably less than 1% (root-sum-square) distortion. Amplitude modulation resulting from the frequency modulation should be kept to a minimum.

The frequency and amplitude modulation of the output voltage due to power-supply ripple should be negligible, in comparison with the effects under observation. The proper connection of a balanced-output signal generator for testing a balanced receiver is shown in Fig. 37.2."

(B) **Audio-output and distortion-measuring devices** are the same as those required for the testing of amplitude modulation receivers. See Sect. 1(iii) of this chapter.

(C) **Two-signal tests** are carried out using two signal generators and dummy antennas of twice the standard 300 ohms value with each generator as shown in Fig. 37.3. The output terminals of the two dummy antennas are then connected in parallel and to the input terminals of the receiver. With this connection the impedance connected across the receiver input terminals is the normal value and the open-circuit signal voltages are half the values indicated by each generator.

(D) **A standard-signal generator for amplitude-suppression testing** should be capable of simultaneous 400 c/s amplitude modulation and 1000 c/s frequency modulation with preferably less than 1% of incidental frequency modulation in the amplitude modulation process. Alternatively two signal generators may be used, connected as described above, but precautions must be taken that the beat note between the two carriers does not influence the undesired output and that the amplitude modulated generator is free of incidental frequency modulation.

FIG. 37.3

Fig. 37.3. Standard v-h-f dummy antenna for two-signal test and method of connection (from Ref. 12).

(iii) Test procedures and operating conditions

(A) **Input measurements** are made through a standard 300-ohm dummy antenna on receivers designed for a balanced antenna. If only a single-sided signal-generator output is available, one terminal of the input circuit of the receiver is connected to the grounded terminal of the generator output circuit, and the correct value of dummy antenna resistance must be used.

There are two simple tests for unbalance, the balanced receiver input coil can be reversed, or the power-line connection for either the receiver or the signal generator is moved to a different outlet. Any change in the sensitivity observed on alternating these connections indicates an error due to unbalance.

(B) **Output measurements** are made as described in Sect. 1(iv)A of this chapter.

(C) **Operating conditions** are similar to those in Sect. 1(iv)B of this chapter.

(iv) Receiver adjustments

The **tuning control** is adjusted until the desired a-f output is obtained either with the least possible r-f input power or with the lowest possible setting of the volume control. This is an **approximate** adjustment.

A receiver for frequency-modulated waves is tuned **accurately** to a desired signal by first tuning it approximately and then adjusting the tuning controls until either the undesired noise is a minimum or the harmonic distortion of the demodulated desired signal is a minimum. In many receivers these two tuning positions coincide.

When they do not coincide it should be stated whether the tuning is for minimum noise or for minimum distortion.

A simple method of tuning for minimum distortion in many receivers is by observing the audio wave form on a cathode ray oscilloscope while increasing the deviation somewhat beyond 100%.

The **tone control** is adjusted to give maximum modulation-frequency output unless otherwise specified.

(v) Performance tests

(A) Sensitivity

There are three sensitivity values of general interest in relation to frequency-modulation receivers. Each gives information as to the usefulness of the receiver, and in expressing results the type of sensitivity should be specified.

The **maximum sensitivity** is measured with the signal generator connected to the receiver through the dummy antenna. The receiver controls are adjusted for greatest sensitivity, and the output of the generator, which is modulated 30% (22½ Kc/s) at 400 c/s, is adjusted to obtain standard test output from the receiver.

When the tuning for minimum noise does not coincide with that for minimum distortion, the above test and the following test should be repeated with the receiver tuned for minimum noise.

The **maximum-deviation sensitivity** is measured by applying to the receiver a strong signal-input modulated 100% (75 Kc/s) at 400 c/s, tuning the receiver for minimum distortion and adjusting the receiver volume control to give standard output. The output distortion should be observed and the signal input reduced, keeping the indicated receiver output constant by readjusting the volume control if necessary, until the output distortion increases to 10%, or until the input is below that required for standard output. The signal input at which the distortion reaches 10% is the maximum-deviation sensitivity input and is expressed in decibels below 1 watt or in microvolts.

The **deviation sensitivity** is measured with the receiver volume control at maximum and with the standard mean-signal input (1100 μ V) applied. The generator is modulated at 400 c/s and the deviation adjusted to the value which gives standard test output. The value of deviation required is the deviation sensitivity, and it is expressed in Kc/s or as a percentage of rated system deviation.

The **quieting-signal sensitivity** is measured by applying a signal of mean value, 30% modulated at 400 c/s, to the receiver with the volume control adjusted to give a convenient output below audio overload. The modulation should then be switched off and the signal intensity reduced to the least value which will produce a 30 db rise in indicated output with standard test modulation as compared with the indicated output with the unmodulated carrier. The results are expressed in decibels below 1 watt, or in microvolts.

(B) Co-channel interference

This test is intended to show the effect of an interfering signal of the same frequency as the desired signal, and includes the inherent effect of the detector, the limiter and the automatic volume control.

Two signal generators are required, only one of which need be capable of frequency modulation. The outputs of both are applied simultaneously to the receiver under test at the mean carrier frequency of 98 Mc/s.

With the desired signal frequency having standard test modulation and an intensity equal to one of the standard input values, the a-f output of the receiver is adjusted by means of the volume control to the standard test output.

The modulation of the desired signal is then removed, keeping the intensity of its carrier unchanged, the interfering signal, frequency-modulated 30% at 400 c/s, is turned on and the output of the receiver read as the level of the interfering signal is increased from zero to 1 volt or more.

The result of the test includes the effects of both the cross-talk and the beat-note components of the interference. If the results are desired for the cross-talk only, a 400 c/s filter is used in the output.

The co-channel interference characteristic may be expressed as the interfering-signal input, in decibels below the desired-signal input, which produces an output 30 decibels below the standard test output

(C) Masking interference

The masking effect of an unmodulated interfering signal is obtained by a test similar to that for the co-channel interference but with the desired signal 30% modulated at 400 c/s and with the interfering signal unmodulated. The output signal is noted as the level of the interfering signal is increased from zero.

(D) Selectivity

Test conditions are similar to those described for the co-channel interference test [(B) above] except that the interfering signal generator is separated in frequency from the desired signal by one standard channel separation.

The desired signal, unmodulated, is applied at the lowest value of standard input and the output of the receiver is recorded as the level of the interfering signal, frequency modulated 30% at 400 c/s, is varied from zero to a value capable of producing standard test output. This procedure is repeated for all values of standard test input. The measurements are then repeated with the interfering signal generator separated from the desired signal by twice the standard channel separation.

The adjacent-channel and second-channel interference may be expressed as the interfering signal input which produces an output 30 decibels below the standard test output.

(E) Amplitude-modulation suppression

This test measures the suppression of amplitude modulation which may be present in a frequency modulated signal. It is carried out at the standard mean carrier frequency. The frequency modulation is at a 1000 c/s rate with a deviation of 30% of maximum system deviation. The standard mean input-signal value having this modulation is applied to the receiver in the usual manner. The volume control is adjusted to produce standard output. The input signal is then amplitude-modulated at 400 c/s and 30% modulation. The intensity of the undesired output of the receiver is measured by filtering out the 1000 c/s frequency.

The amplitude suppression is the ratio of the undesired output to standard test output expressed in decibels. In order to determine the variation of amplitude-modulation suppression with input, the test is repeated with the other standard input-signal values.

(F) Electric fidelity (frequency response)

Methods similar to those for A-M receivers [Sect. 1(vi)C of this chapter] are used at the standard mean carrier frequency and with a standard mean signal input. The standard pre-emphasis characteristic is employed in the standard-signal generator and the modulating voltage is to be maintained constant at that value which provides a modulation of 30% of maximum rated system deviation when the modulation frequency is 400 c/s.

(G) Harmonic distortion

The tests are similar to those used for A-M receivers [Sect. 1(vi)D of this chapter] but variation of input signal testing is recommended with 30% and 100% of maximum rated system deviation. In addition there is a deviation distortion test.

The **maximum-deviation distortion** test is the measurement of the distortion due to inadequate bandwidth and/or inadequate amplitude-modulation rejection. It is measured at 98 Mc/s with the signal generator connected to the receiver through the 300-ohm dummy antenna. Distortion at standard test output is measured at full system deviation over the range from maximum sensitivity levels to 30 decibels below 1 watt.

(H) Maximum undistorted output

As for A-M receivers—Sect. 1(vi)E of this chapter.

(I) Automatic-volume-control characteristic

This test is similar, except for carrier frequency, to the I.R.E. test for A-M receivers—Sect. 1(vi)F of this chapter.

(J) Spurious responses

The testing of F-M receivers for spurious responses is carried out in a similar manner to that specified for the tuning of A-M receivers—Sect. 1(vi)J of this chapter. However spurious response sensitivity test inputs up to 1.1 volts are recorded and an additional intermediate frequency response test is specified.

The procedure is to inject the intermediate-frequency test input signal, amplitude modulated 30%, between the two antenna terminals of the receiver, connected in parallel, and ground, through a standard 300-ohm dummy antenna. The frequency of the test signal is adjusted for maximum receiver output.

(K) Hum

Hum in F-M receivers has similar characteristics to hum in A-M receivers, and is measured in the same way—See Sect. 1(vi)H of this chapter.

(L) Noise audibility

The noise audibility test for F-M receivers is the same as that for A-M receivers—Sect. 1(vi)K of this chapter.

(M) Tuning characteristic test

The tuning characteristic shows the variation in audio output of the receiver as it is tuned through a signal. This characteristic is of importance in frequency-modulation receivers since they may have spurious output responses adjacent to the correct tuning point. The effect is usually more easily measured by variation of the signal-generator frequency than by variation of receiver tuning, since the signal generator usually has better frequency control and calibration than the receiver.

The receiver is tuned to the mean carrier frequency for each standard input signal value with standard test modulation and the volume control adjusted to standard output. The output is then measured as the signal is detuned to each side of the carrier frequency. A tuning curve is plotted for each signal input value (Fig. 37.4)

FIG. 37.4

Fig. 37.4. Tuning characteristics (from Ref. 12).

(N) Frequency drift

This test is carried out in the same way as that for frequency shift in A-M receivers—Sect. 1(vi)I of this chapter—except that it is to be performed at the standard signal carrier frequency.

(O) Low-frequency instability

This test is intended to evaluate the limiting conditions for unstable operation of the receiver as affected by low frequency feed-back which may be electrical or acoustical in nature, and which may involve both carrier frequency and audio frequency and the audio-frequency circuits. At any given frequency, the variables employed to induce instability are the signal-input power, the tuning control, the manual volume

control and tone control, the modulation frequency and degree of modulation, and, in battery receivers, the age and condition of the batteries. All parts of the receiver, including the loudspeaker, are mounted in their normal relations.

The test is performed at the standard test frequencies. The receiver is tuned to a modulated test signal, after which the modulation is switched off. The conditions most conducive to the detection of any tendency to instability are found by trial. It is suggested that the frequency of the signal be varied manually over a range of about 100 Kc/s above and below the normal test frequency as the test input power is varied from zero to a maximum of 0.01 watt. An observation is made of the maximum signal-input power at which any unstable operation appears. The maximum of such input power is also recorded if less than 0.01 watt.

(P) Radiation from local oscillator

Tests are made in a manner similar to that for the A-M receiver tests—Sect. 1(vi)L of this chapter. Observations are made with the receiver tuned to each of the standard test frequencies. Results are expressed in field intensity as a function of distance from the receiver under test.

(Q) Mistuning

The degree of mistuning is represented by the total signal output distortion resulting when the receiver is adjusted to a frequency other than the desired signal frequency. The measurement is made by setting the signal generator to standard input voltages successively, modulating the signal generator to 75 kc deviation at standard test output. The signal generator is then adjusted off tune by successive increments, the volume control is adjusted for standard test output, and the total distortion in per cent (or db) is measured. For each value of input signal a curve is plotted, having as abscissa the frequency difference of detuning, and as ordinate the distortion expressed in per cent, or db. Distortion components will comprise all frequencies present except the fundamental frequency of the modulating tone. In these tests the signal generator is adjusted off tune on each side of the signal frequency.

The standard measurement will comprise setting the signal generator on each side of the signal frequency and noting the amount of mistuning that will produce 10% distortion, expressing the degree of mistuning as the average of the measured plus and minus frequency excursions. The signal input for this test shall be the standard mean signal input (1100 microvolts).

This mistuning test should be correlated with the frequency drift test—Sect. 2(v)N.

(R) Downward modulation

This test will define the ability of the receiver to withstand the effects of downward amplitude modulation. In this test it is assumed that the principal forms of distortion are caused by the downward component of modulation.

The test is made at the standard mean-carrier frequency (98 megacycles). Frequency modulation is impressed at a 400-cycle modulation rate at 30% of maximum rated system deviation and the volume control is adjusted for standard output. The input signal is then simultaneously amplitude modulated at a 100-cycle rate. By means of a band cut-off filter, the 100-cycle modulation is eliminated in the receiver output. The amplitude modulation is then increased until the total distortion reaches 10%. The percentage modulation at this point is the downward modulation capability of the receiver. The test is made at all values of standard input signal voltages.

(S) Open field method of measurement of spurious radiation from frequency modulation and television broadcast receivers

See I.R.E. Standard (Ref. 41).

SECTION 3 : AUDIO FREQUENCY AMPLIFIERS

(i) *Equipment and measurements* (ii) *Tests.*

(i) **Equipment and measurements**

The equipment already specified for testing the a-f end of a radio receiver is sufficient for the testing of a-f amplifiers. There are however additional tests commonly used in the design of a-f amplifiers and these tests need more instruments.

Intermodulation testing requires at least another a-f signal generator, and equipment is available (Refs. 19, 22 and 27) which is specifically designed for the purpose. The technique of square-wave testing (Refs. 16 and 20) also needs an appropriate generator as do similar techniques using other wave shapes (Ref. 18).

Measurements of voltage, current, dissipation and heating differ if at all only in the higher values found in high-power a-f amplifiers and the appropriate parts of Section 1 of this chapter are applicable.

(ii) **Tests**

The American R.M.A. Standard SE-101-A on Amplifiers for Sound Equipment gives details of tests for noise level, amplifier gain, amplifier frequency response, distortion and power output. The following conditions of measurement apply to each of the tests mentioned.

“The amplifier shall be operated at its rated power supply voltage and frequency. When a range of line voltage values is indicated for specified power input terminals, the arithmetic mean of the voltages specified for this range shall be applied except when R.M.A. standard M3-217* applies. The frequency of the power supply shall be within $\pm 2\%$ of the lowest frequency specified. The rms harmonic voltage of the power supply voltage shall not exceed 10%.

Manufacturers of amplifiers designed to work from crystal microphones or other capacitive devices and photocells, may provide additional ratings based on the stated source impedance applicable to condition of use.

“The input and output shall be terminated† in pure resistance equivalent to the rating impedance within $\pm 5\%$. Grounding of the circuits and chassis shall be as normally used.

“The gain control shall be adjusted to give a maximum gain” (except when measuring noise and frequency response when it is set to give maximum noise and to reduce the gain 6 db below maximum respectively) “and any other controls shall be adjusted to give the most nearly uniform frequency response.

“The measurements shall be made after the amplifier has been operated for not less than one hour at an output 6 db less than the rated output at 400 cps, and at a room temperature of not less than 20°C.”

The vacuum tubes used shall be selected to have the rated values of those characteristics which particularly affect the amplifier characteristic under test.

(A) **Amplifier distortion**

Definition (R.M.A. standard SE-101-A) :—“Amplifier distortion is the difference between the harmonic content of the voltage at the output terminals and that of the input voltage expressed as a percentage of the total rms output voltage”

Additional test conditions are :—

“Three distortion measurements shall be made with signals having frequencies of 100, 400 and 5000 cps applied to the input terminals. The harmonic content of these signals shall inappreciably affect the distortion of the amplifier.

“A distortion factor meter shall be used that is capable of filtering out or suppressing the fundamental frequency with respect to its harmonics by at least 60 db, without affecting the phase or amplitude of the generated distortion.”

*R.M.A. Standard M3-217 states “When no means for adapting an electric radio receiver to the line voltage is provided, it shall be standard to adjust the secondary voltages so that the filaments and heaters of tubes are supplied with rated voltage when a line voltage of 117 volts is applied to the receivers.”

†The input is effectively a low-impedance generator in series with a resistance equal to the rating source impedance. See Fig. 19.3.

If the amplitude of individual harmonics is measured and the distortion is small, the percentage of total harmonic distortion is given approximately by

$$D \approx \sqrt{(H_2\%)^2 + (H_3\%)^2 + \dots}$$

where H_2 = second harmonic percentage, etc.

with an error not exceeding 1% if D does not exceed 10%—see Chapter 14 Sect. 2(iv).

A knowledge of the manner in which distortion decreases as output is reduced is desirable. Amplifiers with a large amount of feedback usually have very little distortion until the output is almost a maximum, but a class B amplifier may even give increased distortion with decreased output.

A simple test which can be used as an indication of freedom from distortion at low levels is the plotting of a linearity curve, i.e. a graph of input voltage against output voltage. Over the range of output for which the curve is a straight line the amplifier can be assumed to have a low distortion level. However in many cases the graph is curved almost from the zero point.

Intermodulation measurements are made with two signals applied to an amplifier through a suitable mixing network (e.g. bridge), either from separate a-f oscillators or from a combined unit designed for intermodulation testing. The usual procedure is for one frequency to be low (40, 60, 100, 150 or 400 c/s are used) and for the other to be high (1000, 2000, 4000, 7000 or 12 000 c/s). One test is carried out with the low frequency approximately at the low frequency limit of the amplifier and another at 100 or 150 c/s. The low frequency signal is usually made four times larger than the high frequency signal, although a 1:1 ratio is also used. The low frequency test will show distortion due to transformer saturation and the latter will be more representative of normal operation.

Distortion is mainly dependent on the peak voltage output so that an amplifier delivering at the same time two output voltages of 4 units and 1 unit (total output voltage = 5 units) would have distortion equivalent to a power output of 5^2 whereas the true output would be only $4^2 + 1^2$. Because of this, the indicated output power is multiplied by 25/17 when intermodulation tests are carried out under the conditions above.

The intermodulation products from the two signals can be measured separately or collectively. If they are measured separately and the lower frequency is f_1 and the higher f_2 , then the intermodulation products to be investigated—considering f_2 as the carrier—are $(f_2 - f_1)$, $(f_2 + f_1)$, $(f_2 - 2f_1)$, $(f_2 + 2f_1)$, $(f_2 - 3f_1)$, $(f_2 + 3f_1)$, ... The intermodulation distortion percentage referred to f_2 , based on the r.m.s. sum, is

$$\frac{\sqrt{(E_{f_2 - f_1} + E_{f_2 + f_1})^2 + (E_{f_2 - 2f_1} + E_{f_2 + 2f_1})^2 + (E_{f_2 - 3f_1} + E_{f_2 + 3f_1})^2 + \dots}}{E_{f_2}}$$

If the r.m.s. sum of the intermodulation products is measured collectively a high-pass filter can be used to separate the low and high frequencies and their respective intermodulation products. The modulated high frequency is then rectified and passed through a low pass filter, the remainder being low frequency components previously modulating the high frequency signal. Descriptions and circuits of equipment of this type will be found in Refs. 19, 22, 23 and 27.

The **peak sum modulation method** is described in Chapter 14 Sect. 3(v).

Le Bel's Oscillographic method is described in Chapter 14 Sect. 3(vi).

Another method of measurement is to keep a **constant difference frequency** (say 400 c/s) between the outputs of two a-f generators and determine the magnitude of the difference frequency as the generators are tuned through the a-f range of the amplifier (Ref. 28)—see Chapter 14 Sect. 3(iii).

For an indication of the distortion tolerable under different conditions, reference should be made to Chapter 14 Sect. 2(iii). Intermodulation distortion is covered in Chapter 14 Sect. 3 and References (B).

Hum distortion may be overlooked if the individual distortion components are measured separately. It is due to intermodulation between signal and hum frequencies and with a 50 c/s power supply (100 c/s hum) and a 1000 c/s signal, hum distortion products will be found at 900 and 1100 c/s and also as sidebands to the harmonics

of the signal. Hum modulation is most likely to be experienced at full output in an amplifier in which the filtering of the plate supply to the output valves is inadequate.

(B) Amplifier Power Output

Definition (R.M.A. standard SE-101-A) :—" Amplifier power output is the maximum rms power output (including distortion) at rated distortion which the amplifier will deliver into its rated load under normal operating conditions."

An additional requirement is that "The power output shall be measured using an indicator which measures rms values, such as thermally actuated meters, simultaneously with the distortion . . ."

During design it is helpful to measure power output over a range of frequencies as it may decrease at both low and high frequencies. When bass and treble boosts are available to the user it is particularly important for the power output to be maintained over the range of frequencies to which the boosting applies. At high frequencies the response may be falling and the degree of overloading may not be apparent because the amplitude of the harmonics may be appreciably decreased, for instance by a capacitor across the primary of the output transformer. It is in such a case that the value of intermodulation measurements becomes apparent.

When measuring amplifier power output and other characteristics it is advisable to connect an oscilloscope across the output terminals so that the presence of parasitic oscillations can be detected.

(C) Amplifier Gain

Definition (R.M.A. standard SE-101-A) :—" Amplifier gain is the ratio expressed in db of the power delivered to the load, to the power which would be delivered to the same load if the amplifier were replaced by an ideal transformer which matches both the load and source impedances."

Additional test requirements are

"The gain shall be measured at a frequency of 400 cycles per second and at an output 3 db less than the rated power output. The harmonic content of the input signal shall inappreciably affect the gain of the amplifier.

"The gain shall be measured using input and output meters and associated measuring equipment that does not affect the frequency response or gain of the amplifier."

(D) Amplifier Frequency Response

Definition (R.M.A. standard SE-101-A) :—"The amplifier frequency response is the variation of gain as a function of frequency over the range specified, expressed in db relative to the gain at 400 cycles per second."

Additional test requirements are

"Any automatic limiting or dynamic range control in the amplifier shall be disconnected during this test.

"The frequencies for testing shall be obtained from a source whose rms harmonic voltage does not exceed 5% of the fundamental voltage at any point in the frequency range of measurement.

"Measurements shall be made with the input voltage adjusted at each frequency to produce output levels of 3 db and 10 db respectively below rated power output.*

"The input and output meters and associated measuring equipment shall not discriminate as to frequency over the frequency range of measurement."

The frequency response of an amplifier is usually measured in terms of the output voltage across a resistive load. If feedback from the output stage is used it is advisable also to check the response with the normal loudspeaker load and with the minimum and maximum loads liable to be used.

In all cases the signal input must be small enough for the input-output characteristic to be linear over the frequency range being investigated. The frequency response may vary with output level at the low frequency end of the range and more than one curve may be necessary for this reason.

The effect of any controls which alter the frequency response should be shown by suitable curves.

*Frequency response is also sometimes measured at levels of 30 and 60 db below rated power output.

Square wave testing is used to obtain a rapid indication of frequency response (or phase shift) during design and in production. Two test frequencies can be used, one low enough for some low frequency attenuation or phase shift to be present at the fundamental frequency and the other high enough for some of the harmonics in the square wave to be attenuated. In production testing, limits for the wave shape can be indicated on a blank in front of the screen of the oscilloscope. Peaks in response are indicated (the approximate frequency of the peak being readily determined) as well as the degree of damping of the transient response and parasitic oscillation (Refs.16 and 20).

Details are given in Ref. 18 of a technique in which stepped sine waves are used in a similar manner.

(E) Noise Level

Definition (R.M.A. standard SE-101-A). (This is proposed as an interim standard for the measurement of steady state noise, and of pulse noise waves having a peak factor (ratio of peak to rms) approximating the maximum obtainable in speech) :—
“ Noise level is the level of any noise signals appearing at the output terminals with no signal applied to the input.

“ The weighted noise level is the noise level weighted in accordance with the 70 decibel equal loudness contour of the human ear and expressed in dbm, i.e. decibels referred to a level of 1 milliwatt.”

An additional testing requirement is “ The measuring amplifier shall be one whose audio frequency response is weighted with the 70 db equal-loudness contour of the human ear in accordance with Curve B of the ASA Specification Z24.3-1944 (Sound level Meters for Measurement of Noise and Other Sounds) with a standard VU meter as defined by ASA Specification C16.5-1942 (American Recommended Practice for Volume Measurements of Electrical Speech and Program Waves) as an indicator.

“ Illustrative : A properly weighted amplifier may be obtained by applying an RC network with a 1 millisecond time constant to an amplifier having frequency response of ± 1 db from 50 to 15 000 cycles. This will give an attenuation of 1 db at 300 cycles, 5.7 db at 100 cycles and 9 db at 60 cycles.”

(F) Microphony

High gain, high output a-f amplifiers may be subject to microphony under some conditions of use. A test similar to the one described in Sect. 1(vi)M of this chapter enables variations between microphonic tendencies between different amplifiers to be checked reliably.

(G) Stability

In amplifiers without feedback the most probable type of instability is parasitic oscillation. This can best be observed on an oscilloscope while the signal input is varied from zero past the overload point at various frequencies (including very low and very high).

Varying load impedances and high mains voltages may also cause trouble and the test should be repeated at least for design purposes with the highest power supply voltage liable to be encountered in the field and with a range of load impedances varying from an open circuit through capacitive and inductive loads to a short circuit. The plate dissipation of the output valves in AB or B class amplifiers should be observed during tests with the load impedance smaller than specified as it may become excessive. On occasions, variation in input impedance can provoke trouble and all possible types of pickup and microphone inputs should be tried. Square wave, instead of sine wave, excitation may induce parasitic oscillation.

(H) Feedback

Probably the most important feedback test is that for stability and the tests under (G) should be adequate, although instability experienced may be due to causes other than parasitic oscillation. For example an amplifier with voltage feedback from the output stage may oscillate when operated with open-circuited output, due to excessive feedback.

The output impedance is liable to be variable with frequency in a feedback amplifier. It can be estimated by varying the output impedance and noting the change in voltage

across it (Ref. 26). However a variation in output impedance alters the amount of feedback and thus the impedance being measured. A more accurate determination can be made by connecting the correct load and driving source to the amplifier (it is only necessary to complete the input circuit if feedback is applied to the input stage, see Chapter 7 Sect. 2(vi)A) then connecting an a-f oscillator through a high impedance to the amplifier output and measuring the current flowing into the output circuit and the voltage across it. The impedance of the load in parallel with the output impedance of the amplifier is then obtainable and since the load is known the output impedance can be calculated. If output impedance is important it is desirable to make a measurement at least at the speaker resonant frequency as well as at mid-frequencies.

Another useful feedback test is a measurement of gain reduction vs. frequency. Such a curve is readily plotted and draws attention to any points at which the feedback may become positive. The shape of this curve is similar to an inverted output-impedance curve.

SECTION 4 : MEASUREMENTS ON COILS

(i) *Measurement of coefficient of coupling* (ii) *Measurement of primary resonant frequencies of aerial and r-f coils* (iii) *Measurement of distributed capacitance across coils.*

(i) Measurement of coefficient of coupling

The measurement of k , the coefficient of coupling, has been covered in Chapter 26 Sect. 4(ii)E and (iii)B.

(ii) Measurement of primary resonant frequencies of aerial and r-f coils

The usual methods of measuring primary resonant frequencies are either

- (a) connecting a valve voltmeter across the secondary circuit, which is tuned to a much higher frequency than that to be measured (or a much lower frequency in the case of low impedance primaries), and feeding in a signal from the signal generator. The primary resonant frequency shows up by a sharp increase in the voltage across the valve voltmeter as the generator is tuned through this frequency. The secondary detuning is readily effected by rotating the rotor of the gang condenser, say, half-way across the band, or
- (b) connecting the valve voltmeter straight across the primary winding, finding the resonant frequency, and then finding the true primary frequency by calculation after allowing for the input capacitance of the valve voltmeter, which can be measured on a Q meter or found by other means.

(iii) Measurement of distributed capacitance across coils

The distributed capacitance across a coil can be found with the use of a Q meter, following the methods given in most Q meter instruction books, as summarized below.

Approximate method ($\pm 2 \mu\mu\text{F}$)

This is suitable for large inductors only

1. Connect the inductor under test to the coil (L) terminals of the Q meter.
2. Set the tuning capacitor to about $200 \mu\mu\text{F}$ (C_1) and adjust the oscillator frequency for resonance.
3. Note the oscillator frequency f_1 .
4. Change the oscillator to a frequency exactly twice f_1 .
5. Set the tuning capacitor to a new value C_2 for resonance.

6. The distributed capacitance C_0 may then be calculated,

$$C_0 = (C_1 - 4C_2)/3 \text{ } \mu\mu\text{F.} \quad (1)$$

If it is not convenient to use a frequency ratio of 2 : 1, the more general expressions for determining distributed capacitance are :

$$C_0 = \frac{(C_1 - C_2) - C_2(\alpha^2 - 1)}{\alpha^2 - 1} \text{ } \mu\mu\text{F} \quad (2)$$

where $\alpha = (f_2/f_1)$.

The true inductance is given by

$$L = \frac{25\,330}{f_2^2(C_2 + C_0)} \text{ } \mu\text{H,} \quad (3)$$

f being expressed in Mc/s

C_2 and C_0 in $\mu\mu\text{F}$.

$$\text{Natural resonant frequency of inductor} = f_n = f_2\sqrt{1 + (C_2/C_0)}. \quad (4)$$

Accurate method (accuracy about $\pm 4\%$)

This method involves measuring the natural resonant frequency of the inductor.

1. Connect the inductor to the coil (L) terminals of the Q meter, set the Q circuit tuning capacitor to about 400 $\mu\mu\text{F}$ and adjust the oscillator frequency for resonance. Call the frequency f_1 and the tuning capacitance C_1 .

2. Replace the inductor under test by a shielded coil having an inductance about 1/25 of that of the inductor under test.

3. Set the oscillator to a frequency about 10 times f_1 , and adjust the Q circuit tuning capacitor for resonance.

4. Connect the inductor under test to the coil (L) terminals of the Q meter, in parallel with the shielded coil, taking care to avoid coupling between the two coils. Then adjust the Q circuit tuning capacitance for resonance, observing whether the capacitance has to be increased or decreased from its previous setting. If the capacitance has to be increased, increase the oscillator frequency by an appreciable amount (10 to 20%). If the capacitance has to be decreased, decrease the oscillator frequency.

5. Disconnect the inductor under test and adjust the Q circuit tuning capacitance to resonance at the new frequency, repeating the procedure of (4) above, changing the oscillator frequency by smaller increments as it approaches the resonant frequency of the inductor under test, until the frequency reaches a value at which the Q tuning capacitance is unchanged when the inductor under test is connected or disconnected. The corresponding oscillator frequency is called f_0 .

6. The distributed capacitance, C_0 , of the inductor may then be calculated :

$$C_0 = \frac{C_1}{\frac{f_0^2}{f_1^2} - 1} \quad (5)$$

or by the close approximation

$$C_0 \approx \frac{f_1^2}{f_0^2} \cdot C_1. \quad (6)$$

The accuracy of this measurement depends on the inductance of the coil remaining constant over the two frequencies. This is reasonably accurate for commonly used coils, although it may not hold for coils having iron cores.

This method often requires a considerable amount of trial and error. As a starting point it is helpful to measure L (this is not the true inductance of course) and make a guess at the value of C_0 . The natural resonant frequency f_n can then be calculated to give a rough guide for starting more accurate measurements.

‡The internationally accepted value of gravitational acceleration at latitude 45° and sea level.

(ii) Electrical and magnetic units

There are several systems of units in common use, but they may be divided into three clearly distinguished groups :

1. Unrationalized systems, including

- (a) Absolute† c.g.s.* electrostatic system.
- (b) Absolute† c.g.s.* electromagnetic system.
- (c) Absolute† m.k.s. (metre-kilogram-second) system. Otherwise known as the Giorgi system.

2. Rationalized systems including

- (a) Rationalized m.k.s. system (Giorgi).

3. Practical systems

The common practical system includes the volt, ampere, coulomb, ohm, farad, henry and watt.

All fundamental physical relationships are normally worked out in one of the unrationalized systems, and the final result may be converted into practical units for general use.

Rationalized systems have been developed to simplify certain calculations. They may be used as alternatives to unrationalized systems.

The m.k.s. system is increasing in popularity because neither the c.g.s. electrostatic system nor the c.g.s. electromagnetic system is convenient for use with all problems, and the combined use of the two systems has been generally adopted in the past. Another reason for its popularity is that it includes many of the practical units, the second, joule, watt, coulomb, ampere, volt, ohm, mho, farad and henry. The rationalized m.k.s. system has been standardized by the American I.R.E. (January 1948).

The Giorgi m.k.s. system absolute system was adopted by the International Electrotechnical Commission (I.E.C.) in Bruxelles, June 1935 (see Proceedings of National Academy of Sciences Vol. 21 No. 10 pp. 579-583, October 1935 ; reprinted by Harvard University, Publications from the Graduate School of Engineering 1935-36 No. 167). See also A. E. Kennelly "I.E.C. adopts MKS System of Units," *Electrical Engineering* 54.12 (Dec. 1935) 1373. See also References below.

In any one sequence of calculations it is essential to retain the same system throughout. The final result may then, if desired, be converted to any other system. Table 2 should enable any engineer to convert from one quantity in any system to any other of the major systems.

A brief description of all systems including the m.k.s. is given in "Applied Electronics" (Massachusetts Institute of Technology ; John Wiley & Sons Inc. New York ; Chapman & Hall Ltd., London, 1943) Appendix B.

*c.g.s. = centimetre-gramme-second.

†An absolute system is one which includes length, mass and time in its fundamental dimensions.

TABLE 2: THE PRINCIPAL ELECTRICAL AND MAGNETIC UNITS

Quantity	Practical (English)	Giorgi MKS	C.G.S. Electrostatic	C.G.S. Electromagnetic
Length	1 foot, 1 inch	1 metre	1 centimetre	1 centimetre
Mass	1 pound	1 kilogram	1 gram	1 gram
Force	1 pound weight	1 dyne-five = 1 newton	1 dyne	1 dyne
Time	1 second		1 second	1 second
Work, Energy	1 joule		1 erg	1 erg
Power	1 watt		1 erg/second	1 erg/second
Charge	1 coulomb		1 statcoulomb	1 abcoulomb
Current	1 ampere		1 statampere	1 abampere
Electromotive force	1 volt		1 statvolt	1 abvolt
Resistance	1 ohm		1 statohm	1 abohm
Resistivity	1 ohm/cm cube or 1 ohm- centimetre			
Conductance	1 siemens = 1 mho		1 statmho	1 abmho
Conductivity	1 mho/cm cube			
Capacitance	1 farad		1 statfarad	1 abfarad
Inductance	1 henry		1 stathenry	1 abhenry
Flux (ϕ)	1 line = 1 maxwell	MKS unrationalized	MKS rationalized	1 line = 1 maxwell
		1 weber	1 weber	
Flux density (B)	1 line/sq in	1 weber/sq metre	1 weber/sq metre	1 gauss
Magnetizing force (H)	1 ampere-turn /in	1 praoersted	1 ampere-turn /metre	1 oersted
Magnetomotive force (F)	1 ampere-turn	1 pragilbert	1 ampere-turn	1 gilbert
Reluctance		1 pragilbert/ weber	1 ampere-turn/ weber	1 gilbert/ maxwell
Permeability of free space (μ_0)		10^{-7} henry/ metre (or 10^{-7} weber/sq metre/praoersted)	4×10^{-7} henry/metre	1 abhenry/cm (or 1 gauss/ oersted)

RELATIONSHIPS BETWEEN UNITS

1 metre = 100 centimetres	1 centimetre = 1/100 metre
1 kilogram = 1000 grams	1 gram = 1/1000 kilogram
1 newton = 10^5 dynes	1 dyne = 10^{-5} newton
1 joule = 10^7 ergs	1 erg = 10^{-7} joule
1 watt = 10^7 ergs/second	1 erg/second = 10^{-7} watt
1 coulomb = 3×10^9 statcoulombs = 0.1 abcoulomb	
1 statcoulomb = 3.33×10^{-11} abcoulomb	1 abcoulomb = 3×10^{10} statcoulombs
1 ampere = 3×10^9 statamperes = 0.1 abampere	
1 statampere = 3.33×10^{-11} abampere	1 abampere = 3×10^{10} statamperes
1 volt = 3.33×10^{-3} statvolt = 10^8 abvolts	
1 statvolt = 3×10^{10} abvolts = 300 volts	1 abvolt = 3.33×10^{-11} statvolt
1 ohm = 1.11×10^{-12} statohm = 10^9 abohms	
1 statohm = 9×10^{20} abohms	1 abohm = 1.11×10^{-21} statohm
1 mho = 9×10^9 statmhms = 10^{-9} abmho	
1 statmho = 1.11×10^{-21} abmho	1 abmho = 9×10^{20} statmhms
1 farad = 9×10^{11} statfarads = 10^{-9} abfarad	
1 statfarad = 1.11×10^{-21} abfarad	1 abfarad = 9×10^{20} statfarads
	$1 \mu\mu\text{F} = 0.9$ statfarad
1 henry = 1.11×10^{-12} stathenry = 10^9 abhenrys	
1 stathenry = 9×10^{20} abhenrys	1 abhenry = 1.11×10^{-21} stathenrys
1 weber = 10^8 maxwells = 10^8 lines	1 maxwell = 10^{-8} weber
1 weber/sq metre = 10^4 gauss	1 gauss = 10^{-4} weber/sq metre
1 praoersted = 10^{-3} oersted	1 oersted = 10^3 praoersted
1 ampere-turn/inch = 0.495 oersted	= 495 praoersteds
1 ampere-turn/metre = 0.01257 oersted	= 12.57 praoersteds
1 ampere-turn = 1.257 gilberts	1 gilbert = 0.796 ampere-turn
1 pragilbert = 0.1 gilbert	1 gilbert = 10 pragilberts
1 ampere-turn = 12.57 pragilberts	1 pragilbert = 0.0796 ampere-turn
1 pragilbert/weber = 10^{-9} gilbert/maxwell	= 0.0796 ampere-turn/weber
1 ampere-turn/weber = 1.257×10^{-8} gilbert/maxwell	

(iii) Photometric units

TABLE 3 : PHOTOMETRIC UNITS

Quantity	Symbol	Unit	Relationship
Luminous Flux	F	Lumen	$1 \text{ lumen} = \frac{1}{4\pi} \times \text{flux emitted by one candle}$
Light Intensity	I	Candle	Flux emitted by 1 candle = 4π lumens
Illumination	E	Footcandle	= lumens/ft ²
		Phot	= cm candle = lumens/cm ²
		Lux	= metre candle = lumens/m ²

Relationship between units of illumination

Unit	Foot-candle	Phot	Lux
1 Foot-candle	1	0.001076	10.76
1 Phot	929	1	10 ⁴
1 Lux	0.0929	10 ⁻⁴	1

(iv) Temperature

TABLE 4 : TEMPERATURE

Freezing point of water (normal pressure) }	= 32° Fahrenheit = 0° Centigrade* = 273.16° Kelvin (Absolute)
Boiling point of water (normal pressure) }	= 212° Fahrenheit = 100° Centigrade* = 373.16° Kelvin (Absolute)
1 Fahrenheit degree	= $\frac{5}{9}$ Centigrade* degree = 0.5556 Centigrade* degree
1 Centigrade* degree	= 0.5556 Kelvin degree = 1.800 Fahrenheit degree = 1.0 Kelvin degree
Temperature in °C	= $\frac{5}{9} (^{\circ}\text{F} - 32)$
Temperature in °F	= 1.8 (°C) + 32
Temperature in °K	= (°C) + 273.16
Absolute temperature	= (°K) - 273.16
Temperature in °C	= 0°K
Absolute Zero	= -273.16°C = -459.68°F

*The Ninth General Conference on Weights and Measures held in Paris in October, 1948, decided to abandon the designation Centigrade and use Celsius (International Temperature Scale) instead. For most practical purposes the two scales may be regarded as identical.

SECTION 2 : COLOUR CODES

(i) Colour code for fixed composition resistors (ii) Colour code for fixed wire-wound resistors (iii) Table of R.M.A. colour code markings for resistors (iv) Colour code for moulded mica capacitors (v) Colour code for ceramic dielectric capacitors (vi) Colour code for i-f transformers (vii) Colour code for a-f transformers and output transformers (viii) Colour code for power transformers (ix) Colour code for loud-speakers (x) Colour code for chassis wiring (xi) Colour code for battery cables (xii) Colour code for metallized paper capacitors.

(i) Colour code for fixed composition resistors

(A) R.M.A. Standards GEN-101, REC-116, July 1948.

In fixed composition resistors with axial leads the nominal resistance value is indicated by bands of colour of equal width around the body of the resistor (Fig. 38.1).

Band A indicates the first significant figure.

Band B indicates the second significant figure.

Band C indicates the decimal multiplier.

Band D, if any, indicates the tolerance limits about the nominal resistance value.

FIG. 38.1

FIG. 38.2

Fig. 38.1. R.M.A. colour code for fixed composition resistors (axial leads).

Fig. 38.2. R.M.A. colour code for fixed composition resistors (radial leads).

TABLE 5 : COLOUR CODE

Colour	Significant Figure	Decimal Multiplier	Tolerance %
Black	0	1	
Brown	1	10	
Red	2	10 ²	
Orange	3	10 ³	
Yellow	4	10 ⁴	
Green	5	10 ⁵	
Blue	6	10 ⁶	
Violet	7	10 ⁷	
Grey	8	10 ⁸	
White	9	10 ⁹	
Gold	—	10 ⁻¹	±5
Silver	—	10 ⁻²	±10
No Colour	—	—	±20

Body colour : Black indicates uninsulated. Any other colour indicates insulated.

Colour code with radial leads

Resistors with radial leads may use the same colour code as those with axial leads, but alternatively* they may be colour coded as in Fig. 38.2 where

Body A corresponds to Band A above,

End B corresponds to Band B above,

Dot C (or band C) corresponds to Band C above,

Band D corresponds to Band D above.

See also Sect. 3(i)—Standard fixed composition resistors.

*As JAN-R-11 and old R.M.A. specification.

(B) British Standard BS. 1852 : 1952

for fixed resistors for telecommunication purposes.

Interpretation of marking :

Fig. 38.3A	Fig. 38.3B or Fig. 38.3C	Interpretation
1st band (A)	Body (A)	Indicates first significant figure of resistance value.
2nd band (B)	First tip (B)	Indicates second significant figure.
3rd band (C)	Spot (C)	Indicates multiplier.
4th band (D)	Second tip (D)	If present, indicates percentage tolerance on nominal resistance value. If no colour appears in this position the tolerance is ± 20 per cent.
5th band (E)	—	If present, indicates grade of resistor.

Colour values :

As Table 5 with the addition of

FIG. 38.3

*Fig. 38.3A. British Standard coloured band marking (preferred).**Fig. 38.3B. British Standard body, tip and spot marking.**Fig. 38.3C. British Standard body, tip and central band marking.***(ii) Colour code for fixed wire-wound resistors**

(A) R.M.A. Standard REC-117, July 1948

In fixed wire-wound resistors with axial leads the nominal resistance value is indicated by bands of colour around the body of the resistor (Fig. 38.3).

FIG. 38.3

Fig. 38.3. R.M.A. colour code for fixed wire wound resistors (axial leads).

Band A is of double width, thereby indicating a wire-wound resistor. The colour of Band A, and those of bands B, C and D, have the same indications regarding resistance and tolerance as for composition resistors. The body colour also has the same indications as for composition resistors.

See also Sect. 3(ii) for standard fixed wire wound resistors.

(B) British Standard colour code for fixed resistors. See (i) (B) above.

(iii) Table of R.M.A. colour code markings for resistors

(iv) Colour code for moulded mica capacitors

The Standard American R.T.M.A. Colour Marking (R.C.M.) uses six dots for moulded mica capacitors.

(R.T.M.A. Standard REC-115-A, May 1951) (Fig. 38.4).

Dot (1): White indicates R.T.M.A. moulded mica capacitor colour coding.

Black indicates JAN colour coding (see below).

Any other colour indicates old R.M.A. 6 dot system.

Dot (2): First digit of capacitance (see Table 7 below).

Dot (3): Second digit of capacitance (see Table 7 below).

Dot (4): Class of capacitor (see REC-115-A).

Dot (5): Tolerance (see Table 7 below).

Dot (6): Multiplier for capacitance (see Table 7 below).

Fig. 38.4. Colour code for moulded mica capacitors (6 dot).

Fig. 38.5. Colour code for moulded mica capacitors (3 dot).

Fig. 38.6. Colour code for moulded mica capacitors (4 dot).

TABLE 7: R.T.M.A. MOULDED MICA CAPACITORS

Colour	Numeral	Multiplier	Tolerance	Class
Black	0	1	20%	A
Brown	1	10		B
Red	2	100	2%	C
Orange	3	1000	3%	D
Yellow	4	10 000		E
Green	5		5%	
Blue	6			
Violet	7			
Grey	8			I
White	9			J
Gold		0.1		
Silver		0.01	10%	

JAN-C-5 six dot colour marking (Fig. 38.4)

In the JAN-C-5 code the black Dot 1 signifies a mica dielectric capacitor. Dot 4 gives the capacitor characteristic (for details see JAN specification). The remaining dots have the same significance as in the R.C.M. system.

Old R.M.A. six dot colour marking (Fig. 38.4)

Dots 1, 2 and 3 signify the first three significant figures of the capacitance. Dot 4 signifies the rated direct working voltage. Dot 5 gives the percentage tolerance. Dot 6 gives the decimal multiplier.

Three dot system

This applies only to capacitors with 500 volt ratings and $\pm 20\%$ tolerances in capacitance (Fig. 38.5).

Dot 1 gives the first significant figure.

Dot 2 gives the second significant figure.

Dot 3 gives the decimal multiplier.

Four dot system

To extend the usefulness of the three dot system, a fourth dot is sometimes added in the top left-hand corner (Fig. 38.6) to indicate the percentage tolerance.

See also Sect. 3(v) for standard moulded mica capacitors.

(v) Colour code for ceramic dielectric capacitors**(A) R.M.A. Standard REC-107, Oct. 1947**

The colour markings consist of five colours, one of which unambiguously marks the end of the capacitor bearing the inner-electrode terminal while the remaining four colour markings are successively closely adjacent along the length of the capacitor; an indicator is provided to avoid ambiguity in the interpretation of the significance of the position of the colour markings.

The end colour indicates the temperature coefficient in accordance with Table 8 below.

The first and second colour markings indicate the first and second digits of the value of the capacitance in micro-microfarads.

The third colour marking indicates the decimal multiplier of the value of the capacitance.

The fourth colour marking indicates the capacitance tolerance in accordance with Table 8 below.

TABLE 8

Position	End	Nos. 1, 2	No. 3	No. 4	
Colour	Temperature coeff. parts/million/°C	Significant figure	Decimal multiplier	Capacitance tolerance	
				$C > 10 \mu\mu\text{F}$	$C \leq 10 \mu\mu\text{F}$
black	0	0	1	$\pm 20\%$	$\pm 0.1 \mu\mu\text{F}$
brown	-30	1	10	$\pm 1\%$	
red	-80	2	10^2	$\pm 2\%$	
orange	-150	3	10^3	$\pm 2.5\%$	
yellow	-220	4	10^4		
green	-330	5		$\pm 5\%$	$\pm 0.5 \mu\mu\text{F}$
blue	-470	6			$\pm 0.25 \mu\mu\text{F}$ $\pm 1.0 \mu\mu\text{F}$
violet	-750	7			
grey	+30	8	0.01		
white	General purpose condenser*	9	0.1	$\pm 10\%$	

Capacitance change

silver +25% (Class 4 capacitors)

silver +25%, - 50% (Class 5 capacitors)

*May have any nominal temperature coefficient between +120 and -750 parts per million per degree Centigrade, at option of the manufacturer.

(B) British R.I.C. colour code for ceramic dielectric capacitors, RIC/133 (Ref. F7)

Colour	End Colour (Temperature Coefficient)*	1st dot, 1st significant figure	2nd dot, 2nd significant figure	3rd dot Multiplier	4th dot Tolerance	
					10 $\mu\mu\text{F}$ or less	More than 10 $\mu\mu\text{F}$
Black	NP0.	0	0	1	$\pm 2.0 \mu\mu\text{F}$	$\pm 20\%$
Brown	N030	1	1	10	$\pm 0.1 \mu\mu\text{F}$	$\pm 1\%$
Red	N080	2	2	100		$\pm 2\%$
Orange	N150	3	3	1000		$\pm 2.5\%$
Yellow	N220	4	4	10 000		
Green	N330	5	5		$\pm 0.5 \mu\mu\text{F}$	$\pm 5\%$
Blue	N470	6	6			
Violet	N750	7	7			
Grey	P030	8	8	0.01	$\pm 0.25 \mu\mu\text{F}$	
White	P100	9	9	0.1	$\pm 1.0 \mu\mu\text{F}$	$\pm 10\%$

*N signifies negative, P signifies positive temperature coefficient. Figures give parts per million per °C.

See also Sect. 3(vi) for standard ceramic dielectric capacitors.

(vi) Colour code for i-f transformers

(R.M.A. Standard REC-114, March 1948, for 455 Kc/s)

Blue—plate lead.

Red—B + lead.

Green—grid (or diode) lead.

White—grid (or diode) return.

(For "full-wave" transformer, the second diode lead will be violet).

(vii) Colour code for a-f transformers and output transformers

(R.M.A. Standard U.S.A. S410, M4-507, May 1935)

Blue—plate (finish) lead of primary.

Red—B+ (this applies whether primary is plain or centre-tapped).

Brown—plate (start) lead on C.T. primaries. Blue may be used for this lead if polarity is not important.

Green—grid (finish) lead to secondary (hot end of voice coil).

Black—grid return (this applies whether the secondary is plain or centre tapped).

Yellow—grid (start) lead on centre-tapped secondaries. (Green may be used for this lead if polarity is not important).

Note : These markings apply also to line-to-grid and valve-to-line transformers.

(viii) Colour code for power transformers

(R.M.A. Standard S410, M4-505, May 1935)

1. Primary leads—no tap

If tapped—Common

Tap : Black and yellow 50/50 striped design

Finish : Black and red 50/50 striped design

2. Rectifier—Plate winding

Centre tap : Red and yellow 50/50 striped design

3. Rectifier—Filament winding

Centre tap : Yellow and blue 50/50 striped design

4. Amplifier—Filament winding No. 1

Centre tap : Green and yellow 50/50 striped design

Black
Black

Red

Yellow

Green

5. Amplifier—Filament winding No. 2 Brown
 Centre tap : Brown and yellow 50/50 striped design
6. Amplifier—Filament winding No. 3 Slate
 Centre tap : Slate and yellow 50/50 striped design

(ix) Colour code for loudspeakers

(R.M.A. Standard U.S.A. M5-181 Nov. 1936)

Loudspeaker field coils

- Black and red*—start.
- Yellow and red*—finish.
- Slate and red—tap (if any).

Note : If two field coils are fitted to the same loudspeaker, the basic colour coding is used for the lower resistance field, and green is substituted for the red in the higher resistance field.

Loudspeaker transformer primaries

Centre-tapped

- Blue or brown—start
- Blue—finish
- Red—centre tap

Untapped

- Red†—start
- Blue—finish

Loudspeaker transformer secondaries

- Black—start
- Green—finish

Standard pin arrangement 4A

- Pin 1 (large) Yellow and red (field finish).
- Pin 2 Blue or brown (transformer start) for push-pull.
 No connection or red (transformer start).
- Pin 3 Blue (transformer finish).
- Pin 4 (large) Black and red (field start).

Standard pin arrangement 5A

- Pin 1 Yellow and red (field finish).
- Pin 2 Blue or brown (transformer start).
- Pin 3 Red (transformer centre-tap).
- Pin 4 Blue (transformer finish).
- Pin 5 Black and red (field start).

The start, tap and finish of all windings occur in clockwise order around the plug pins when the plug is viewed from the socket end.

(x) Colour code for chassis wiring

(A) R.M.A. Standard U.S.A. REC-108-A (December 1949)

Colour	Circuit
Black	Grounds, grounded elements, and returns
Brown	Heaters or filaments, off ground
Red	Power supply B+
Orange	Screen grids
Yellow	Cathodes
Green	Control grids
Blue	Plates
Violet	Not used
Grey	A.C. power lines
White	Above or below ground returns, a.v.c., etc.

*Some manufacturers use a single colour, omitting the red.

†Some manufacturers use brown whether tapped or untapped.

When leads for antenna and ground connections are provided on the receiver, it shall be standard to colour code the antenna lead blue and the ground lead black. Special antenna connection leads shall be coded with combinations of blue and black.

(B) RTMA Standard Colour marking of thermoplastic insulated hook-up wire, GEN-104 (July 1951)

Colour coding for thermoplastic hook-up wire without fabric braids shall be accomplished either by the use of solid coloured insulation or by natural colour or white insulation with coloured helical stripes. It is intended that these wires be interchangeable by colour with fabric braid wires. Where, in fabric, braids consist of solid colours with tracer threads of contrasting colours, this standard implies that base colour stripe (wide stripe) is used in lieu of solid coloured fabric braid. Helical tracer stripes are used in lieu of contrasting colour threads in fabric braid-covered wire.

(xi) Colour code for battery cables

(American R.M.A. Standard S-410, M4-508, April 1939)

A +	Red	B intermediate	White
A -	Black	C +	Brown
B +	Blue	C intermediate	Orange
B -	Yellow	C -	Green

(xii) Colour code for metallized paper capacitors

A 3 dot colour code may be used to indicate capacitance in $\mu\mu\text{F}$. Dot 1 gives the first significant figure. Dot 2 gives the second significant figure (Table 7 col. 2). Dot 3 gives the multiplier (Table 7 col. 3).

SECTION 3: STANDARD RESISTORS AND CAPACITORS

(i) *Standard fixed composition resistors* (ii) *Standard fixed wire wound resistors*
 (iii) *Fixed paper dielectric capacitors in tubular non-metallic cases* (iv) *Metal encased fixed paper dielectric capacitors for d.c. application* (v) *Standard fixed mica dielectric capacitors* (vi) *Standard ceramic dielectric capacitors* (vii) *Standard variable capacitors* (viii) *Standard variable composition resistors* (ix) *Standard metallized paper dielectric capacitors* (x) *Standard electrolytic capacitors* (xi) *References to standard resistors and capacitors.*

The information in this Section is in the form of summaries or extracts from certain recognized standards, and is necessarily incomplete. The purpose of this Section is, in part, to draw the attention of design engineers to the importance of the information obtainable from such standards. However, all design engineers are urged to secure up-to-date copies of the official standard specifications under which they work.

See also Chapter 4 Sect. 9 for general information.

(i) Standard fixed composition resistors

(A) American R.M.A. Standard REC-116, July 1948

Values of resistance from 1 ohm to 100 megohms. The preferred values of resistance, over the range from 50 ohms to 10 megohms, are shown in Table 6 in Sect. 2(iii). The complete list is given in the R.M.A. Standard REC-116. These preferred values have been adopted in U.S.A. and to some extent in England, but not universally. The old standard resistance values, shown in bold typeface, are generally used where the preferred values have not been adopted.

The tolerance in resistance is $\pm 5\%$, $\pm 10\%$ or $\pm 20\%$ as desired.

The **resistance-temperature characteristic** is expressed as the change of resistance between ambient temperatures of +25°C and +85°C in the form of the percentage of the resistance at 25°C.

The **voltage coefficient** is given by

$$\text{Voltage coefficient} = \frac{100 (R_1 - R_2)}{R_2 (E_1 - E_2)} = \frac{111 (R_1 - R_2)}{E_1 R_2}$$

where E_1 = rated continuous working voltage (to give rated power dissipation, or maximum continuous voltage rating, whichever is the higher)

$$E_2 = E_1/10$$

R_1 = resistance measured with applied voltage E_1

and R_2 = resistance measured with applied voltage E_2 .

The test is carried out firstly with reduced voltage (E_2), and immediately afterwards with voltage E_1 .

The **noise** is measured by connecting the resistor in a d.c. circuit and comparing the noise voltage with an audio frequency of 1000 c/s. The measuring equipment includes an amplifier, filter and valve voltmeter (for details see REC-116). The noise is expressed in microvolts per volt (applied direct voltage).

Ambient temperature—effect on maximum working voltage

Temperature	40°	60°	80°	85°	100°	110°C
Max. voltage	100%	77.5%	55%	50%	20%	0

For colour code see Sect. 2(i).

(B) American JAN-R-11 (Ref. E1)

Some commercial resistors are manufactured in accordance with JAN-R-11 specifications while these are compulsory for use in American Army/Navy equipment.

There are two resistance-temperature characteristics; characteristic F has one half the change in resistance of characteristic E. The de-rating curve is tabulated on page 187. The maximum surface temperature is 135°C. The maximum continuous working voltage is:

Type	RC15	($\frac{1}{4}$ watt)	200	volts (d.c. or r.m.s.)
	RC10, 16	($\frac{1}{4}$ watt)	250	„ „
	RC20, 21, 25	($\frac{1}{2}$ watt)	350	„ „
	RC30, 31, 35	(1 watt)	500	„ „
	RC38	(1 watt)	1000	„ „
	RC40, 41, 45	(2 watts)	500	„ „
	RC65	(4 watts)	500	„ „
	RC75, 76	(5 watts)	500	„ „

The voltage coefficient shall not exceed 0.035% per volt for $\frac{1}{4}$ and $\frac{1}{2}$ watt ratings, or 0.02% per volt for larger ratings. Tests are specified for temperature cycling, humidity, vibration, effect of soldering, overloading etc., also salt water immersion and insulation strength where applicable. The root mean-square value of the noise generated shall not exceed 3.0 r.m.s. $\mu\text{V/V}$ at the rated continuous working voltage for $\frac{1}{4}$ and $\frac{1}{2}$ watt ratings, or 1.2 r.m.s. $\mu\text{V/V}$ for larger ratings, frequency characteristic —3 db at 70 and 5000 c/s). Marking, resistance values and tolerances are as R.M.A. REC-116.

Amendment No. 3 provides for a characteristic G which has an ambient temperature of 70°C with a linear de-rating characteristic which reaches zero at 130°F.

(C) British R.I.C. Specification No. RIC/112

Grade 1 (high stability). Issue No. 1, May 1950. Resistance values follow the series, 1, 1.1, 1.2, 1.3, 1.5, 1.6, 1.8, 2.0, 2.2, 2.4, 2.7, 3.0, 3.3, 3.6, 3.9, 4.3, 4.7, 5.1, 5.6, 6.2, 6.8, 7.5, 8.2, 9.1, 10 for all tolerances. Range 10 ohms to 10 megohms with some limitations.

Tolerances $\pm 1\%$, $\pm 2\%$, $\pm 5\%$.

Ratings $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, 1, 2 watts.

Colour code (five colours)—see Sect. 2(i)B.

The surface temperature shall not exceed 150°C. The voltage coefficient shall not exceed 0.002% per volt. The noise shall not exceed 0.5 μV per volt (d.c.). Resistance change with soldering shall not exceed $\pm 0.3\%$.

Temperature coefficient :

Watts	$\frac{1}{8}$	$\frac{1}{4}$	$\frac{1}{2}$	$\frac{3}{4}$	1 and 2	Temp. coeff.
Res. up to	100K	250K	0.5M	1M	2M	0 to -0.0004
Res. up to	0.5M	1M	2.5M	5M	10M	0 to -0.0008
Res. up to	2.5M	5M	10M	10M	—	0 to -0.001

Permissible variation in resistance after climatic and durability tests, endurance, tropical exposure, humid atmosphere, salt atmosphere :

Permissible variation	$\frac{1}{8}$ W	$\frac{1}{4}$ W	$\frac{1}{2}$ W	$\frac{3}{4}$ W	1 and 2 W
1% up to resistance of	10K	25K	50K	100K	200K
1½% " " " "	100K	250K	0.5M	1M	2M
2% " " " "	0.5M	1M	2.5M	5M	10M
3% " " " "	2.5M	5M	10M	10M	—

Rating curve (dissipation) 100% to 70°C ambient temperature, then decreasing linearly to 0% at 150°C.

(D) British R.I.C. Specification No. RIC/113

Grade 2. Issue No. 1, June 1950.

Resistance values as Table 5 for corresponding tolerances.

Range 10 ohms to 10 megohms with some limitations.

Tolerances $\pm 20\%$, $\pm 10\%$, $\pm 5\%$.

Ratings—axial, non-insulated : $\frac{1}{8}$, 1 watt

radial, non-insulated $\frac{1}{10}$, $\frac{1}{4}$, 1, 2½ watts.

axial, insulated : $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, 1 watt.

Colour code—see Sect. 2(i)C.

The surface temperature shall not exceed 120°C. The voltage coefficient shall not exceed 0.025% per volt (below 1 megohm), or 0.05% (1 megohm and above). Temperature coefficient shall not exceed 0.12%. Resistance change with soldering shall not exceed $\pm 2\%$. Rating curve (dissipation) : 100% at 70°C, decreasing linearly to 0% at 110°C, and increasing to 175% at 40°C ambient temperature.

(ii) Standard fixed wire wound resistors

(A) American R.M.A. Standard REC-117, July 1948

There are three styles :

Style No.	RRU3	RRU4	RRU6
Max. watts dissipation at 40°C ambient	$\frac{1}{8}$	1	2
Minimum resistance, ohms	0.24	0.47	1.0
Maximum resistance, ohms	820	5100	8200
Standard tolerances :			
More than 10 ohms	5% 10% 20%	5% 10% 20%	5% 10% 20%
10 ohms or less	10% 20%	10% 20%	10% 20%

The preferred values of resistance are as for composition resistors, except for the extension to lower values.

Ambient temperature—effect on max. working voltage

Temperature	40°	70°	100°	110°C
Max. voltage	100%	60%	20%	0

Power rating—in still air at 40°C ambient temperature the temperature rise should not exceed 70°C for styles 3 and 4, and 95°C for style 6, for the rated power input. At temperatures higher than 40°C, with reduced working voltage and power dissipation as tabulated above, the hot spot temperature should not exceed 110°C for styles 3 and 4, and 135°C for style 6.

Resistance change with temperature

The change in resistance referred to an ambient temperature of 25°C shall not be more than $\pm 0.025\%$ per 1°C for all resistors over 10 ohms, and not over $\pm 0.15\%$ per 1°C for 10 ohms and lower.

Marking

Typical marking RRU3 511 J.

RRU3 indicates fixed wire wound resistor, style 3.

511 indicates resistance. The first two digits are the significant figures of the value of resistance in ohms, while the last digit indicates the number of zeros which follow the significant figure. The letter R indicates a decimal point e.g. 511 indicates $51 \times 10 = 510$ ohms.

R56 indicates 0.56 ohms.

J indicates the tolerance :

symbol

tolerance

J

$\pm 5\%$

K

$\pm 10\%$

L

$\pm 20\%$

(B) American JAN-R-26A, JAN-R-19, JAN-R-184 should also be examined. See (xi) below for list.

(C) British R.I.C. Specification No. RIC/111

Resistors, fixed, wirewound, non-insulated. Issue No. 1, July 1950.

Resistance values (all tolerances) as column 3 in Table 6.

Tolerances $\pm 1\%$, $\pm 2\%$, $\pm 5\%$, $\pm 10\%$.

Colour code as Fig. 38.2B, with Table 5.

(iii) Fixed paper dielectric capacitors in tubular non-metallic cases

(A) American R.M.A. Standard REC-118, Sept. 1948

TABLE 9

Nominal capacitance	Standard tolerance	Voltage Ratings					
1.0 μF	+20%, -10%	100	200	400	—	—	—
0.5	+20%, -10%	100	200	400	600	—	—
0.25	+20%, -10%	100	200	400	600	—	—
0.15	+20%, -10%	100	200	400	600	1000	—
0.10	+20%, -20%	100	200	400	600	1000	—
0.05	+20%, -20%	100	200	400	600	1000	1600

Insulation Resistance at 25°C

TABLE 10

Nominal capacitance	Insulation resistance not less than:
1.0 μF	1000 megohms
0.5	2000 megohms
0.25	4000 megohms
0.001 to 0.15	5000 megohms

To determine the minimum insulation resistance at temperatures from 20°C to 40°C, multiply the values above by the factor :

°C	20	25	30	35	40
Factor	1.42	1.00	0.71	0.51	0.35

At still higher temperatures see Table 11.

TABLE 11

Capacitance μF	Insulation resistance at elevated temperatures	
	65°C Class W*	85°C Class M*
1.0	not less than 25 megohms	not less than 10 megohms
0.5	not less than 50 megohms	not less than 20 megohms
0.25	not less than 100 megohms	not less than 40 megohms
0.15	not less than 166 megohms	not less than 66 megohms
0.10	not less than 250 megohms	not less than 100 megohms
0.05	not less than 250 megohms	not less than 200 megohms
0.03 to 0.001	not less than 250 megohms	not less than 250 megohms

*Classification

Class W Operating temperature range -30°C to $+65^{\circ}\text{C}$. Power factor not greater than 2%. Resistance to humidity as below. Insulation resistance at 65°C as below.

Class M Operating temperature range -30°C to $+85^{\circ}\text{C}$. Power factor not greater than 1%. Insulation resistance at 85°C as above.

Humidity resistance (Class W only)

After humidity treatment (see REC-118 for details), the insulation resistance shall not be less than :

Nominal capacitance	0.001 to 0.15	0.25	0.5	1.0 μF
Insulation resistance	1750	1400	700	350 $\text{M}\Omega$

Power Factor Class M—not more than 1%.

Class W—not more than 2%.

Marking. Typical marking RCP10 W 6 504 K

RCP10 = RMA Standard Capacitor employing Paper Dielectric, with non-metallic cylindrical enclosure equipped with axially positioned wire leads.

W = Class (see above).

6 = Voltage in units of 100 volts.

504 = Indicating capacitance 50×10^4 giving capacitance in micro-microfarads.

K = tolerance.

K indicates +10%, -10%

X indicates +40%, -20%

L indicates +20%, -10%

Y indicates +60%, -25%

M indicates +20%, -20%

(B) **American JAN-C-91** should also be examined. See (xi) below for list.

(C) **British R.I.C. Specification No. RIC/131**

Issue No. 1, July 1950.

Capacitance values conform to the series 1, 2, 5, 10, etc.

Capacitance range 0.001 to 2 μF .

Tolerances $\pm 25\%$ up to and including 0.01 μF .

$\pm 20\%$ above 0.01 μF .

$\pm 10\%$ (Red Group only).

Maximum voltage ratings (d.c.) 150, 350, 500, 750, 1000 volts at rated temperature

Rated temperature 70°C (Red and Yellow); 60°C (Green).

Power factor shall not exceed 0.01.

38.3 (iii) PAPER CAPACITORS IN TUBULAR NON-METALLIC CASES 1349

Insulation resistance (one month after delivery) shall not be less than 2000 ohm-farads or 10 000 M Ω whichever is the less, for Red and Yellow, or 500 ohm-farads or 2500 M Ω , whichever is the less, for Green.

Tests are specified for climatic and durability, humid atmosphere, tropical exposure, endurance etc.

This specification also includes capacitors in metallic and ceramic cases.

(iv) Metal encased fixed paper dielectric capacitors for d.c. application

(A) American R.M.A. Standard TR-113 (April 1949)

TABLE 12

Nominal Capacitance	Standard Tolerance	Voltage ratings* (up to 40°C)

0.02	+20%, -20%	100		600 1000 1500
0.01	+40%, -20%	100	200	600 1000 1500
0.006	+40%, -20%	100		600 1000 1500
0.003	+40%, -20%			600 1000 1500
0.001	+60%, -25%	100		

* Voltage ratings above 1500V are not shown here.

Life : The voltage ratings given above, and the reduced voltage ratings for temperatures above 40°C, are based on an expected life of 1 year continuous operation at these temperatures. Longer life can be expected by operation at still lower voltages, e.g. 5 years at 70% of the values indicated.

Working voltage : The average working voltage over 24 hours should not exceed the adjusted rated voltage by more than 5%. A voltage of 110% of the rated voltage may be applied for not more than 10% of the operating time in any 24 hour period.

Alternating current component : In cases where alternating voltages are present in addition to direct voltages, the capacitor working voltage should be taken as the sum of the direct voltage and the peak value of the alternating voltage, provided that the peak alternating voltage does not exceed 20% of the direct voltage and that the frequency is 60 c/s or less. At higher frequencies the voltage should be adjusted as tabulated below :

Frequency	60	100	200	400	1000	4000	10 000 c/s
Ripple	20	16	12	9	6.2	2.8	1 %

Insulation resistance

Minimum insulation resistance in megohms :

TABLE 13

Temperature	25°C	40°C	55°C	70°C	85°C	
Characteristic A	3000	1000	300	100	30	MΩ
Characteristic B	1000	300	100	30	10	MΩ
Characteristic C	500	150	50	15	5	MΩ

Effect of temperature on capacitance (basis = 25°C)

TABLE 14

Temperature	85°C	50°C	25°C	0°C	-40°C
Maximum tolerances :					
Characteristic A	±5%	±2%	±0	± 2%	± 5%
Characteristic B or C	±5%	±2%	±0	{ + 2% -30%	+ 5% -30%

Effect of ambient temperature on voltage rating

Where condensers are used at ambient temperatures in excess of 40°C, the working voltage shall be reduced as indicated below :

TABLE 15

Temperature	40°C	50°C	60°C	70°C	80°C	85°C
Voltage rating (1)	100%	98%	94%	86%	74%	65%
Voltage rating (2)	100%	97.5%	92%	82.5%	66%	55%

Voltage rating (1) applies to condensers with a watt-second rating from 0 to 5. Voltage rating (2) applies to watt-second ratings over 5 (Voltage ratings over 2000 V are not included here).

Watt-second rating

$$\text{Watt-second rating} = \frac{1}{2}CE^2$$

where C = capacitance in microfaradsand E = nominal rating in kilovolts.

For other details and standard tests see TR-113-A.

Marking—Typical marking 71 B 1 A H 205 K.

71 indicates style (case form)*

B indicates terminal designation

(A indicates wire lead, B indicates solder lug, C indicates screw and nuts).

1 indicates schematic circuit and number of terminals*.

A indicates characteristic (A, B or C)—see above.

H indicates nominal voltage rating, as under :

Code letter	B	C	E	F	G	H	etc.
Voltage	100	200	400	600	1000	1500	etc.

205 indicates capacitance (here $20 \times 10^5 \mu\text{F}$).

K indicates tolerance :

Code letter	K	L	V	M	W
Tolerance	±10%	±15%	-10%, +20%	±20%	-0, +25%
Code letter	X	Y			
Tolerance	-20%, +40%	-25%, +60%			

*For details see TR-113-A.

The tolerance code may be omitted if the tolerance is standard (see table above).
(B) American JAN-C-25 should also be examined. See (xi) below for list.

(C) **British R.I.C. Specification No. RIC/131**

This specification includes both metallic and non-metallic cases—see Sect. 3(iii)C.

(v) **Standard fixed mica dielectric capacitors**

(A) Standard molded mica capacitors (American R.M.A. Standard REC-115-A, May 1951).

Nominal capacitance (μF)

TABLE 19

10	36	100	300	820	2400	6800	.020 μF
12	39	110	330	910	2700	7500	.022 μF
15	43	120	360	1000	3000	8200	.024 μF
18	47	130	390	1100	3300	9100	.027 μF
20	51	150	430	1200	3600	.010 μF	.030 μF
22	56	160	470	1300	3900	.011 μF	.033 μF
24	62	180	510	1500	4300	.012 μF	.036 μF
27	68	200	560	1600	4700	.013 μF	.039 μF
30	75	220	620	1800	5100	.015 μF	.043 μF
33	82	240	680	2000	5600	.016 μF	.047 μF
	91	270	750	2200	6200	.018 μF	

These are available in 11 styles, but any one value of capacitance is only available in a limited number of styles.

Standard d.c. voltage ratings

At temperature -20°C to $+85^{\circ}\text{C}$; barometric pressure 28 in. to 32 in. of mercury; relative humidity 10% to 80%.

TABLE 20

Voltage rating	Available in styles
300	20, 25, 30, 35, 40
500	20, 25, 30, 35, 40
600	45, 50, 55, 56, 60, 61
1000	40
1200	45, 50, 55, 56, 60, 61
2500	45, 50, 55, 56, 60, 61

Standard Classification

TABLE 21

Class	Q* not less than	Insul. Resist. not less than	Temp. coeff.† not more than	Capacit. drift not more than
A	30%	3000 M Ω	± 1000 ppm	$\pm (5\% + 1) \mu\text{F}$
B	100	6000	± 500	$\pm (3\% + 1)$
C	100	6000	± 200	$\pm (0.5\% + 0.5)$
I	100	6000	$+ 150, -50$	$\pm (0.3\% + 0.2)$
D	100	6000	± 100	$\pm (0.3\% + 0.1)$
J	100	6000	$+ 100, -50$	$\pm (0.2\% + 0.2)$
E	100	6000	$+ 100, -20$	$\pm (0.1\% + 0.1)$

*Not less than this percentage of values tabulated below:

Nomin. capacit. 7 10 20 40 60 100 200 1000 μF
Minimum Q 120 160 280 450 580 760 1000 1000

(Q is measured at approximately 1 Mc/s).

†Temperature coefficient of capacitance, being capacitance change in parts per million per $^{\circ}\text{C}$.

Insulation resistance after humidity cycle :

Class A capacitors—not less than 1000 megohms.

Other classes—not less than 2000 megohms.

Marking (alternative to colour code for which see Sect. 2(iv)).

Typical marking RCM 20 A 050 M

RCM = RMA Standard Capacitor employing Mica dielectric.

20 = style designation (see SP158B).

A = class designation (see above).

050 = $05 \times 10^0 = 5 \mu\text{F}$ (capacitance).

M indicates tolerance as under :

Code letter	G	H	J	K	M
Tolerance	$\pm 2\%$	$\pm 3\%$	$\pm 5\%$	$\pm 10\%$	$\pm 20\%$

(B) American JAN-C-5 should also be examined. See (xi) below for list.**(C) British R.I.C. Specification RIC/132**

Mica dielectric, stacked foil (Ref. F6).

Tolerance $\pm 20\%$. Power factor shall not exceed 0.001. Insulation resistance shall not be less than 10 000 megohms. Capacitance values conform to the series 10, 15, 22, 33, 47, 68 and 100. Range from 100 to 10 000 μF . Voltage ratings 350, 750 volts.**(D) British R.I.C. Specification RIC/137**

Mica dielectric, metallized (Ref. F10).

Tolerances $\pm 20\%$, $\pm 10\%$, $\pm 5\%$, $\pm 2\%$, subject to a minimum of $\pm 1 \mu\text{F}$. Power factor shall not exceed 0.001 except on values below 47 μF where the limit is 0.002. Insulation resistance shall not be less than 10 000 megohms. Capacitance values conform to the series, according to tolerance, given by the first three columns of Table 6. Range from 10 to 10 000 μF . Voltage ratings 350, 750 volts (d.c.) at 70°C.**(vi) Standard ceramic dielectric capacitors****(A) American R.M.A. Standard REC-107, Oct. 1947**Nominal capacitances (μF)

Tolerances in capacitance

TABLE 23

Classes 1, 2, 3	Classes 4, 5	All classes
$\pm 20\%$	$\pm 20\%$	(Capacit. 10 μF or less)
$\pm 10\%$		$\pm 2.0 \mu\text{F}$
$\pm 5\%$		$\pm 1.0 \mu\text{F}$
$\pm 2\frac{1}{2}\%$		$\pm 0.5 \mu\text{F}$
$\pm 2\%$		$\pm 0.25 \mu\text{F}$
$\pm 1\%$		$\pm 0.1 \mu\text{F}$

Working voltage (peak)

Classes 1, 2, 3 : 500 volts (down to 3.4 in. mercury)

Classes 4, 5 : 350 volts (down to 3.4 in. mercury)

Q and insulation resistance

Class	Q not less than	Insulation resistance not less than
1	1000*	7500 megohms
2	650*	7500
3	335*	7500
4	100	1000
5	40	1000

*For capacitances 30 μF and over. Lower values for lower capacitances.

Capacitance drift with temperature cycling

Classes 1, 2, 3 : not more than 0.3% or 0.25 μF whichever is the greater.

Capacitance-temperature characteristic

Classes 1, 2 and 3 :

Standard characteristics—Change of capacitance over the range -55°C to $+85^{\circ}\text{C}$ per unit of capacitance at 25°C per degree change in temperature : +100, +30, zero, -30, -80, -150, -220, -330, -470, -750 parts per million per $^{\circ}\text{C}$.

Classes 4 and 5 :

Maximum change in capacitance from its value at 25°C over temperature range from -55°C to $+85^{\circ}\text{C}$:

Class 4 $\pm 25\%$; Class 5 -50% , $+25\%$.

Tolerances on temperature coefficient

(when based on 2 point measurement, one at 25°C and one at 85°C) ± 15 , ± 30 , ± 60 , ± 120 , ± 250 , ± 500 parts per million per $^{\circ}\text{C}$.

An alternative method of measurement, with unsymmetrical tolerances, is also given in REC-107.

Humidity tests—see REC-107.

Marking

Inner electrode terminal indicated by dot or depression.

Typical marking : R2 CC 20 CH 100 G

R2 indicates RMA Class 2

CC indicates ceramic capacitor

20 indicates style (see REC-107)

CH indicates temperature characteristic and capacitance tolerance (see Table 1 below)

100 indicates capacitance (here $10 \times 10^0 = 10 \mu\text{F}$). For values incorporating decimal fractions, R indicates decimal point, e.g., 1R5 indicates 1.5 μF ,

R75 indicates 0.75 μF

G indicates tolerance (see Table 24 below)

TABLE 24

Letter symbol	Tolerance for capacitance of	
	10 μF or less	more than 10 μF
B	$\pm 0.1 \mu\text{F}$	
C	± 0.25	
D	± 0.50	
F	± 1.0	$\pm 1\%$
G	± 2.0	$\pm 2\%$
H		$\pm 2.5\%$
J		$\pm 5\%$
K		$\pm 10\%$
M		$\pm 20\%$

For alternative colour code see Sect. 2(v).

TABLE 25

First letter symbol	Capacitance-temperature coefficient or per cent decrease* in	Second letter symbol	Capacitance tolerance on temp. coeff. or per cent increase* in
A	+ 100 parts/mln/°C		
B	+ 30 parts/mln/°C	F	15 parts/mln/°C
C	Zero parts/mln/°C	G	30 parts/mln/°C

(B) American JAN-C-20A and JAN-C-81 should also be examined. See (xi) below for list.

(C) **British R.I.C. Specification RIC/133**

Ceramic dielectric, Grade 1. (Ref. F7).

Capacitance values conform to the series, according to tolerance, given by the first 3 columns of Table 6. Range from 1 to 1000 $\mu\mu\text{F}$. Tolerances $\pm 20\%$, $\pm 10\%$, $\pm 5\%$, $\pm 2\%$, subject to minimum of $\pm 1 \mu\mu\text{F}$. Voltage ratings 500 and 750 volts (d.c.).

Temperature coefficient (standard) +100, −30, −80, −470, −750 parts per million per °C, with tolerance ± 40 ppm or $\pm 15\%$, whichever is the greater. A special tolerance (available only on values of 47 $\mu\mu\text{F}$ and above) shall be ± 40 ppm or $7\frac{1}{2}\%$, whichever is the greater.

The power factor shall not exceed 0.0015. The insulation resistance shall not be less than 10 000 megohms.

Colour code (optional): see Sect. 2(v)B.

(vii) **Standard variable capacitors**

(A) **R.M.A. air dielectric, tuning**

The standard capacitance range (American R.M.A. REC-106-A Class A) without trimmers (compensators) is given by table 27.

TABLE 27

No. of plates	Difference in capacitance ($\mu\mu\text{F}$)	Min. capacitance ($\mu\mu\text{F}$)	
		R-F	Osc.
25	530.0	not greater than 15.0	—
23	485*	not greater than 15.0	—

**With smaller number of plates, the capacitance values given above should be determined in proportion to the number of dielectrics.

*180° from 100% rotation position (i.e. mechanically maximum position).

Trimmers (compensators) : Each adds a maximum of 2.0 μF to the minimum capacitance of the section. The minimum capacitance change of each compensator is 15 μF .

Rotor torque : Class A : From 2 to 6 inch-ounces. Class B : From 2 to 5 inch-ounces.

Slotted plates : The outside rotor plates shall be slotted radially.

(B) R.I.C. air dielectric, tuning

RIC/141 (Ref. F11). This specification was incomplete at the time of going to press.

(C) R.I.C. Capacitors, variable, preset, air dielectric

RIC/142 (Ref. F12). This specification was incomplete at the time of going to press.

(D) R.I.C. Capacitors, variable, preset, mica dielectric

RIC/143 (Ref. F13). Single plate : variable between 2 to 15, 3 to 30, or 4 to 40 μF . Multiple plate types with max. capacitance up to 3000 μF are included. The specification was incomplete at the time of going to press.

(viii) Standard variable composition resistors ("potentiometers")

(A) American RTMA Standard variable control resistors REC-121-A, July 1952.

Resistance values 5 000, 10 000, 25 000, 100 000, 250 000, 500 000 ohms, 1.0, 2.0 megohms (total)

Tapers

Linear :

Midpoint resistance = half total resistance. Minimum resistance between either terminal and shaft = 0.05% of total resistance for total resistances 100 000 ohms and greater (higher percentages for lower total resistances).

"S" taper :

25% resistance with 25% \pm 3% rotation

50% resistance with 50% \pm 3% rotation

75% resistance with 75% \pm 3% rotation

Minimum resistance as for linear type.

10% clockwise modified logarithmic taper

10% resistance with 50% \pm 3% rotation. Min. resistances 0.02% and 1% of total resistance for 100 000 ohms and greater.

20% clockwise modified logarithmic taper

20% resistance with 50% \pm 3% rotation.

Minimum resistances as for 10% logarithmic taper.

10% counterclockwise modified logarithmic taper

20% counterclockwise modified logarithmic taper

(both as for clockwise type with ends reversed).

(B) American JAN-R-94 should also be examined. See (xi) below for list.

(C) British Radio Industry Council Specification No. RIC/122 for rotary variable resistors (Ref. F1).

Resistance in multiples of 1, 2, 5. Tolerances \pm 20%.

Dissipation range : 0.1 to 1.5 watts.

Resistance range : 1000 ohms to 2 megohms.

Logarithmic taper : (1) resistance between 5% and 15% of actual overall resistance at 45% to 55% effective rotation (2) resistance between 2% and 5% of actual overall resistance at 20% to 30% effective rotation

Linear law : resistance between 35% and 65% of actual overall resistance at 45% to 55% effective rotation.

Hop-on resistance : less than 50 ohms or 0.05% of overall resistance, whichever is the greater.

Hop-off resistance : less than 1% of overall resistance.

Noise : not greater than 50 mV when tested under specified conditions with 20 volts d.c. applied.

(ix) Standard metallized paper dielectric capacitors

RIC/136 (Ref. F9).

Capacitance values conform to series 1, 2, 5, 10 etc. Range of values from 0.0001 to 2 μF . Tolerance $\pm 25\%$. Voltage ratings 150, 250, 350, 500 volts (d.c.), 300 volts r.m.s. (20 to 120 c/s). The power factor shall not exceed 0.015 at 1000 c/s. The insulation resistance shall not be less than (a) for 2-foil types: 200 ohm-farads or 1200 megohms, whichever is the less, (b) for single-foil—castellated—types (below 0.05 μF): 10 000 megohms, (c) to case: 10 000 megohms, Colour code—see Sect. 2(xii).

(x) Standard electrolytic capacitors**(A) JAN-C-62 specification: Capacitors, dry-electrolytic, polarized****Working temperature**

Designation	A	B	C	D	E	F
Temp. ($^{\circ}\text{C}$)	0 to 85	-20 to +85	-40 to +85	0 to 65	-20 to 65	-40 to 65

Voltage limits

TABLE 30

Designation	Working voltage (d.c.)	Surge voltage (d.c.)
E	15	20
F	25	40
G	50	75
H	100	150
J	150	200
K	200	250
M	250	300
N	300	350
P	350	400
Q	400	450
R*	450	500

*Available only with working temperature designations D, E and F.

Direct current leakage (under specified test conditions at rated working voltage) shall not exceed either 10 mA or the value calculated below, whichever is the smaller.

$$I = KC + 0.3$$

where I = d.c. leakage current in milliamperes C = rated capacitance in microfaradsand K = 0.01 for rated working voltage 15 to 100,

0.02 for rated working voltage 101 to 250,

0.025 for rated working voltage 251 to 350,

0.04 for rated working voltage 351 to 450.

Tolerance in capacitance -10% ; $+250\%$.

Equivalent series resistance (under specified test conditions at maximum rated voltage) shall not exceed the value of P tabulated below, divided by the rated capacitance in microfarads.

Rated working voltage	P	Rated working voltage	P
15	600	250	230
25	500	300	210
50	400	350	200
100	330	400	200
150	300		
200	250	450	200

Test conditions: 20°C to 40°C . Frequency 120 c/s.

Maximum r.m.s. ripple current (extracts from table)

Rated cap.	Working voltage					
	100	150	200	250	350	450 V
10 μF	—	—	130	130	140	150 mA
20 μF	130	170	170	170	180	180 mA
30 μF	160	180	180	200	200	200 mA
40 μF	170	190	190	190	200	200 mA
50 μF	190	200	200	200	200	200 mA

(B) British R.I.C. Specification RIC/134 (Ref. F8)

Range of capacitance 1 to 1000 μF .

Voltage ratings : At 60°C—12, 25, 50, 150, 275, 350, 450, 500.

At 70°C—12, 25, 50, 120, 220, 280, 360, 400.

Tolerances : +50%, -20% for working voltages above 100 V (except etched foil types up to and including 16 μF) ; +100 -20% for working voltages of 100 V and less, and all etched foil types up to and including 16 μF . Ripple rating at 70°C is 0.75 of the ripple rating at 60°C. Power factor at 50 c/s shall not exceed 0.2 for working voltages up to and including 100 V ; 0.15 for working voltages above 100 V. The leakage current of single winding capacitors shall not exceed $0.5 V\sqrt{C}\mu\text{A}$ or 100 μA , whichever is the greater, where V is the rated voltage and C the actual capacitance in μF .

*It is hoped that these Radio Industry Council Specifications will, in due course, be incorporated into British Standard Specifications.

SECTION 4 : STANDARD FREQUENCIES

(i) *Standard frequency ranges* (ii) *Frequency bands for broadcasting* (iii) *Standard intermediate frequencies.*

(i) Standard frequency ranges

The Final Acts of the International Telecommunication and Radio Conferences at Atlantic City, 1947, proposed the following nomenclature of frequencies.

Frequencies shall be expressed in kilocycles per second (Kc/s) at and below 30 000 Kc/s and in megacycles per second (Mc/s) above this frequency.

TABLE 32

Frequency sub-division	Frequency range	Metric sub-division
v-l-f (very low frequency)	below 30 Kc/s	myriametric waves
l-f (low frequency)	30 to 300 Kc/s	kilometric waves
m-f (medium frequency)	300 to 3 000 Kc/s	hectometric waves
h-f (high frequency)	3 000 to 30 000 Kc/s	decametric waves
v-h-f (very high frequency)	30 000 Kc/s to 300 Mc/s	metric waves
u-h-f (ultra high frequency)	300 to 3 000 Mc/s	decimetric waves
s-h-f (super high frequency)	3 000 to 30 000 Mc/s	centimetric waves
e-h-f (extremely high frequency)	30 000 to 300 000 Mc/s	millimetric waves

(ii) Frequency bands for broadcasting

The International Telecommunication and Radio Conference at Atlantic City, 1947, allocated the following frequency bands for broadcasting purposes.

TABLE 33

Band shared with maritime mobile	150—160 Kc/s
Low frequency (not world-wide)	160—285 Kc/s
Medium frequency (Region 1 only)	525—535 Kc/s
Medium frequency (world wide)	535—1605 Kc/s
Short wave frequencies (world wide)	5.95—6.2 Mc/s
	9.5—9.775 Mc/s
	11.7—11.975 Mc/s
	15.1—15.45 Mc/s
	17.7—17.9 Mc/s
	21.45—21.75 Mc/s
	25.6—26.1 Mc/s
Very high frequency (world wide)	88—100 Mc/s
(U.S.A.)	88—108 Mc/s

In Australia, the band 100-108 Mc/s has been allocated for the aeronautical mobile service until required for broadcasting service.

(iii) Standard Intermediate Frequencies

It is recommended that superheterodyne receivers operating in the medium frequency broadcast band use an intermediate frequency of 455 Kc/s. This frequency is reserved as a clear channel for the purpose in most countries of the world.

The European "Copenhagen Frequency Allocations" provide the following two intermediate frequency bands : 415—490 Kc/s and 510—525 Kc/s.

An intermediate frequency of 175 Kc/s is also used.

The American RTMA has standardized the following intermediate frequencies (REC-109-B, March 1950) : Standard broadcast receivers—either 260 or 455 Kc/s. V-H-F broadcast receivers—10.7 Mc/s.

SECTION 5 : WAVELENGTHS AND FREQUENCIES

				60	5.00	108	2.78

(ii) Wavelengths of electromagnetic radiations

TABLE 36

Rays	Wavelengths		
	Angstrom units	Microns	Metres
Cosmic rays	10^{-6} — 10^{-2}	10^{-10} — 10^{-6}	
Gamma rays	10^{-2} —1	10^{-6} — 10^{-4}	
X-Rays	10^{-1} — 10^2	10^{-5} — 10^{-2}	
Ultraviolet rays	100—3900	10^{-2} —0.39	
Visible light rays	3900—7600	0.39—0.76	
Infrared rays	7600— 10^6	0.76— 10^2	
Electric or radio rays		10^2 — 10^{10}	10^{-4} — 10^4
Radio broadcasting rays		10^7 — 10^9	10 — 10^3

SECTION 6: STANDARD SYMBOLS AND ABBREVIATIONS

(i) *Introduction* (ii) *Multipliers* (iii) *Some units and multipliers* (iv) *Magnitude letter symbols* (v) *Subscripts for magnitude letter symbols* (vi) *Magnitude letter symbols with subscripts* (vii) *Mathematical signs* (viii) *Abbreviations* (ix) *Abbreviations of titles of periodicals* (x) *References to periodicals* (xi) *References to standard symbols and abbreviations.*

(i) Introduction

Owing to the lack of international standardization, the editor has been forced to select suitable symbols for use in this Handbook. The choice which has been made is believed to be a reasonable compromise, and capable of being understood readily throughout the English-speaking world.

(ii) Multipliers

In general, small letters are used for quantities below unity, and capital letters for quantities above unity.

d = deci	= 1/10	= 10^{-1}
c = centi	= 1/100	= 10^{-2}
m = milli	= 1/1000	= 10^{-3}
μ = micro	= 1/1000 000	= 10^{-6}
$\mu\mu$ = micromicro	= 1/1000 000 000 000	= 10^{-12}
K or k = kilo	= 1000	= 10^3
M = meg	= 1000 000	= 10^6

(iii) Some units and multipliers

A = ampere	mA = milliampere	μ A = microampere
F = farad	μ F = microfarad	$\mu\mu$ F* = micromicrofarad
H = henry	mH = millihenry	μ H = microhenry
Ω = ohm	M Ω = megohm	
V = volt	mV = millivolt	KV or kV = kilovolt
W = watt	mW = milliwatt	
m = metre	cm = centimetre	mm = millimetre

*Alternatively, pF = picofarad = $\mu\mu$ F = micromicrofarad.

(iv) Magnitude letter symbols†

B	= susceptance
C	= capacitance
C_r, g	= conductance
D	= total harmonic distortion
E, e	= electromotive force
F_p	= power factor
f	= frequency
g, C_r	= conductance
H_1	= fundamental frequency component of distortion
H_2, H_3 , etc.	= second (third etc.) harmonic components of distortion
I, i	= current
K	= dielectric constant
L	= inductance
M	= mutual inductance
P	= power
Q	= charge, quantity of electricity
also Q	= figure of merit of a reactor
R	= resistance
X	= reactance
X_L	= inductive reactance
X_c	= capacitive reactance
Y	= admittance
Z	= impedance (scalar)
Z	= impedance (vector)
	Δ = increment of
	ϵ = 2.7182818
	η = efficiency
	λ = wavelength
	π = 3.14159
	ω = $2\pi f$ = angular velocity.

Magnetic units

B	= magnetic flux density
H	= magnetic field strength, magnetizing force
ϕ	= magnetic flux
μ	= magnetic permeability

Operators

d	= differential ;	δ	= partial differential
j	= 90° rotational	=	$\sqrt{-1}$.

(v) Subscripts for magnitude letter symbols

in	= input
out	= output
max	= maximum (reduced to m when combined with another subscript)
min	= minimum
av	= average
b	= plate—steady or total value
bb	= plate supply
c	= grid—steady or total value
c_1	= grid no. 1 ; similarly c_2, c_3 etc.
cc	= grid supply
co	= at point of plate current cutoff
f	= filament
g	= grid—varying component

†A magnitude letter symbol is used to designate the magnitude of a physical quantity in mathematical equations and expressions. Two or more magnitude symbols printed together represent a product.

g_1	= grid no. 1 ; similarly g_2, g_3 etc.
h	= heater
k	= cathode
o	= quiescent (no signal)
p	= plate (anode)—varying component
s	= screen or metal shell or other self-shielding envelope
t	= triode

N.B. Grids are numbered in order, beginning at the cathode and working outwards towards the plate.

(vi) Magnitude letter symbols with subscripts

Symbols for filament or heater circuits

E_f	= filament or heater (terminal) voltage
E_{hk}	= voltage of heater with regard to cathode
I_f	= filament or heater current.

Symbols for plate circuits

All voltages are taken as being with respect to the cathode unless otherwise indicated.

E_{bb}	= plate supply voltage
E_b	= average or quiescent value of plate voltage
E_{bo}	= quiescent (no signal) value of plate voltage
E_{bm}	= maximum value of plate voltage
E_p	= r.m.s. value of varying component of plate voltage
E_{pm}	= maximum value of varying component of plate voltage
e_b	= instantaneous total plate voltage
e_p	= instantaneous value of varying component of plate voltage
I_b	= average or quiescent value of plate current
I_{bm}	= peak total plate current
I_{bo}	= quiescent (no signal) value of plate current
I_p	= r.m.s. value of varying component of plate current
I_{pm}	= maximum value of varying component of plate current
I_s	= total electron emission
i_b	= instantaneous total plate current
i_p	= instantaneous value of varying component of plate current.

Symbols for grid circuits

E_c	= average or quiescent value of grid voltage
E_{cm}	= maximum value of grid voltage
E_g	= r.m.s. value of varying component of grid voltage
E_{gm}	= maximum value of varying component of grid voltage
e_c	= instantaneous total grid voltage
e_g	= instantaneous value of varying component of grid voltage
I_c	= average or quiescent value of grid current
I_g	= r.m.s. value of varying component of grid current
i_c	= instantaneous total grid current
i_g	= instantaneous value of varying component of grid current.

Symbols for valve characteristics

(A) Inside the valve

E_{pg}	= voltage of plate with regard to grid
μ	= amplification factor
μ_t	= amplification factor (triode connected)
μ_{g1g2}	= mu factor from grid no. 1 to grid no. 2, and similarly for other electrodes
g_m	= mutual conductance (= g_{sp}) or "slope"
g_c	= conversion conductance
g_d	= dynamic conductance (slope of dynamic characteristic)
g_p	= plate conductance
g_o	= grid conductance
g_n	= plate-grid transconductance (inverse mutual conductance) = g_{pn}
g_{jk}	= transconductance from electrode j to electrode k

r_p	= plate resistance
r_g	= grid resistance
r_{g2}	= screen (grid no. 2) resistance
C_{gp}	= grid-plate capacitance
C_{gk}	= grid-plate cathode capacitance
C_{pk}	= plate-cathode capacitance
C_{gh}	= grid-heater capacitance
C_{ph}	= plate-heater capacitance
C_{in}	= input capacitance
C_{out}	= output capacitance.

(B) Valve and circuit

R_L	= plate load resistor
Z_L	= plate load impedance
R_k	= cathode resistor
C_k	= cathode by-pass capacitor
C_c	= coupling condenser
R_{g1}	= grid resistor
R_{g2}	= following grid resistor
r_i	= input resistance
r_o	= output resistance
R_s	= screen series resistor
C_s	= screen by-pass capacitor
P_i	= power input
P_o	= power output
P_p	= plate (anode) dissipation
P_{g2}	= screen (grid no. 2) dissipation
A	= amplification (voltage gain of stage)
A_o	= amplification (voltage gain of stage) at mid-frequency
I_{hm1}	= peak fundamental current
I_{hm2}	= peak second harmonic current.

(vii) Mathematical signs

+	plus	\therefore	therefore
-	minus	\propto	varies as
\pm	plus or minus	$\sqrt{\quad}$	square root
\times or \cdot	multiplied by	$\sqrt[n]{\quad}$	nth root
\div or $/$	divided by	$!$	factorial
=	equal to	F	function
\neq	not equal to	\int	integration
\approx	approximately equal to	∞	infinity
$>$	equal to or greater than	$^\circ$	degree
\leq	equal to or less than	$'$	minutes of degree
\equiv	identical with	$''$	seconds of degree
$>$	greater than	δ or Δ	increment
$<$	less than	Σ	summation

$\log x$	logarithm of x to base 10
$\log_e x$	logarithm of x to base e
j	square root of minus one (90° angular rotation)
e	base of natural logarithms (2.71828)
π	ratio of circumference to diameter of circle (3.141593 approx.)

For trigonometrical symbols and differentiation refer to Chapter 6.

(viii) Abbreviations

a.c.	= alternating current
d.c.	= direct current
a-f	= audio frequency

i-f	= intermediate frequency
r-f	= radio frequency
v-h-f	= very-high-frequency
u-h-f	= ultra-high-frequency
	(For other frequency designations see Sect. 4.)
AWG	= American Wire Gauge
B & S	= same as AWG
SWG	= Standard Wire Gauge
E	= enamelled
r.m.s	= root mean square
db	= decibel
dbm	= decibels of power referred to 1 milliwatt
c/s	= cycles per second
Kc/s	= kilocycles per second (kc/s may also be used)
Mc/s	= megacycles per second
Hz	= Hertz = cycles per second
a.v.c.	= automatic volume control
a.a.v.c.	= audio automatic volume control
A-M	= amplitude modulation
F-M	= frequency modulation
SSC	= single silk covered
DSC	= double silk covered
SCC	= single cotton covered
DCC	= double cotton covered.

Note : Abbreviations are used to indicate either singular or plural, either as a noun or as an adjective.

(ix) Abbreviations of titles of periodicals

Standard Abbreviations	Title and Publisher
A.R.T.S. & P.	Australian Radio Technical Services and Patents Bulletin (47 York St., Sydney, Australia).

(x) References to periodicals

The references to periodicals in this Handbook follow substantially the form recommended in British Standard 1219 : 1945.

Example : Lamson, H.W. "Permeability of dust cores" W.E. 24.288 (Sept. 1947) 267.

Lamson, H. W. indicates the author.

"Permeability of dust cores" indicates the title.

W.E. indicates the periodical (see abbreviations above).

24 indicates the volume number.

288 indicates the number.

Sept. 1947 indicates the date.

267 indicates the first page of the article.

(iii) Composition of some common plastics

TABLE 39

Trade Name	Composition
Bakelite	Phenol formaldehyde
Bakelite	Urea formaldehyde
Bakelite	Cellulose acetate
Bakelite	Polystyrene
Beetle	Urea formaldehyde
Cellophane	Regenerated cellulose film
Celluloid	Cellulose nitrate
Distrene	Polystyrene
Duperite	Phenol formaldehyde
Erinoid	Casein
Formica	Phenol formaldehyde (lamination)
Glyptal	Glycerol-phthalic anhydride
Lucite	Methyl methacrylate polymer
Micarta	Phenol formaldehyde (lamination)
Mycalex	Mica bonded glass
Neoprene	Chloroprene synthetic rubber
Nylex	Polyvinyl chloride
Nylon	Synthetic polyamides and super polyamides
Paxolin	Phenol formaldehyde
Perspex	Methyl methacrylate polymer
Plexiglass	Methyl methacrylate polymer
Polythene	Polyethylene
PVC	Polyvinyl chloride
Scarab	Urea formaldehyde
Synthane	Phenol formaldehyde
Trolitul	Polystyrene
Vinylite A	Polyvinyl acetate
Vinylite Q	Polyvinyl chloride
Vinylite V	Vinyl chloride-acetate copolymer
Vinylite X	Polyvinyl butyral
Xylonite	Nitrocellulose

(iv) Weights of common materials

The weights of the following materials are given in pounds per cubic inch.

TABLE 40

Aluminium	0.098	Polystyrene	0.038
Armco iron	0.284	Radio metal	0.299
Brass	0.304	Rho metal	0.292
Constantan	0.321	Steel	
Copper	0.310	Cast	0.278
German silver	0.323	2% silicon	0.278
Iron (cast)	0.281	4% silicon	0.271
Mumetal	0.318	Synthetic wax	
Perm-Alloy B	0.299	Seekay	0.056
Perm-Alloy C	0.310	Halowax	0.056
Perspex	0.043	2129 Alloy	0.292
Polyamide (Nylon)	0.041		

See Sect. 10(viii) for weight of metal sheets.

(v) Resistance of a conductor at any temperature

To find the resistance of a conductor at any temperature :

$$R_t = R_{20}[1 + (t - 20)\alpha]$$

where R_t = resistance at temperature $t^\circ\text{C}$

R_{20} = resistance at 20°C

t = temperature of conductor $^\circ\text{C}$

and α = temperature coefficient of resistivity at 20°C .

Most conductors increase in resistance when their temperature is increased.

(vi) Reference to properties of materials

1. English readers are referred to the Radio Industry Council Specification No. RIC/1000/A "Choice of materials for radio and other electronic equipment and for components therein" Issue No. 1—July 1949.

2. British Standard 1598 : 1949 "Ceramic materials for telecommunication and allied purposes." Gives summary of electrical, mechanical, thermal and general properties of insulators.

3. British Standard 1540 : 1949 "Moulded electrical insulating materials for use at radio frequencies".

4. D. W. Thomasson "Silicones and other silicon compounds" Electronic Eng. 22.272 (Oct. 1950) 422.

5. Federal Telephone and Radio Corporation "Reference Data for Radio Engineers" 3rd ed. 31-39, 47-53.

6. "Standard Handbook for Electrical Engineers," McGraw-Hill Book Co. Inc. 8th ed. 1949, Sect. 4.

Extensive treatment ; also gives bibliography of insulating materials Sect. 4-619.

(vii) Chemical and physical constants

Some Chemical and Physical Constants as at 1 Dec. 1950, extracted from Table VII, "A re-evaluation of the fundamental atomic constants" Physical Review 81.1 (Jan. 1, 1951) 73.

Electron mass $m = (9.10710 \pm 0.00022) \times 10^{-28}g$

Electronic charge $e = (4.80217 \pm 0.00006) \times 10^{-10}\text{esu}$
 $= (1.601844 \pm 0.000021) \times 10^{-20}\text{emu}$

Boltzmann's constant $k = (1.38020 \pm 0.00007) \times 10^{-16}\text{erg deg}^{-1}$

Ratio proton mass to electron mass

$$M/m = (1836.093 \pm 0.044)$$

Velocity of light $c = (299790.0 \pm 0.7) \text{ km/sec}$

The velocity of light in a vacuum, following the recommendation of the International Scientific Radio Union (U.R.S.I.), is to be taken as $299792 \pm 2 \text{ km/sec}$ (see W.W. March 1953 page 121).

(iii) Impedance of reactance and resistance in parallel

Table 43 has been prepared to permit the finding of any one of the three quantities X , R or Z when the other two are given. When X and R are given, divide the larger of the two quantities into the smaller one and thus get a ratio less than 1. Find this ratio in the left column and multiply the number obtained in the second column by R or X whichever is the larger and find Z .

Suppose R equals 1000 ohms and X is 200 ohms, which makes $X/R = .20$. Table 43 shows us that Z/R is then 0.1961. Multiplying by R , we have $Z = 0.1961 \times 1000 = 196.1$ ohms.

By means of Chart 38.1 it is possible to determine either the parallel impedance (Z), reactance (X) or resistance (R) knowing the other two values. Expressing the

38.9 (iii) IMPEDANCE OF REACTANCE, RESISTANCE IN PARALLEL 1381

capacitance (C) in microfarads, the inductance (L) in henrys and the frequency (F) in cycles use the bottom scale and read directly on to the chart.

REACTANCE AND RESISTANCE IN PARALLEL

CHART 38.1

(iv) Impedance of reactance and resistance in series

To use Table 44, find the ratio R/X or X/R , refer to the table and find the corresponding ratio Z/X or Z/R . The table can also be used when Z is given together with one of the other quantities. It was for this reason that the table had to be extended for values of R/X or X/R from 0.1 to 1.0 since otherwise it would have been sufficient to include values from 1 upwards or downwards but not both. Example: suppose $X = 1600$ ohms and $R = 1000$ ohms. Then $X/R = 1.6$; the table shows $Z/R = 1.8868$. Then Z equals $1\ 8868\ R$ or 1886.8 ohms.

From Chart 38.2 (page 1384) it is possible to determine either the series impedance (Z), reactance (X) or resistance (R) knowing the other two values. Expressing the capacitance (C) in microfarads, the inductance (L) in henrys and the frequency (f) in c/s, use the top scale and read directly on to the chart.

Tables 43, 44 and charts 38.1, 38.2 are reprinted from the Aerovox Research Worker 11, Nos. 1 and 2 (Jan. and Feb. 1939) by courtesy of the Aerovox Corporation.

CHART 38.2

REACTANCE AND RESISTANCE IN SERIES

Resistance and reactance in series—Alternative method

Chart 38.3 assists in the evaluation of the impedance Z and its phase angle θ when the values of resistance R and reactance X are known. Firstly read R along the horizontal scale, then read upwards to the value of jX ; the magnitude of Z is given by the radius which may be read by running the eye down the arc to the horizontal axis. The angle of Z is given directly by the angle at the point of intersection. For example, $R = 15$ ohms in series with $jX = 5.6$ ohms gives $R + jX = 16$ ohms, $\angle 20^\circ$ (approx.). When any value of R or X is greater than the limits on the chart, both scales should be multiplied by the same factor. For example, $R = 150$ ohms in series with $jX = 56$ ohms gives $R + jX = 160$ ohms, $\angle 20^\circ$. Negative reactances may be treated as positive when using the chart, but the angle of Z will then be negative.

CHART 38.3

(v) Resonance**(A) Resonance frequency table (audio frequencies)**

TABLE 45 : RESONANCE FREQUENCY C/S

$C(\mu F)$	50	100	200	400	1000	2000	5000	10 000
1	10.1	2.53	633	158	25.3	6.33	1.01	0.253

0.01	1010	253	63.3	15.8	2.53	633	101	25.3
0.005	2030	507	127	31.7	5.07	1.27	203	50.7
0.002	5070	1270	317	79.1	12.7	3.17	507	127
0.001	10 100	2530	633	158	25.3	6.33	1.01	253

Inductance values above the stepped line are in millihenrys and those below in henrys.

(B) R-F solenoid design chart

Chart 38.4 enables the radio engineer to determine the approximate number of turns on a solenoid of specified diameter and length, to resonate at a specified frequency with a specified capacitance. (Chart by P. G. Sulzer in Tele-Tech, May 1951, p. 45 and reproduced by kind permission).

The following example will indicate the method :

It is desired to design a coil for a harmonic generator which is to operate at a frequency of 10 Mc/s with a total capacitance of $50 \mu F$. Drawing a straight line between 10 Mc/s on the f scale and $50 \mu F$ on the C scale, the inductance L is found to be approximately $5 \mu H$. This value need not be recorded unless it is required for some other purpose. Assuming that the winding is to be one inch in diameter by two inches long, the intersection of the appropriate lines is found in the graph at the right-hand side of the chart. This intersection is projected horizontally to the left as shown, and then a straight line is drawn to the $5 \mu H$ point on the L scale. The result is found to be 22 turns, as indicated on the n scale.

(vi) Approximations in the calculation of impedance for reactance and resistance in series and parallel

When a resistance and a reactance are in series, and the reactance is numerically smaller than the resistance, the value of the resistance may be taken as being an approximation to the impedance, with the errors indicated below :

$R/X =$	1	2	3	4	5	7	10
error =	29%	11%	5%	3%	2%	1%	0.5%

When a resistance and a reactance are in parallel, and the reactance is numerically larger than the resistance, the value of the resistance may be taken as being an approximation to the impedance, with the errors indicated below :

$X/R =$	1	2	3	4	5	7	10
error =	41%	12%	5.5%	3%	2%	1%	0.5%

(vii) Reactance chart

A very complete form of reactance chart, including reactance, frequency, inductance, capacitance, susceptance, wavelength and time constant, is given by H. A. Wheeler "Reactance Chart" Proc. I.R.E. 38.12 (Dec. 1950) 1392.

CHART 38.4: R-F SOLENOID DESIGN CHART—see page 1386.

*Based on 41.820 lb. per sq. foot per inch thick ; variations in thickness are to be expected.

Other gauges are based directly on thickness ; variations in weight per square inch are to be expected.

American Standard Preferred Thicknesses for uncoated thin flat metals (ASA. B32.1—1941).

This series of thickness is given in inches.

SECTION 11 : TEMPERATURE RISE AND RATINGS

FIG. 38.7

Fig. 38.7. Curves of temperature rise of power wire-wound resistors in free air. The temperature is considerably affected by the radiating properties of the coating. Type A coating refers to a vitreous enamel which is used for "tropic proofed" application and type B coating refers to an organic cement coating.

SECTION 13 : CHARACTERISTICS OF LIGHT ; PANEL LAMPS

(i) *Visibility curves of human eye, and relative spectral energy curves of sunlight and tungsten lamp* (ii) *Velocity of light* (iii) *American panel lamp characteristics.*

(i) Visibility curves of human eye, and relative spectral energy curves of sunlight and tungsten lamp (Fig. 38.8)

The wavelength of light is measured in Angstrom[†]Units (A°). One Angstrom Unit is equal to 1/10 000 of a micron, that is 1/10 of a milli-micron. A micron is 1/1 000 000 (10⁻⁶) of a metre.

The wavelengths visible to the human eye extend from about 4000 to 7000 A°. Beyond these extends the region of "invisible light" which, although invisible to the human eye, may be detected by the photo-tube or other means.

The eye, when accustomed to high light intensity, is most sensitive to a wavelength of 5550 A°, in the green-yellow region. The relative visibility curve for these conditions is Curve A, which is taken after H. E. Ives*. As the light intensity is reduced, the wavelength at which the eye is most sensitive decreases until at very low intensity it is approximately as shown in Curve B.

Different light sources have different spectral energy curves. The curve for sunlight (Curve C is for sunlight at the earth's surface at a zenith distance of 25°) is more nearly constant over the range of visible light than that for a tungsten lamp (Curve D is for a 1000 watt gasfilled tungsten lamp, 20 lumens per watt). The relative positions of curves C and D are quite arbitrary.

Fig. 38.8. Relative visibility curves, etc. (for description see text).

(ii) Velocity of light

Velocity of light in a vacuum = 2.9979×10^8 metres/sec.
 $\approx 3 \times 10^8$ metres/sec.

See Editorial, W.E. 28.331 (April 1951) 99.

Also Electronic Eng. (Dec. 1950) 524.

Photometric units—see page 1334.

See also page 1376 (vii) Chemical and Physical Constants.

*See R. A. Houston, "Vision and Colour Vision," Longmans Green and Co. (1932) Chapter 5.

†The name Angstrom is Swedish, pronounced "ongstrem."

(iii) American panel lamp characteristics

(RTMA Standard REC-137, October 1951).

SECTION 15 : DEFINITIONS

Most words which need explanation are explained or defined in the text and a reference is given in the index. The definitions below are supplementary and not inclusive.

See also other references at end of definitions (pp. 1403-1404).

A

A-battery Battery for supplying power to the valve filaments. (English name L.T. battery).

Absolute value Refers to magnitude without regard to direction or sign. Designated $|A|$.

A.C./D.C. receiver One which operates from either power source.

Acoustical feedback The operation of a microphone by the return to it of sound waves from the loudspeaker in the same sound system, reinforcing the input. It can cause sustained oscillation, or howling. A similar effect can occur from a microphonic valve.

Air-core Having no iron in its magnetic circuit.

Algebraic sum The sum of two or more quantities paying due regard to the positive or negative sign before each quantity.

Alternating current (or voltage) One that alternates regularly in direction, which is periodic and has an average value (over a period) of zero.

Ambient temperature The temperature of the air at a particular point, usually as indicated by a thermometer.

Amplification Increase in signal voltage (or power).

Angular velocity of a rotating body is the angle through which any radius turns in one second, generally expressed in radians per second.

Anode Positive electrode or plate.

Antinode A point on a stationary wave system which has a maximum amplitude.

Asymmetrical Having different characteristics for conduction in the two directions.

Attenuation Decrease in signal voltage or power.

Audio frequency A frequency within the range of frequencies audible to the normal human ear (say 25-16 000 c/s).

Axial leads Leads from the ends of resistors, capacitors, etc.

B

B-battery The battery which supplies power to the plate and screen circuits. (English name is H.T. battery).

B-supply A plate and screen voltage source for a receiver and amplifier.

Band Frequencies between a specific upper and lower limit.

Band-pass Passing a specific band of frequencies only.

Bandspread A means for spreading the coverage, on the dial, of a band of frequencies.

Bass Low audio frequencies.

Bass boost To boost the amplification at bass frequencies relatively to that at higher frequencies.

Beating A periodic variation in the amplitude of an oscillation (or sound) which is the resultant of two or more oscillations (or sounds) of different frequencies.

Bias Voltage applied to the grid to obtain the desired operating point.

Bleeder resistor Resistor connected across a voltage source to provide an additional load. The term is sometimes applied to a voltage divider carrying a relatively heavy current to provide good regulation.

Blocking Cutting off the plate current by a high negative bias on the grid. For Grid Blocking see page 21.

Bogie Each individual characteristic in the manufacturing specification is normally prescribed as a bogie value with plus and minus tolerances. The bogie value of a characteristic is the exact value specified for that characteristic by the valve manufacturing specifications.

Bucking Two forces opposing one another.

By-pass condenser One which allows alternating current to by-pass part of a circuit.

C

C-battery Battery which supplies voltage to the grid. Also known as bias battery.

Capacitor Condenser.

Carrier frequency The frequency of a component of a modulated wave which is the same as that of the wave before modulation is applied.

Carrier wave The unmodulated wave radiated by a broadcast station.

Cascade In an amplifier, when the output of one valve is used to control the grid circuit of another valve, the valves are said to be in cascade.

Cathode Negative electrode.

Cathode current The total electronic current passing through the cathode.

Channel The assigned band of frequencies within which a broadcast station is expected to keep its modulated carrier.

Choke coil Inductance.

Co-axial Having a common axis.

Compliance The ratio of the displacement of a body to the force applied. The inverse of stiffness.

Condenser Capacitor. See Chapter 4.

Consonance The agreeable effect produced by certain intervals (in music).

Constant A quantity which retains its fixed value under all conditions.

Converter The stage in a receiver which converts the frequency from radio frequency to intermediate frequency.

Co-planar In the same plane.

Core The centre of a coil.

Cross modulation The modulation of the carrier of the desired signal by an undesired signal.

Cut-off frequency The frequency beyond which the attenuation increases rapidly.

Cycle A cycle is one complete series of values of a periodic quantity. These values repeat themselves at regular intervals.

D

Delay Time delay is when an interval of time occurs between cause and effect. Voltage delay, as in an a.v.c. system, is when a specified voltage has to be developed before there is any effect.

Demodulation A process by which the carrier frequency is removed, and the modulating frequencies retained.

Denominator The part of a fraction below the fraction bar.

Detection Demodulation by means of an asymmetrical conducting device.

Dissipation Loss of electrical energy.

Dissonance The disagreeable effect produced by certain intervals (in music).

Dividend Number to be divided by divisor.

Divisor Number by which the dividend is to be divided.

Drain To take current from a voltage source.

Driver A power amplifier stage which drives a Class B or other following stage requiring input power.

Dynamic (1) Having a moving coil in a magnetic field.

(2) When applied to a valve with signal voltage on the grid, usually with plate load in circuit.

(3) "Dynamic characteristic" is the mutual characteristic when a (usually resistive) load is in the plate circuit.

E

Effective current The value of alternating or varying current which produces the same heating effect as the same value of direct current. It is the same as r.m.s. current.

Efficiency The ratio or percentage of output to input.

Electromotive force That force which tends to cause an electric current to flow in a circuit. The practical unit is the volt.

Empirical Obtained from experimental data.

Envelope The envelope of a periodic wave is obtained by passing one smooth curve through the maximum, another through the minimum, points or peaks of the wave.

Equation A mathematical equation is a statement that the terms to the left of the equal sign are equal to those on the right.

Equivalent circuit A relatively simple circuit which may be used in calculations as having the same effect as the actual circuit.

Excitation A signal voltage applied to the control electrode of a valve.

Exponential curve The same as a logarithmic curve. See Chapter 6 Sect. 2(xvii) for exponential functions.

Expression A mathematical expression is a combination of terms giving the value of some quantity.

F

Factor Any of the numbers whose product equals the given number.

Factorial n Is the multiple product $n(n-1)(n-2) \dots 3 \times 2 \times 1$.

First detector The same as Converter.

Frequency The number of cycles per second; the reciprocal of the period.

Frequency changer The same as Converter.

Function A function is a quantity whose value depends on the value of a variable quantity.

Fundamental frequency The lowest frequency of a number of harmonically related frequencies.

G

Generator A device which develops electrical voltage either direct or alternating at any frequency.

Gramophone Also known as a Phonograph.

Ground Earth, or conductor serving as the earth.

H

Hard valve A valve which has reverse grid current less than the specified maximum for its type.

Harmonic frequency A frequency which is a multiple of the fundamental frequency. Twice fundamental frequency is called the second harmonic, etc.

Hertz Cycles per second.

High level A relative term indicating the level of the final stages of an amplifier.

High-pass filter A filter which passes all frequencies above a critical value.

Honeycomb winding A coil winding in which spaces are left between turns so as to give the appearance of a honeycomb.

Hunting (of a rotary machine) An oscillation of angular velocity about a state of uniform rotation.

I

Integer A whole number, having no fraction or decimal portion

Intensity The strength of a quantity such as current, voltage or pressure.

Intermediate frequency A frequency to which the incoming signal is changed in superheterodyne reception.

Intermodulation The modulation of the components of a complex wave by each other, in a non-linear system.

L

Layer winding A coil winding in which one layer is wound over another.

Lead A connecting wire.

Linear Having an input versus output characteristic which, when plotted on ordinary graph paper, is a straight line. A distortionless amplifier is linear, because its amplification is constant for all values of input voltage.

Linear reflex detector (also called infinite input impedance detector) An anode-bend detector having its negative bias supplied from a high resistance cathode bias resistor which is by-passed for radio frequencies only.

Line voltage The voltage of the power lines. Mains voltage.

Load Any device which absorbs electrical power.

Locus The path followed by a moving point.

Loudness A subjective evaluation which is primarily a function of intensity but is strongly influenced by frequency.

Low level A relative term indicating the level of the early stages of an amplifier (e.g. pre-amplifier).

Low-pass filter A filter which passes all frequencies below a critical value.

M

Manual Adjusted by hand.

Maximum signal Usually applied to the conditions under which the amplifier just reaches the point of "maximum undistorted power output."

Maximum undistorted power output The maximum power output for a specified distortion.

Microphonic A valve or other component which amplifies sound waves or vibration sufficiently to produce a loud sound or continuous howl in the loudspeaker.

Mirror image One curve is a mirror image of another when the first one, seen through a mirror, is identical with the second.

Mixer The stage in a superheterodyne receiver in which the incoming signal is mixed with the voltage from a local oscillator to produce the intermediate frequency signal. Also a control which combines the output from a number of microphones in any desired proportion to the input of the main amplifier.

Modulation The process by which the amplitude, frequency or phase of a carrier wave is modified in accordance with the characteristics of a signal.

Monaural Hearing with one ear only.

Motorboating Regeneration at low audio frequencies causing sounds like those of a motor boat.

N

Network An electrical circuit. See Chapter 4.

Neutralization The process of balancing out an undesirable effect, such as regeneration.

Node A point on a stationary wave system which has zero amplitude.

Non-linear The opposite of linear. Distorted.

Numerator The part of a fraction above the fraction bar.

O

Open circuit A circuit which is not complete and can therefore carry no current.

Order "Of the order of" indicates "that the value is in the general vicinity of." The expression is looser than "approximately equal to."

Output stage The final stage in an amplifier which supplies audio frequency power to a loudspeaker. Also known as power amplifier.

P

Parallel Conductors or components are in parallel when the current flowing in the circuit is divided between them.

Parameter Where there are three variables, any one of them (called the parameter) may be given a series of fixed values, and two dimensional curves may then be drawn to show the relationships between the remaining two variables.

Penultimate Last but one.

Period The time for one complete cycle of values ; the reciprocal of the frequency.

Phonograph Also known as a gramophone.

Pitch A subjective observation of a musical sound, principally dependent on frequency but also affected by intensity.

Polarity (1) electrical—a term applied to electrical apparatus when it is desired to indicate which terminal is positive and which is negative ;

(2) magnetic—that quality of a body by virtue of which certain characteristic properties are manifested over certain regions of its surface, which are known as poles, and whose polarity is indicated by the term north or south pole.

Potential The potential at a point is the potential difference between that point and earth.

Potential difference The potential difference between two points is equal to the work done in transferring unit quantity of positive electricity from one point to the other. The practical unit is the volt.

Power pack The power supply of a radio receiver or amplifier. It converts the available voltage to the values required by the plate, screen, and grid circuits.

Q

Q factor The ratio of reactance to resistance of a coil, condenser or resonant circuit.

Quiescent Stationary. The quiescent operating point is that with instantaneous zero signal voltage.

R

Radial lead A lead at 90° to the axis.

Radio frequency Any frequency at which electromagnetic radiation is used for telecommunication.

Reciprocal of a number is 1 divided by the number.

Rectification The process of converting an alternating current to unidirectional current by means of an asymmetrical conducting device.

Ripple frequency The frequency of the a.c. component of a current when this component is small relative to the d.c. component.

Roll-off A frequency response characteristic is said to have a roll-off when the attenuation at high or low frequencies has the same form as that of a single section low- or high-pass RC filter. The term is also used in a loose sense to cover any characteristic with gradually increasing attenuation at high or low frequencies, in distinction to a sharp cut-off.

S

Scalar Has magnitude and sign but no direction.

Series Conductors or components are in series when traversed by the same current.

Short circuit A low resistance connection, usually accidental, across part of a circuit, resulting in excessive current flow.

Shunt Same as parallel.

Sideband A band of frequencies within which lie the frequencies of the waves produced by modulation.

Side frequency A frequency produced by modulation.

Signal voltage The audio frequency voltage in an a-f amplifier ; the modulating voltage in an r-f or i-f amplifier, also applied to the whole modulated carrier voltage.

Sinusoidal Having the form of a sine (or cosine) wave.

"Small compared with" A vague term indicating that it may be neglected in a rough approximation, or that its square may be neglected with only a small error—say "less than one tenth of."

Soft valve One which has reverse grid current in excess of the specified maximum for its type.

Space current The same as cathode current.

Steradian The solid angle subtended at the centre of a sphere by an area on its surface numerically equal to the square of the radius. The maximum possible value is 4π steradians.

Strain Is the deformation produced by an applied stress, for example change in length per unit length produced by a tensile stress.

Stress is the deforming force per unit area. Examples are tensile stress, compressive stress and bending stress.

Subharmonic A component of a complex wave having a frequency which is an integral sub-multiple of the basic frequency. Example : basic frequency 300 c/s ; subharmonics 150, 100, 75, 60, 50 c/s.

Subscript Printed below the line. For example the letter m in g_m is a subscript.

Superscript Printed above the line. For example the figure 2 in x^2 is a superscript.

N.B. Q' is called " Q dash."

Supersonic Air waves having frequencies above those which may be heard by the human ear. The preferred term is ultrasonic.

Symmetrical Having the same characteristics for conduction in both directions.

T

Tap A connection at some point other than the ends.

Term A portion of an expression which is separated from the other portions by + or — signs. In a sequence, series or progression the terms may be separated by commas.

Terminal A point to which electrical connections may be made.

Tertiary Third.

Tolerance The maximum permissible variation from an assigned value.

Transducer A transducer is a device by means of which energy may flow from one or more transmission systems to one or more other transmission systems. The energy transmitted by these systems may be of any form (for example it may be electrical, mechanical or acoustical), and it may be of the same form or different forms in the various input and output systems (e.g. electro-acoustical).

An **electrical transducer** is an electrical network by means of which energy may flow from one or more transmission systems to one or more other transmission systems ; in most cases it has two input and two output terminals. An **electron-tube transducer** is an electrical transducer containing one or more electron tubes (valves). Examples are an amplifier, and a frequency converter.

Treble High audio frequencies.

U

Ultrasonic Air waves having frequencies above those which may be heard by the human ear.

Unidirectional current Current which may change in value but never reverses its direction.

Unity The figure 1.

V

Variable A quantity whose value changes.

Variational The variational slope of a curve at a point is the differential slope at that point.

Vector A quantity having both magnitude and direction.

"Very small compared with" A vague term indicating that it may be neglected with only a small error—say "less than one twenty-fifth of."

Voice coil Moving coil of a dynamic loudspeaker.

W

Work function The thermionic work function of a conductor is the definite amount of work which must be applied to release one electron. An electron must possess kinetic energy at least as great as the work function of the conductor to pass out through the surface.

Z

Zero signal Having no signal input voltage.

**Wire produced by some manufacturers differs considerably from the resistance values given.

*D.S.C. wound on spool.

†Bare wire on slab—well ventilated. Spacing between turns equal to wire diameter.

N.B.—To find current for Advance wire wound on slab, multiply Nichrome Current column by approx. 1.5.

**Wire produced by some manufacturers differs considerably from the resistance values given.

*D.S.C. wound on spool.

†Bare wire on slab—well ventilated. Spacing between turns equal to wire diameter.

N.B.—To find current for Eureka wire wound on slab, multiply Nichrome Current column by approx. 1.5.

SECTION 22 : LOG. SCALES AND LOG. SCALE INTERPOLATOR

(i) *Log scales* (ii) *Log scale interpolator.*

(i) Log scales

The exact (to 3 significant figures) relationship between the log. and linear scales are set out in Fig. 38.9. It will be seen that the approximation of Fig. 38.10 is very close and the error is negligible in comparison with ordinary graphical errors. To plot the approximate log. scale, use a decimal rule (inches or centimetres etc.) and mark 0.3, 0.6, 0.9 and 1.0 for each major division, and continue similarly. If linear graph paper is available, select values for 1 and 10 on the log. scale such that the linear scale is 10 or a convenient multiple of 10, then mark log. values as in Fig. 38.10.

See also Chapter 19 Sect. 1(xii) for decibels, slide rules and mental arithmetic.

Fig. 38.9. Log. and linear scales (exact).

Fig. 38.10. Log. and linear scales (approx.).

(ii) Log. scale Interpolator

Often it is desired to know the exact value of a point on a logarithmic scale, when it does not come on one of the scale markings. In such a case, mark on a straight edge of paper the distance from the point to the next lower scale marking which is a multiple of 10, also marking the distance to the next higher marking which is a multiple of 10. The piece of paper with the three pencil marks should then be placed on the Log Scale Interpolator (see opposite page) so that the edge of the paper is roughly horizontal, and the two extreme points come exactly on the outer radial lines, the lower value to the left and the higher value to the right. The value of the point may then be read on the top scale, multiplied by the appropriate multiple of 10.

 Admittance of arms and networks, 153–158
 Admittance of parallel connections of L, C and R, 147–149
 Admittance of series connections of L, C and R, 144–147
 Admittance of series-parallel connections of L, C and R, 149–153
 Admittance, short-circuit feedback, 50–55
 Admittance, short-circuit feedback, methods of increasing in i-f amplifiers, 1064
 Admittance, short-circuit feedback, test for, 117
 Admittance, short-circuit forward, 50–55
 Admittance, short-circuit forward, test for, 117
 Admittance, short-circuit input, 50–55
 Admittance, short-circuit input, test for, 113–117
 Admittance, short-circuit output, 50–55
 Admittance, short-circuit output, test for, 117
 Admittance, signal grid input, of converters, 970, 973, 976–978, 980–981
 Admittances, short circuit, 69
 Admittances, valve, 49–57, 69, 70
 Aerial coin gain, 916–917, 920
 Aerial coupling, 912–913
 Aerial coupling capacitance, 921
 Aerial coupling transformer, mutual inductance, 916–920
 Aerial coupling transformer, tapped inductance, 920–921
 Aerial coupling transformer, three special cases for, 918–920
 Aerial coupling units, generalised, 915–916
 Aerial primary windings of short-wave coils, 474
 Aerial stages, 912–913, 915–922
 Aerial stages, fixed tuned, 921
 Aerials (Chapter 22), 890–911
 Aerials and power transfer, 892–893
 beam width of, 894
 broadside array, 893–894
 car radio, aerials for, 1276–1277
 characteristics of, 893–894
 dipoles, 892–895, 898, 904–906, 908–911, 919
 effect of spacing between aerial and reflector, 905–906
 discone, 910
 dummy, 906–907, 1299, 1315, 1316
 effective area of receiving, 893–894, 896
 effects of earth on performance of height above earth, desirable, 895
 imperfectly conducting earth, 896–900
 attenuation between transmitter and receiver, 896–900
 attenuation charts, 897–900
 attenuation of radio waves due to, 896–900
 conductivity of earth, 896–900
 effective area with, 896
 field intensity at receiver—charts, 897–900
 height of receiving aerial above earth, effect of—charts, 898–900
 power-flux per unit area at receiver, 896–897
 resistivity of earth, 896
 space waves, 896, 897
 surface wave, 896, 897
 perfectly-conducting earth, 894–895
 vertical and horizontal aerials, comparison between, 895, 896
 equivalent circuit of aerial and input circuit of receiver, 904
 equivalent circuit of aerial-earth system, 903
 field intensity of wave, electric, and power-flux per unit area, relation between, 896
 F-M receivers, aerials for, 1288, 1294
 function of a receiving, 892
 half wave dipole, 893, 919
 half wave dipole, folded, 910–911
 horizontal, 895–896, 910
 impedance of, 901–906
 characteristic, 903
 equivalent series loss resistance, 902
 example of calculations, 903–904
 input impedance, 904
 voltage at receiver terminals, 904

 By-pass condenser, definition, 1399
 By-pass condensers, series resonant, 944, 1289, 1291
 By-passing radio or ultrasonic frequencies in a-f amplifiers, 636
 By-passing—*see under* Plate, Screen, Grid, Cathode, etc.
- ### C
- C-battery, definition, 1399
 C.G.S. electromagnetic system, 1331, 1332
 C.G.S. electrostatic system, 1331, 1332
 Cabinet, design of, 850, 1248-1249
 Cables, battery, colour codes, 1344
 Calculus, differential and integral, 289-299
 Candle, measure of light intensity, 1334
 Cans for i-f transformers, 1043
 Capacitance, general, 134-140
 calculation of, cylindrical condenser, 136
 calculation of, parallel plates, 135-136
 coupled aerial transformer, 921
 coupling, interelectrode, 943, 944
 coupling, shunt, in i-f transformers, 1023-1024
 coupling, top, in r-f amplifiers, 923
 distributed, across coils, measuring, 1325-1326
 grid-cathode, published values of, 56
 grid input, 49-53
 grid input, components of, 51
 grid-plate, 7
 grid-plate, maximum permissible for stability, 943
 heater-cathode, effect of variation in, on Hartley oscillator, 957, 959
 input capacitance, effect of space charge on, 51
 input, of cathode follower, 323, 325
 input, of high- μ r.c.c. triodes, 656
 input, of i-f pentodes, effect of neutralization on, 1063
 input, of pentodes, published values of, 56
 input, of pentodes with feedback to screen, 345
 input, of receiving valves at radio frequencies, change in, 927, 932-933
 interelectrode, 73
 interelectrode, effect of, 7, 46, 51, 53, 69
 interelectrode, ratings, 75
 interelectrode, tests for, 73, 95-99
 output, of cathode follower, 323-324, 325
 resistors, of, 189
 self, of coils, 451-453
 self, of coils, measurement of, 453
 self, of short-wave coils, 472-474
 short-circuit input, change with a.v.c., 927, 928, 932-934, 971, 978, 984, 1061-1062
 short-circuit input, change with transconductance, 55
 timing, for vibrators, 1207-1209
 units of, 1332
 Capacitive coupling within valve, hum due to, 788, 1196-1197, 1198
 Capacitive reactance, 138
 Capacitive reactance, sign of, 50
 Capacitive susceptance, sign of, 50
 Capacitor (condenser), 134
 see also under Condenser.

Capacitor, definition, 1399
 Carbon microphones, 775, 777-778
 Carbon resistors, characteristics of, 186
 cracked, characteristics of, 186, 190
 Cardioid microphones, 780
 Carrier frequency, definition, 1399
 Carrier wave, definition, 1399
 Cartesian coordinates, 279
 Cascade, definition, 1399
 Cascode amplifiers, 533-534, 914
 Catenoidal horn loudspeakers, 854
 Cathamplifier, Parry, 586
 Cathode and screen by-passing, r.c.c.
 pentodes, incomplete, attenuation
 and phase shift characteristics, 498-501
 Cathode bias in power amplifiers, 547, 552-553,
 565-566, 582, 585
 Cathode bias loadlines, r.c.c. triodes,
 29-30, 486-487
 Cathode bias operation, determination of
 maximum grid circuit resistance, 82-84
 Cathode bias, r.c.c. triodes, 484-487
 Cathode bias resistor, r.c.c. pentode, de-
 termination of, 505-506
 Cathode bias resistor, r.c.c. triodes, choice
 of, 486
 Cathode bias, single Class A pentodes,
 565-566
 Cathode bias with push-pull Class A,
 AB₁, 582, 585
 Cathode by-passing, attenuation slope and
 phase angle, 360
 Cathode by-passing, incomplete, effect
 on hum, 786
 Cathode by-passing of r.c.c. pentodes,
 incomplete, attenuation characteris-
 tics, 499-501
 Cathode by-passing of r.c.c. triodes, in-
 complete, attenuation characteris-
 tics, 484-485
 Cathode by-passing of r.c.c. triodes, in-
 complete, phase shift, 485-487
 Cathode by-passing of single Class A
 triodes, 554
 Cathode connections, two, valves with,
 928
 Cathode-coupled amplifiers, 348, 529, 531
 Cathode-coupled phase inverter, 347-348, 532
 Cathode current, average, maximum, 75
 Cathode current characteristics of pen-
 todes, 16-17
 Cathode current, definition, 1399
 Cathode current, peak, maximum, 75
 Cathode current, total available peak and
 average, 73
 Cathode current—*see also* Space current.
 Cathode definition, 1399
 Cathode degenerative amplifier, 327-329
 Cathode emission—*see under* Emission.
 Cathode follower 316-327
 Cathode follower as driver for Class B
 stage, 591, 596
 Cathode follower as low-noise pre-ampli-
 fier input stage, 789-790
 Cathode follower as transformerless
 driver, 591, 596
 Cathode follower, direct-coupled, 531
 Cathode follower power amplifiers, 596
 Cathode injection circuit for converters,
 969
 Cathode loadlines, 29-30
 Cathode neutralization in a-f circuits, 1285
 Cathode resistor, unbypassed, in r-f and
 i-f amplifiers, 933-934, 1064, 1288, 1292
 Cathode resistor, unbypassed, to give
 compensation of input capacitance
 change with grid bias, 56
 Cathode resistors in push-pull voltage
 amplifiers, 527
 Cathode to heater leakage—*see under*
 Heater to cathode leakage.
 Cathodes, general, 4, 5
 activation of, 69
 as negative electrode, 2, 80
 directly heated (filaments), 4-5
 on a.c. supply, 6
 indirectly heated, 4-5
 ion bombardment of, 3

Cathodes, general (continued)
 oxide coated, 2
 low temperature operation, 3
 temperature of, 2
 sleeve, 2, 5
 thermal expansion of, 51
 valves with two or more cathode leads, 928
 virtual, 3, 70, 71, 973, 978, 986
 Cells (batteries) in series and parallel, 129
 Celsius, 1334
 Centigrade, 1334
 Centimetre, unit of length, 1329, 1331, 1332,
 1333
 Centre tracking frequency, 1004
 Ceramic dielectric condensers, 196
 Ceramic piezo-electric microphones, 779
 Change in operating conditions, effect
 of, 26, 42-44
 Changes in filament and plate voltages in
 d.c. amplifiers, compensation for, 533
 Changes in supply voltage, effect on os-
 cillator frequency variation, 949, 953, 955
 Channel, definition, 1399
 Characteristic curves, valve, 15-24
see also under Valve characteristic curves.
 Characteristic impedance of aerial, 903
 Characteristic impedance of 4-terminal
 networks, 179
 Characteristics—*see under* Valve charac-
 teristics, etc.
 Charge on condenser, energy stored in, 135
 Charge, units of, 1332
 Charging characteristic of condenser, 136-137
 Charts, tables and sundry data, 1329-1423
 Chatter (needle talk), 714, 718, 719, 760, 762
 Chemical and physical constants, 1376
 Choke-capacitance coupling in r-f ampli-
 fiers, 924
 Choke coil, definition, 1399
 Choke-coupled a-f amplifiers, 521
 Choke-coupled power amplifier, Class A
 triode, 559-560
 Choke input filters for rectifiers, 1162-1164,
 1167-1169, 1182-1185
 Choke, swinging, 249-250, 1182
 Chokes, r-f, checking resonant frequencies, 944
 Chokes, r-f, design of, 474-475
 Chokes, r-f, self resonant, 475
 Chokes, r-f, pie-wound, 474
 Circuits used for tracking analysis, 1002
 Circular mil, 1329
 Circle, 273
 Circle, equation to, 280
 Clippers, speech, 693-694
 Closure, percentage, of vibrator, 1208
 Co-axial and co-planar loudspeaker
 mounting, 860
 Co-axial, definition, 1399
 Co-channel interference in F-M re-
 ceivers, tests for, 1317-1318
 Coefficient of coupling in tuned circuits—
 see under Coupling factor.
 Coercive force, 231
 Coil data (table) for power transformers, 240
 Coil design, oscillator, 947-957, 959-960
 Coil magnification factor, 144
 Coil, oscillator, position in receiver, 957
 Coils
 baking of, 476-477
 flash dipping of, 477
 i-f, air-cored, design of, 453-454, 1041-1043
 i-f, amount of coupling, 458
 i-f, direction of winding, 458
 i-f, iron-cored, design of, 454-455, 1041-1043
 impregnation of, 477
 measurements on, 1325-1326
 coefficient of coupling, 1025, 1030-1031,
 1033-1034, 1102
 distributed capacitance across coils, 1325-1326
 primary resonant frequencies of aerial
 and r-f coils, 1325
 medium wave-band, air-cored, 459-460
 medium wave-band, design of, 459-463
 medium wave-band, iron-cored, 460-461
 multilayer, design of, 443-444

- Coils (continued)
- multilayer, inductance of, 441-444
 - r-f, design of, 450-480
 - r-f, self-capacitance of, 451-453
 - short wave, aerial primary windings, 474
 - short wave, design charts, 466-473
 - short wave, design of, 463-468
 - short wave, matching, 468-471
 - short wave, self-capacitance, 472-474
 - tropic proofing of, 476-478
 - universal, gear ratios for, 456-457
 - universal, inductance of, 444

- mutual, triode, of pentode, 34
- of arms and networks, 153-154
- plate, definition, 14
- plate, testing of, 124
- short-circuit input, typical values of, 55, 1028, 1029
- Conductance and susceptance from resistance and reactance, chart for determining, 155, 156

Conductance, grid input, 49-53
 Conductance in resistive circuits, 133
 Conductance, signal grid input, of converters, 976-978, 980-981, 982, 987-988
 Conductance, units of, 1332
 Conducting materials, properties of, 1374
 Conductivity of earth, 896-900
 Conductivity, units of, 1332
 Cone movement, amplitude of loudspeaker, 834
 Cone, volume of, 275
 Cones, practical loudspeaker, 834, 835-836, 839
 Conical horn loudspeakers, 851, 854
 Conjugate impedances, 165
 Connections to valve sockets, 80, 81
 Connoisseur pickup, 718
 Constancy of characteristics with feedback, 388
 Constant amplitude recording, 703-704, 727
 Constant bandwidth, coupled tuned circuits, 420
 Constant current curves, 22-23
 Constant, definition, 1399
 Constant k filters, 179-182
 Constant velocity recording, 703-704, 727
 Constants, chemical and physical, 1376
 Constants in algebra, 265
 Consonance, definition, 1399
 Contact potential
 biasing, 1280-1281
 diode, effects of, 1079, 1080, 1082, 1106, 1108, 1118
 drift during life, 23-24, 84, 533
 grid-cathode, 18, 20, 39, 69, 70
 Continuity, 265-266
 Continuity of electrodes, tests for, 73, 91-93, 123
 Continuous functions, 265-266
 Convergent infinite series, 268
 Conversion, English to metric units, 1329-1330
 Conversion factors applied to complete r.c.c. stage, 512
 Conversion factors, valve, 36-40, 57, 493, 511, 568
 Conversion transconductance, definitions, 14, 109
 Converter, definition, 1399
 Converters, frequency—*see under* Frequency converters.
 Coordinates, 279
 Coordinates, Cartesian, 279
 Coordinates, polar, 283
 Co-planar, definition, 1399
 Copper oxide rectifiers, 1169
 Copper, temperature coefficient of resistivity, 237
 Core, definition, 1399
 Core materials for transformers, 206-209, 210, 214
 Cores, i-f and r-f—*see under* Inductors, r-f; Iron cores.
 Cores, transformer—*see under* Transformers, practical, a-f, output, power; *also under* Inductors, iron-cored.
 Corner horns, 856
 Corrugations in loudspeaker cones, 835, 839
 Cosecant of an angle, 272
 Cosine of an angle, 272, 275
 Cosine wave, 278
 Cosmic rays, wavelength of, 404, 1363
 Cotangent of an angle, 272
 Coulomb, measure of charge, 1332, 1333
 Counter-modulation in receivers, 1264
 Coupling between oscillator and signal circuits in converters, 973, 974-975, 980, 988, 992, 994, 1000
 Coupling between two coils, 142
 Coupling, coefficient of, 142
 Coupling condenser of r.c.c. amplifier, 483-484, 496
 Coupling factor (coefficient), 142
 critical, 415, 426
 in aerial transformers, 918-920

Coupling factor (continued)
 in i-f transformers, 416, 1023-1024
 calculation of, 414-416, 419-421, 1023-1024, 1043-1048
 measurement of, 1025, 1030-1031, 1033-1034, 1102
 in phase discriminator transformers, 1090
 in r-f transformers, 923
 of tuned circuits, 413-426
 transitional, 416, 1031
 Coupling, mixed, in i-f transformers, 1025, 1044-1048
 Coupling of tuned circuits, 418-421
 Coupling, unity, 142
 Cracked carbon resistors, characteristics of, 186, 190
 Creeping plate current in power amplifiers, 596
 Critical bandwidth of noise, 621
 Critical coupling factor, 415, 426
 Critical damping, conditions for, in feedback amplifiers, 385-388
 Critically coupled i-f transformers, 1026-1031
 Cross-coupled phase inverter, 527, 663-664
 Cross-coupling in push-pull amplifiers, 528
 Cross-modulation, definition, 1399
 Cross-modulation, external, 945, 1264
 Cross-modulation in r-f and i-f amplifiers, 927, 945, 1108, 1264, 1303
 Cross-over frequency in recording characteristics, 728
 Cross-over frequency, loudspeaker, choice of, 860-861
 Cross-over point, grid current, 19, 20
 Cross-over point, grid current, drift during life, 23-24
 Cross-talk component in F-M receivers, 1317
 Cross-talk in A-M receivers, 1304
 Crystal constants, 1056-1057
 Crystal detectors, 1136-1139
 Crystal filter as whistle eliminator, 675
 Crystal filters, variable bandwidth, 1051-1061
 behaviour of equivalent circuit, 1050-1051
 design of, 1053-1061
 crystal constants, 1056-1057
 example, 1057-1061
 gain, 1053-1054
 gain variation with bandwidth, 1054
 position in receiver, 1057
 selectivity, 1055-1056
 types other than bridge, 1057
 Crystal loudspeakers, 832
 Crystal microphones, 775, 778-779
 Crystal rectification, theory of, 1138
 Crystal triodes, 1138
 Cube, 275
 Cumulative grid detectors, 62, 1082-1084
 Current, alternating, 129-130
 Current and voltage, 128-130
 Current direct, 128-129
 Current, electric, as electron flow, 1, 2
 Current feedback—*see under* Feedback.
 Current flow, direction of, 128
 Current indicators, peak reading, 119
 Current leading voltage, 138
 Current regulators (barretters), 1213-1214, 1266
 Current sheet inductance, 429, 436-438, 441-442
 Current, units of, 1332
 Currents in windings of power transformers, 236
 Curvature, radius of, in record, minimum 704
 Curve, average height of, 280
 Curve, finding equation to, 281
 Curve tracer methods, valve characteristics by, 119-120
 Curves, typical tracking, 1003
 Cutler tone control, 664
 Cut-off frequency, definition, 1399
 Cycle, 129, 278, 403
 Cycle, definition, 1399
 Cylinder, solid or hollow, 275

Filters (continued)

frequency dividing networks, 184-185, 860, 887-889

half-section, "building out" trans-
former to give, 214

high pass, definition, 172

hum filters for rectifier systems, 1192-1201

image impedances of four-terminal
networks, 177-179

image attenuation constant, 178, 179

image phase constant, 178, 179

image transfer constant, 178-179, 180

impedance mismatching in,
iterative impedances of four-terminal
networks, 176-177

iterative transfer constant, 176-177

low pass, definition, 172

mains, for receivers, 475, 1279-1280

M-derived filters, 182-184, 652

design of multiple section filters,
half section, 182-184

T section, 182-184

pass band, 180

practical, 184

references, 185

reflection effects in, 178

resistance capacitance, 172-176, 1194

attenuation characteristics, 173-176

parallel-T network, 176, 647, 651, 657,
675-676, 737-738, 745-749, 1194-1196

theoretical cut-off frequency, 172

time constant, 172, 173

shunt across load of power pentodes, 567, 636

stop band, 180

symmetrical networks, 179, 180

tone control, elements of, 639

variable bandwidth crystal, 1051-1061

Fine groove recording, 701, 706-709

First detector, definition, 1400

Fixed bias in power amplifiers, 547, 597

Fixed bias operation, determination of
maximum grid circuit resistance, 82-84

Fixed bias, r.c.c. pentodes, 501-502, 506

Fixed bias, r.c.c. triodes, 487-489

Fixed bias, sources of, 597

Flat baffles, 842

Flare cut-off frequency, 852

Flaring constant of horns, 851, 852

Flash dipping of coils, 477

Flat frequency response in feedback
amplifiers, 379-388

Flicker effect, 783

Fluctuations in line voltage for valves, 10

Fluorescence, 4

Flutter in receivers, 955, 958, 993, 998,
1244-1246

Flutter in record reproduction, 761

Flutter in record reproduction, tests for, 1312

Flux density, 229

Flux density in power transformers, 235

Flux density, maximum, 243

Flux density, remanent, 230

Flux density, residual, 230

Flux density, units of, 1332

Flux leakage, 231

Flux, lines of, 229

Flux, luminous, unit of, 1334

Flux produced by inductor, 140

Flux, units of, 1332

Flywheel tuning, 1252

Folded horns, 856-859

Footcandle, 1334

Force, coercive, 230

Force, stylus, vertical, 702, 708, 709, 712,
718-722, 768, 769

Force, stylus, vertical, minimum for
tracking, 712, 715, 719, 720

Force, units of, 1330, 1332

Forecasting frequencies for long distance
short-wave communication, 404, 901

Form factor, 134

Form factor of coils, 414

Formulae or laws (in Algebra), 265

Forward admittance, short-circuit, 50-55

Forward admittance, short-circuit, test for, 117

INDEX

1441

Fourier analysis, 130, 299-302

Fourier analysis of some periodic waves, 301-302

Fourier analysis, references, 305

Fourier series, 299-302

Fourier series, graphical harmonic an-
alysis, 302-304

Fourier series, other applications of, 302, 964

Freezing point of water, 1334

Fremodyne F-M detector, 1088

Frequencies and wavelengths—table, 1362

Frequencies, high roll-off, in a-f ampli-
fiers, 631

Frequencies, primary resonant, of aerial
and r-f coils, measurements of, 1325

Frequencies, standard, 1361

Frequencies, standard intermediate, 1361

Frequencies, standard test, in F-M re-
ceivers, 1314

Frequency, 129, 278, 403

Frequency bands for broadcasting, 1361

Frequency changer, definition, 1400

Frequency characteristics, bass boosting, 641-643

Frequency characteristic of ideal constant
velocity pickups, 724

Frequency compensated volume control,
automatic, 672-674

Frequency conversion, 62, 962-1001, 1017-1019

Frequency converters and mixers, opera-
tion of, 962-986

analysis of operation common to all
types, 964-968

conversion transconductance, de-
finitions, 14, 109

conversion transconductance of con-
verter valves, 966-967

conversion transconductance of
modulator or mixer valves, 964-966

detailed operation of modulator or
mixer section of converter, 968-984

noise in, 967-968, 972-973, 978, 984

oscillator section of converter valves, 968

coupling between oscillator and signal
circuits, 973, 974-975, 980, 988, 992, 994,
1000

harmonic operation of oscillator (har-
monic mixing), 62, 958, 964-966, 991,
994-996, 1000, 1001

input admittance, signal grid, 970, 973,
976-978, 980-981

negative, 977, 985-986

input conductance, signal grid, 976-978,
980-981, 982, 987-988

negative, 976-978, 985-986

input susceptance, signal grid, 976-978

negative, 976-978

loading of input circuit due to valve
admittance, 970, 973, 987-988

methods of frequency conversion, com-
parison—table, 985

methods of operation of mixer or modu-
lator valves, 969

oscillator and signal voltages applied
to same grid, 969-973

oscillator voltage on inner grid, signal
voltage on outer grid, 973-978

oscillator voltage on outer grid, signal
voltage on inner grid, 978-984

negative admittance of current limited
grids, (Appendix), 985-986

neutralization in converters, 959, 969, 970,
975-977, 978, 992, 1000, 1001

noise in, 967-968, 9

oscillator frequency variation due to
a.v.c., 963

oscillator transconductance, phase shift
at high frequencies, 968

references, 1017-1019

see also Oscillators.

space-charge coupling in, 963, 975-977, 980

neutralization of, 975-977, 992

Frequency converters, applications of,
alignment, short wave, 987-1001, 1017-1019, 1244-1248
990-991

- of series-parallel combinations of L , C and R , 149-153
- of two-terminal network, general pro-cedure, 153
- ratio of transformer, effect of losses on, 206
- reactance and resistance
 - in parallel (chart), 1380-1381
 - in parallel (table), 1380
 - in series (charts), 1384-1385
 - in series (table), 1382, 1383
 - in series or parallel, approximations in, 1386
- total effective plate supply per plate, 1165-1167, 1180
- transmission lines, characteristic, 890-891
- transmission lines, impedance-trans-former action, 891-892
- transmission lines, input, 892

Impedance, resonant, of parallel tuned circuit, 411

Impedance, series, of tuned circuit, 409

Impedances, negative stabilized, 389

Impregnation of coils, 477

Impulse, unit, as test for loudspeaker transient response, 870

Incremental change of voltage, 13

Index (indices), 255

Index of a logarithm, 256

Indicating instruments, 825

- decibel meters, 825
- noise meters, 827-829
- power-level indicators, 825
- power output meters, 825
- sound level meters, 828
- volume indicators, 823-824

Indoor aerials, 908

Induced grid noise, 939-940

Inductance, 140-144

Inductance, calculation of (Chapter 10)

- flat spirals, 445-446
- iron core, powdered, effect of, 1042
- multilayer solenoids, 441-444
 - approximate formulae, 442-443
 - correction for insulation thickness, 442
 - current-sheet inductance, 441-442
 - design of multilayer coils, 443-444
 - effect of concentric screen, 444
 - universal coils, 444
- mutual inductance, 446-448
- references, 448-449
- single layer coils or solenoids, 429-441
- approximate formulae, 432

- Inductance, calculation of (continued)
 current-sheet inductance, 429, 436-438
 curves for, 436-438
 design of single layer solenoids, 433-435
 difference between L_s and L_o , 435-437
 effect of concentric screen, 438-441, 473
 solenoid wound with spaced round wires, 430
 straight wire, 1287
 toroidal coils, 445
- Inductance, critical value of, with choke input filter, 1182-1185
- Inductance, grid input, 49-53
- Inductance, ideal, 144
- Inductance in a.c. circuits, 142-143
- Inductance, mutual, 142
- Inductance of composition resistors, 189
- Inductance of iron-cored inductors, 242
- measurement of, 250-251
- Inductance of leads and electrodes, effect of, 46, 50, 51, 53, 69, 930, 931, 932
- Inductance of transformer primary, a-f, 204, 207, 209
 output, 212-214
 variation with signal, 547
- Inductance ratio of iron-cored inductors, 242
- Inductance, units of, 1332
- Inductances in d.c. circuits, 141
- Inductances in series and parallel, 141
- Inductive circuits, impedance in, 143
- Inductive circuits, power factor in, 144
- Inductive circuits, power in, 143
- Inductive reactance, 142
- Inductive reactance, sign of, 50
- Inductive susceptance, sign of, 50
- Inductor, 140
- Inductor dynamic loudspeaker, 832
- Inductor, electromagnetic field due to, 140
- Inductor, electromotive force induced in, 140
- Inductor, figure of merit for, 144
- Inductor, flux produced by, 140
- Inductors, iron-cored, 242-253
 design for choke-input filters, 249-250
 design of high Q inductors, 245-247
 design with d.c. flux, 247-249
 Hanna's method, 248-249
 design with no d.c. flux, 243-245
 flux density, maximum, 243
 inductance, calculated, 242
 inductance ratio, 242
 length of magnetic path, 242-243
 measurement of inductance and impedance, 250-251
 permeability, effective, 242-243, 244
 permeability, incremental, 230, 243, 248
 references, 253
 resonant circuits, in, 251
see also under Magnetic circuit theory, Transformers.
- swinging choke, 249, 250, 1182
- Inductors, radio frequency, design of (Chapter 11), 450-480
 intermediate-frequency windings, 453-459
 air-cored coils, 453-454, 1041-1043
 coupling, amount of, 458
 direction of windings, 458
 gear ratios for universal coils, 456-457, 1043
 iron-cored coils, 454-455, 1041-1043
 losses, 458
 other ferromagnetic materials, 458-459
 variable selectivity i-f transformers, 455-456, 1048-1050
see also under Transformers, i-f.
- medium wave-band coils, 459-463
 air-cored coils, 459-460
 iron-cored coils, 460-461
 matching, 462-463
 permeability tuning, 461-462, 912, 913, 953, 1002, 1289
 resonance solenoid design chart, 1386-1387
 radio-frequency chokes, 474-475
 other types, 475
 pie-wound chokes, 474
 references, 478-480
 self-capacitance of coils, 451-453
 calculation for single layer solenoids, 451-452
- Inductors, radio frequency (continued)
 effects of self-capacitance, 451
 measurement of self-capacitance, 453
 short-wave coils, 463-474
 aerial primary windings, 474
 design, 463-468
 design charts, 466-473, 1386-1387
 direction of windings, 474
 matching, 468-471
 resonance design chart, 1386-1387
 self-capacitance, 472-474
 tropic proofing, 476-478
 baking, 476-477
 flash-dipping, 477
 general considerations, 476
 impregnation, 477
 materials, 477-478
- Inequalities, 262
- Infinite impedance detector—*see under* Detectors, A-M reflex.
- Infinite series, 268-269
- Infinity, definition, 261
- Inflection, point of, 293, 508
- Infrared rays, wavelengths of, 1363
- Inharmonic distortion in loudspeakers, 870
- Initial electron velocity of emission, 18
- In-phase a-f amplifiers, 529
- In-phase gain of push-pull amplifier, 528
- Input admittance, components of, 51-53
- Input admittance, converter signal grid, 970, 973, 976-978, 980-981
- Input admittance, grid, 49-53, 113-117, 493-494, 927-934, 970-988
- Input admittance, grid, due to electron transit time, 50, 51, 930-932, 971, 975, 980, 985-986
 grid-screen capacitance coupling, 53
 plate-grid and grid-cathode capacitance coupling, 53
 plate-grid capacitance coupling, 51-53, 493-494
- Input admittance, short-circuit, tests for, 50-55
- Input admittance, valve, effects of, 927-934
- Input, antenna sensitivity test, definition, 1297-1298
- Input capacitance, change in, 927, 932-933
- Input capacitance change with bias change, value of cathode resistor for compensation of, 56
- Input capacitance, components of, 51
- Input capacitance, grid, 49-53
- Input capacitance of cathode follower, 323, 325
- Input capacitance of pentode with feedback to screen, 345
- Input capacitance, short-circuit, change with transconductance, 55
- Input capacitances of pentodes, published values, 56
- Input circuit damping, 20, 70, 489, 1036, 1074, 1077-1078, 1084
- Input circuit of network, definition, 160
- Input conductance
 converter signal grid, 976-978, 980-981, 982, 987-988
 grid, 49-53
 short-circuit, typical values of, 55
 valve, at radio frequencies, 929-932
- Input impedance of aerials, 904
- Input impedance of reflex detector, 1085-1086
- Input impedance, unloaded a-f transformer, 517
- Input inductance, grid, 49-53
- Input loading, valve, at radio frequencies, 928-934
 minimizing by tapping down, 921
- Input measurements on F-M receivers, 1316
- Input power, peak grid, Class B_2 , 590
- Input reactance, grid, 49-53
- Input resistance
 cathode degenerative amplifier, 328
 effect of feedback on, 311-316
 grid, 49-53
 grid, methods of increasing, 53
 minimum grid, Class B_2 , 590

- Input resistance (continued)
 negative, instability due to, in Class B₂ amplifier, 590
 Input signal for pre-amplifiers, standard, 793
 Input, standard mean signal, in F-M receivers, 1314
 Input susceptance, converter signal grid, 976-978
 Input susceptance, grid, 49-53
 Input voltage, standard, A-M, definition, 1297
 Input voltages and powers in F-M receivers, standard, 1314
 Insertion loss of frequency dividing networks, 887
 Insertion loss of mixers and faders, 799
 Instability due to negative input resistance of Class B₂ amplifier, 590
 Instability in A-M receivers, 1243-1244
 Instability in F-M receivers, 1288-1289
 Instability in r-f amplifiers, 942-944
 Instability, low frequency, in F-M receivers, tests for, 1319-1320
 Instability of valve electrical characteristics, 70
 Insulating materials, properties of, 1372-1373
 Insulation between valve electrodes, 69, 70, 73
 Insulation heater to cathode, effect on design, 81
 Insulation resistance, interelectrode, tests for, 73, 94
 Integer, definition, 1400
 Integral, 256, 294-298
 Integral dual loudspeaker systems, 860
 Integral triple, loudspeaker systems, 860
 Integrals, definite, 296-298
 Integrals, definite, average (r.m.s.) value of sine wave, 298
 Integrals, definite, average values by, 297-298
 Integrals, indefinite, 296
 Integrating networks, 160
 Integration, 294-298
 Integration, areas by, 296
 Integration, limits of, 296
 Intensity, definition, 1400
 Intensity of pressure, units of, 1330
 Intensity, reference acoustical, 826
 Intercommunicating systems, 867
 Interference
 co-channel, in F-M receivers, tests for, 1317-1318
 in A-M receivers, reduction of, 1279-1280
 masking, in F-M receivers, tests for, 1318
 tests in A-M receivers, 1313-1314
 Intermediate frequency, 964
 Intermediate frequency, definition, 1400
 Intermediate frequency transformers—*see under* Transformers, i-f.
 Intermediate frequency windings, design of, 453-459
 Intermodulation, definition, 1400
 difference frequency, 62
 distortion, 611-616
 comparison between methods, 616
 difference frequency method, 613, 1322
 effect of high frequency pre-emphasis and de-emphasis, 616
 equivalent single frequency power output, 612
 in amplifiers, 353, 1322
 in loudspeakers, 871
 individual sideband method, 613-614
 Le Bel's oscillographic method, 614-616
 modulation method, peak sum, 614
 modulation method, r.m.s. sum, 612
 of r.c.c. triodes, 492-493
 permissible, 613, 630-631
 references, 633
 relation with harmonic distortion, 612-613, 615
 Williamson amplifier (A515 version), 347
 production of spurious frequencies, 62
 r-f, in A-M receivers, tests for, 1305
 sum frequency, 62
 Inter-station noise suppression, 1125-1130
 Inverse functions, 276-277
 Inversion gain of push-pull amplifier, 528
 Inverted input a-f amplifiers, 325, 529
 Inverted L aerials, 901, 902, 903-904, 907
 Inverted T aerials, 907
 Ion bombardment of cathode, 3
 Ionic loudspeakers, 831
 Ionization, 3
 Ionization current, 19
 Ionization noise, 783, 784
 Ionized layers in atmosphere, 404, 901
 Ionosphere, effect on reception, 901
 Ions, positive, 3, 71
 Iron-cored i-f coils, design of, 454-455, 1041-1043
 Iron-cored medium wave-band coils, design of, 460-461
 Iron cores in r-f inductors, 450, 470, 475, 1023, 1025, 1041, 1042, 1101
 Iterative impedances of 4-terminal networks, 176-177
 Iterative transfer constants, 176-177

J

 j as operator, 283
 j notation, 139, 283-284
 Johnson noise—*see under* Noise, thermal agitation.
 Joule, 133, 1332, 1333

K

 Kelvin temperature scale, 1334
 Kilogram, measure of mass, 1332, 1333
 Kilowatt hour, 133
 Kinkless tetrodes, 8
 Kirchhoff's laws, 159, 160-161
 Klipsch corner horn, 857-859

L

 Labyrinth, acoustical, 850
 Lacquer disc home recording, 701, 766-768
 Ladder type attenuators, 796-797
 Lamb noise silencer, 1130, 1131
 Laminations for power transformers, 234-235, 240
 Lamp characteristics, American panel, 1397
 Lamp, tungsten, spectral energy curves, 1396
 Lamps as control devices in volume expanders, 685, 687-688
 carbon filament, characteristics of, 685
 tungsten filament, resistance characteristic, 685
 Lamps, dial, in a.c./d.c. receivers, 1266-1267
 Lapel microphones, 780
 Lateral recording, 701-774
 Laws, in algebra, 265
 Layer, ionized, in atmosphere, 404, 901
 Layer winding, definition, 1401
 Lead, definition, 1401
 Leading voltage, current, 138
 Leak amplifier, 600
 Leakage current in valves, 19, 20, 51, 69, 70
 Leakage currents in valves, tests for, 101, 102
 Leakage currents of electrolytic condensers, 193
 Leakage flux, 231
 Leakage from any electrode with ripple voltage to another electrode, hum due to, 1196
 Leakage, heater-cathode, hum due to, 81, 84, 540, 785, 1095, 1131, 1196, 1197
 Leakage, heater-cathode, tests for, 73, 94, 123
 Leakage inductance, 204, 207, 209, 210, 212, 217-219, 233
 driver transformer, effect of, 590
 output transformer
 pentodes, effects of, 566
 reduced by bifilar winding, 594
 triodes, effects of, 572-573
 Leakage, valve, noise caused by, 784
 Leaky grid detectors, 62, 1082-1084
 Learned's method of design of feedback amplifiers, 365, 369-371
 Length, units of, 1329, 1332

Level control, L type, 889
 Level, loudness, contours of, 826
 Level, loudness, unit of, 826
 Level, minimum perceptible change in, 807
 Level, recorded, 702-703
 Level, recorded, maximum instantaneous programme peak, 702-703
 Level, recorded, normal maximum, 703
 Life, drift of characteristics during, 23-24, 70, 84, 530, 533
 Life of condensers, service, 192
 Life of valves, when to replace, 121
 Life test, valve, end points, 88-89
 Life tests, valve, 75, 85, 87-89
 Life, ultimate electrical, of valve, 70
 Life, working, of valves, 3, 70, 121
 Light intensity, measure of, 1334
 Light, spectral energy curves of sunlight and tungsten lamp, 1396
 Light, velocity of, 1396
 Light, visibility curves of human eye, 1396
 Light, wavelengths of, 404, 1363
 Limen, 617-618
 Limiters, amplitude, 1023, 1040, 1088, 1090, 1095, 1098, 1099, 1147-1150, 1296
 A-M rejection by ratio detector, 1095-1096, 1103-1104
 applications of, 1023, 1040, 1088, 1090, 1095, 1098, 1099, 1151
 limiting by superregenerative detector, 1087
 references, 1160
 time constant of, 1148, 1149
 typical circuits for F-M receivers, 1149-1150
 cascaded limiters, 1150
 single stage, 1149
 Limiters, noise peak, 694-698, 1130-1132
 Limiters, output, 698-699
 Limiters, peak, 681, 682-683
 Limiters, volume, 681, 683
 Limiting Class A amplifier, definition, 545, 572
 Limiting ratings—*see under* Valve ratings.
 Limits in algebra, 265-266
 Limits of integration, 296
 Line, measure of flux, 1332, 1333
 Line per square inch, 1332
 Line voltage, definition, 1401
 Line voltage fluctuations, 10
 Line voltage operation, valve ratings for, 78, 79
 Linear, definition, 1401
 Linear elements in networks, 158, 948
 Linear equation, 279
 Linear reflex detectors, definition, 1401
 Linearity (transfer) characteristic of a-f amplifiers, 587, 610, 611
 Link, 321
 Link coupling of tuned circuits, 418, 419
 Lip microphone, 780
 Listener fatigue, 626
 Listening levels, preferred, 623
 Listening tests of loudspeakers, 632, 834
 Listening tests of receivers, 1314
 Litre, measure of volume, 1329
 Litz wire in coils, 450, 456, 466, 1042
 Load, definition, 1401
 Load impedance for pre-amplifiers, standard, 793
 Load line, general, 24, 58
 cathode, 29-30
 cathode bias, r.c.c. triodes, 29-30, 486-487
 composite, 576
 curved, driver valve, 591
 diode, 1075
 elliptical, 30-34, 64, 213, 576
 grid, 20
 maximum signal dynamic, 551
 screen, 513-514
 screen and cathode combined, 515-516
 shifted due to rectification, 551
 Load, loudspeaker, maximum output with, 881
 Load, loudspeaker, on power amplifiers, 546, 558, 566-567, 600-601, 881-882
 Load, phase shift of, at low frequencies, 213
 Load resistance
 effect of change of, 43
 matching of, with Class A triodes, 61
 optimum with feedback, 311

Load resistance (continued)
 power amplifiers, critical value of, 546
 Class A pentode, 561
 Class A triode, optimum, 557-558
 r.c.c. pentode, 496
 to give maximum gain, 507
 r.c.c. triode, 482
 Load, standard dummy, of receivers, 1299
 Loading of input circuit by converter valve admittance, 970, 973, 987-988
 Loading of transformer-coupled a-f amplifiers, 519
 Loading, valve, effect of a.v.c. on, 971
 Loading, valve, minimizing by tapping down, 921
 Locked oscillator—F-M detector, 1088, 1292-1293
 Locus, definition, 1401
 Logarithm tables, 1418, 1419
 Logarithmic decrement, 268, 408, 424
 Logarithmic functions, 267-268
 Logarithmic graph paper, 280
 Log. scale interpolator, 1422-1423
 Log. scales, 1422
 Logarithmic series, 269
 Logarithms, 255-257
 Loop aerials, 901, 904, 908, 921-922
 Loop amplification, feedback, 356
 Loop, feedback, 307, 336
 Loss, copper, in power transformers, 235, 236
 Loss, iron, in power transformers, 235
 Loss, playback, 760
 Loss, translation, 759, 770
 Losses in transformers, relation between copper and iron, 205
 Loudness, 826-827
 contours of equal loudness level, 826
 definition, 1401
 loudness directivity index, loudspeaker, 875
 loudness efficiency rating, loudspeaker, 875
 loudness units, 827
 phon, unit of loudness level, 826
 reference intensity, 826
 reference pressure, 826, 828
 reference velocity, 826
 references, 830
 relation between loudness and loudness level, 827
 Loudspeakers (Chapter 20), 831-879
 acoustical data, summary of, 871-874
 definitions, 871-872
 electrical, mechanical and acoustical equivalents, 872
 musical scales, 873-874
 pitch, international standard, 874
 velocity and wavelength of sound, 872
 baffles and enclosures, 842-851
 acoustical labyrinth, 850
 acoustical phase inverter (vented baffle), 845-850
 combination horn and phase inverter for personal radio receivers, 859
 matched vented baffles, 847-849
 equivalent electrical circuit, 848-849
 flat frequency response, design for, 849
 impedance characteristic, electrical, 847-849
 special types of, 1489
 unmatched vented baffles, 849-850
 adjustable vent area, 849
 enclosed cabinet, 843-845
 acoustical damping to eliminate standing waves, 843-845, 849
 bass attenuation with, 844-845
 critical damping, effects, of, 844-845
 damping, 841, 844-845
 equivalent electrical circuit, 844-845
 standing waves, in, 843
 exterior of cabinet, design of, 850
 flat baffles, 842
 damping with, 833, 840-842
 dip in response with, 842
 impedance characteristic with, 837-838, 848

Loudspeakers (continued)

- irregular shape, 842
- off-centre mounting, 842
- open back cabinets, 842-843
- peak in response, 843
- R-J loudspeaker, 850
- bass reflex—*see under* Acoustical phase inverter.
- characteristics, 833-834
- colour codes for, 1343
- cone movement, amplitude of, 834
- damping, 833, 840-842, 844-845, 856
 - critical, 833, 840-841, 844-845
 - critical, definition, 840
 - effect on transient response, 833
 - electro-dynamic, enclosed cabinet, 841, 844-845
 - electro-dynamic, flat baffle, 833, 840-842
 - electro-magnetic damping, 840
 - Q of loudspeaker at bass resonance, 841
 - feedback of voltage, proportional to velocity of cone, 841-842
 - source impedance, effect of zero or negative, 841
- deflectors, 839
- diffusing lenses, 839, 858
- direct radiator loudspeakers, 831-851, 860-864
 - condenser, 832
 - electro-dynamic (moving coil), 831, 833-851, 860-864
 - electro-magnetic, 831-832
 - balanced armature, 831-832
 - inductor dynamic, 832
 - reed armature, 831-832
 - piezo-electric (crystal), 832
 - direct radiators, definition, 831
 - directional characteristics, 834, 839-840, 856
 - directivity index, 875
 - distortion, 854-855, 868-871
 - cross-over, 856, 860-861, 868
 - frequency modulation, 855, 869
 - horn loudspeakers, occurring in, 854-855
 - inharmonic, 870
 - intermodulation, 871
 - non-linear, 836, 855, 868
 - phase shift characteristics, 838, 870
 - selective, below bass resonant frequency, 600-601, 868
 - sub-harmonics and sub-frequencies, 871
 - transient, 833, 869-871
 - effect of other characteristics on, 869-870
 - testing for, 870-871
 - decay characteristic (Shorter's method), 870-871
 - square wave, 870
 - tone burst, 870
 - unit impulse, 870
- dual and triple system loudspeakers, 860-861
 - choice of cross-over frequency, 860-861
 - co-axial and co-planar mounting, 860
 - compromise arrangements, 861
 - frequency dividing networks, 860, 887-889
 - integral dual systems, 860
 - integral triple systems, 860
 - overlap region, 856, 861
 - distortion in, 856, 860-861, 868
 - effects of unequal acoustical paths, 861
 - phasing of, 860
- efficiency, 839, 854-855, 860
- efficiency in terms of acoustical power, 875-876
- electro-dynamic (moving coil), characteristics of, 833-842
 - cone movement, amplitude of, 834
 - cones, practical, 834, 835-836, 839
 - corrugations in cones, 835-839

 - frequency modulation, 855
 - sound chamber, 855
 - suspension, non-linear, 855
 - throat, 854-855
 - driving units, 855
 - efficiency, 855, 860
 - efficiency and frequency range, relation between, 854-855
 - exponential, 851-853, 854
 - dimensions of, 852, 853
 - flare cut-off frequency, 852
 - flaring constant, 851, 852
 - minimum useful frequency, design on basis of, 852-853
 - folded, 856-859
 - concentric, 856-857
 - low frequency, 856-858
 - reflex, directional, 856-857, 867

Loudspeakers (continued)

- frequency limitations, 854
- high-frequency, 857-859
- hyperbolic cosine, 854
- hyperbolic exponential, 853-854
- hypex, 853-854
- impedance, electrical, 856
- multi-cellular construction, 858
- public-address, use in open air, 867
- rooms, use in, 856
- sound chamber, 854-855
- impedance characteristics, electrical, 837-838, 847-849, 856
- impedance, standard for sound systems, 874
- in operation, 861-867
- acoustical feedback, avoidance of, 866
- acoustics of rooms, 864-865
- background music in factories, 867
- effect of noise level, 867
- extension loudspeakers, 883-886
- loudspeaker placement, 865-867
- multiple loudspeakers, 867, 882-883
- Haas effect, 867
- time delay in, 866
- operation at long distances from amplifier, 886
- power required, indoors, 863-864
- absorption coefficient, 863
- chart-acoustical power to produce intensity 80 db v's room volume, 863, 864
- reverberation time, 863-864
- power required, outdoor, 861-863, 866, 867
- chart—intensity v's watts output at specified distances, 862
- public address, open air, 867
- sound reinforcing systems, 866-867
- sound systems (constant line voltage), 874, 883
- stereophonic reproduction, 865-866
- pseudo stereophonic effect, 866
- intercommunicating systems, 867
- ionic, 866-867
- line source, 866-867
- loudness directivity index, 875
- loudness efficiency rating, 875
- loudspeaker load with power amplifiers, 558, 566-567, 600-601, 881-882
- magnetic flux, effect on damping, 831, 840, 841
- magnetic flux, effect on efficiency, 831, 840
- magnetic flux, optimum for frequency response, 840
- magnets, types of, 831, 840
- electromagnet, 831, 840
- permanent magnet, 831, 840
- matching, 880-882
- matching Class A triodes, 881
- matching pentodes, 881-882
- metal cone, 836
- network between power valve and loudspeaker, 880-889
- optimum plate resistance, 880-881
- output expressed in decibels, in terms of acoustical pressure, 812
- power rating from standard distribution lines, 874
- pressure-frequency response (pressure level), 875
- pressure rating, 812, 862, 874
- rating impedance, 812, 874
- references, 876-879
- references to matching, extension loudspeakers and divider networks, 889
- reflections in rooms, effect of, 833, 841, 864-865
- room resonances, 841, 864-865
- sound system rating, 812-813
- sound impedance, effect of, 833, 840-841, 844-845, 848-849
- source impedance, effect of zero or negative, 841
- source impedance, measurement, 812, 874
- standards for loudspeakers, 874-876
- sound equipment, 874-876
- loudspeaker directivity index, 875
- loudspeaker efficiency in terms of acoustical power, 875-876

Loudspeakers (continued)

- loudspeaker impedance, 874
- loudspeaker loudness directivity index, 875
- loudspeaker loudness efficiency rating, 875
- loudspeaker measurement source impedance, 812, 874
- loudspeaker output expressed in decibels, in terms of acoustical pressure, 812
- loudspeaker power rating from standard distribution lines, 874
- loudspeaker pressure-frequency response (pressure level), 875
- loudspeaker pressure rating (pressure efficiency), 812, 862, 874
- loudspeaker rating impedance, 812, 874
- loudspeaker standard test signals, 874-875
- voice coil impedance for radio receivers, 874
- voice coil impedance for sound equipment, 883
- tests, listening, 632, 834
- throttled air flow, 832
- tweeter, 832, 860-861
- types of, 831
- vented baffle—*see under* Baffles and enclosures.
- vibration of walls etc., effects of, 864
- voice coil impedance for radio receivers, standard, 874
- Low level, definition, 1401
- Low-pass filter, definition, 172, 1401
- Lumen, 1334
- Luminous flux, unit of, 1334
- Lux (metre candle), 1334

M

- M.K.S. system, 1331, 1332
- Maclaurin's series, 299
- Magic eye tuning indicators, 1132-1136
- Magnetic and electric fields of wave, relation between, 897
- Magnetic and electrical units, 1331-1333
- Magnetic circuit theory, 229-233
- air loadline, 232
- BH characteristics, 230
- coercive force, 231
- flux density, 229
- flux, lines of, 229
- fringing, 231
- fundamental magnetic relationships, 229-231
- hysteresis loop, 230
- hysteresis loss, 230
- leakage flux, 231
- length of magnetic path, 242-243
- magnetic circuit, 231-232
- magnetic units and conversion factors, 232-233
- magnetization curve, normal, 231
- magnetomotive force, 229
- permeability, 230
- permeability, average, 231
- permeability, effective, 242-243, 244
- permeability, incremental, 230, 243, 248
- potential difference, magnetic, 231-232
- reluctance, 229
- remanence, 230
- remanent flux density, 230
- residual flux density, 230
- see also under* Transformers; Inductors, iron-cored.
- Magnetic field, energy stored in, 141
- Magnetic field of coil, kinetic energy of, 407
- Magnetic field of radiated electromagnetic energy, 404
- Magnetic field set up by inductor, 140
- Magnetic field, valves used in, hum due to, 785, 786, 788, 1198
- Magnetic recording, 701
- Magnetic units, 232-233
- Magnetization curve, normal, 231
- Magnetizing current in power transformers, 235
- Magnetizing force, measure of, 1332

- Magnetomotive force, 229
 Magnetomotive force, measure of, 1332
 Magnets, types of, in loudspeakers, 831-840
 Magnification factor, 144, 409, 424, 425
 see also under Q factor.
 Magnitude of complex quantity, absolute, 140
 Mains filters, 475, 1279-1280
 Mains operation, valve ratings for, 78, 79
 Mains voltage fluctuations, 10
 Mantissa, 256
 Manual, definition, 1401
 Marconiphone Model 12A pickup, 719
 Masking effect of noise, 620-621, 625, 629, 679
 Masking interference in F-M receivers, tests for, 1318
 Mass, units of, 1329, 1332
 Matching and effects of mismatching, push-pull
 pentodes, 584
 triodes, 580-582
 Matching generator to load, section of transmission line for, 892
 Matching, impedance, in networks, definition, 160
 Matching loudspeakers, 880-882
 Matching of load with Class A₁ power triode, 61
 Matching of medium wave-band coils, 462-463
 Matching of short-wave coils, 468-471
 Materials, ferromagnetic, 458-459
 Materials for tropic-proofing coils, 477-478
 Materials, properties of, 1372-1376
 Mathematical signs, 1366
 Mathematics (Chapter 6), 254-305
 Maximal flatness feedback amplifiers, 367, 378, 382-385

 Maximum grid circuit resistance—*see under* Grid circuit resistance.
 Maximum negative grid currents of valves, 101-102
 Maximum power output, distortionless valve, 46, 60-61
 Maximum power transfer theorem, 165
 Maximum ratings, value
 absolute maximum system, 9, 75-80
 design-centre system, 9, 77-80
 see also Valve ratings.
 Maximum signal, definition, 1401
 Maximum undistorted power output, definition, 1298, 1315, 1401
 Maximum value of function, conditions for, 292
 Maxwell, 229, 1332, 1333
 Mayr's method of designing feedback amplifiers with flat frequency response, 379-382
 McIntosh amplifier, 594-596
 McProud test of pickup and arm, 715
 Mean frequency, geometrical, 130
 Mean geometrical progression (geometrical mean), 266-267, 272
 Mean proportional, 272
 Measurements—*see under* Tests and measurements.
 Medium of transmission of a wave, 403
 Medium wave-band coils, design of, 459-463
 Medium wave-band coils, matching of, 462-463
 Mercury, pressure due to, 1330
 Mercury vapour rectifiers, 1161, 1164, 1165
 Mesh, definition, 159
 Metallized paper dielectric condensers, 195
 Meters for testing receivers, 1300
 Metre, measure of length, 1329, 1332, 1333
 Metric ton, 1329
 Mho, 1332, 1333
 Mho per centimetre cube, 1332
 Mica dielectric condensers, 196
 Mica, silvered, condensers, 196
 Microgroove recording, 701
 Micron, measure of length, 1329
 Microphones, 775-782
 carbon, 775, 777-778
 ceramic piezo-electric, 779
 condenser, 778
 crystal, 775, 778-779
 crystal, optimum load for definition, 788
 781
 Microphones (continued)
 directional characteristics, 779-780
 bi-directional, 779, 780
 cardioid, 780
 non-directional, 780
 poly-directional, 780
 uni-directional, 780
 directional pattern, standard for, 781
 effective output level, 776
 equalization of, 781
 field response, definition, 781
 impedance, electrical, 781
 impedance, nominal, 781, 782
 lapel, 780
 lip, 780
 moving coil (dynamic), 775, 779
 output expressed in decibels, 808-810
 output voltage and sound pressure, relation between, 775
 pre-amplifiers, for use with, 788-793
 pressure gradient, 775
 pressure operated types, 775
 pressure ribbon, 775, 779
 rating impedance, 781, 809
 ratings, 776-777
 power, 776
 relationship between voltage and power, 776-777
 system rating, R.M.A., 776, 809-810, 812-813
 typical, 777
 voltage, 776
 volume units, 776
 references, 804
 sound pressure with conversational speech, 775
 standards for, 781-782
 throat, 780
 transformers, 781
 velocity operated types, 775
 velocity ribbon, 775, 779
 Microphonic, definition, 1401
 Microphony
 in a-f amplifiers, tests for, 1311, 1324
 in receivers, tests for, 1311, 1312
 in valves, 73, 84, 786, 957-959, 1241-1242
 in valves, tests for, 74, 107, 113, 121
 other than valves, 1241-1243, 1250-1251, 1253, 1256, 1311
 Mil, measure of length, 1329
 Miller effect, 51, 52, 70, 493-494, 512, 598, 923, 1062, 1157
 Minimum value of function, conditions for, 292
 Minimum volume effect in reflex receivers, 1141, 1142
 Mirror image, definition, 1401
 Mistuning in F-M receivers, tests for, 1320
 Mixed coupling in i-f transformers, 1025, 1044-1048

 Mixer, definition, 1401
 Mixers and faders, 798-805
 constant impedance mixers 801-804
 bridge type, 802
 choice of mixer circuit, 803
 coil mixing, 802
 parallel type, 801-802
 precautions with studio type mixing systems, 803-804
 series type, 802
 series-parallel type, 802
 electronic fader mixer using 6BE6, 797-798
 fader, definition, 799
 insertion loss of, 799
 mixing, definition, 799
 non-constant impedance, 798-801
 common plate load method, 799-800
 control of volume with, 800-801
 parallel network mixer, 799
 series network mixer, 799
 series network mixer, modified, 799
 references, 805
 Mixers, operation of frequency converters and, 962-1001, 1017-1019
 Modulation, anti-, bass frequency, 1116

Modulation, definition, 1401
 Modulation distortion, cross, 945, 1114
 Modulation, downward, in F-M receivers, tests for, 1320
 Modulation envelope distortion, 944-945
 Modulation hum, 1198, 1199, 1239-1241, 1267, 1268, 1290, 1309, 1314
 Modulation of electron stream by magnetic field of filament, hum due to, 1196, 1197
 Modulation of groove in recording, 702
 Modulation percentage applied to detector 1078
 Modulation ratio, critical, in diode detectors, 1076-1077, 1081
 Modulation, reduction in percentage, in reflex receivers, 1143
 Modulation rise in i-f amplifiers, 1112, 1114, 1117, 1118, 1232
 Modulation, standard test, in F-M receivers, 1314
 Modulation systems as d-c amplifiers, 532
 Modulation, systems of, 405-406
 Modulator valve (mixer), 962
 Modulus of complex quantity, 140, 285
 Molecules, 1
 Monaural, definition, 1401
 Monkey chatter, 1303-1304, 1305
 Motorboating, definition, 1401
 Motorboating in a-f amplifiers, 535, 537
 Mounting position for valves, 4, 80
 Moving coil (dynamic) microphones, 775, 779
 Moving coil loudspeakers, 831, 833-851, 860-864
 Mu-factor, definition, 14
 Mu-factor, plate to screen, 35-36
 Mu-factor, screen to control grid, 35
 Mu-factors, interelectrode, 73
 Multi-cellular horns, 858
 Multi-grid valves as r.c.c. amplifiers, 516
 Multi-grid valves in volume expanders, 685, 691-692
 Multi-grid valves, power, Class A, 560-570
 Multi-stage voltage amplifiers, 541
 Multiple channel amplifiers for tone control, 673-674, 676
 Multiple feedback system, 365, 374-378
 Multiple loop feedback amplifiers, 375

 Roll-off, definition, 1402
 Roll-off frequencies in a-f amplifiers, high, 631
 Room noise, 620-621, 625
 Room resonances, 841, 864-865
 Rooms, acoustics of, 864-865
 Root mean square, 134, 1298
 Roots, 255, 261
 Routh-Hurwitz criterion of stability, 356
 Rumble filters, 744-749
 Rumble in phonograph combinations, tests for, 1312
 Rumble in record reproduction, 705, 706, 744, 1312

S

 S-meter, 1263
 Sabin, definition, 863
 Safety margin in feedback amplifiers, 359, 367, 368, 372
 Saw-tooth waves, 130, 301
 Scalar, definition, 1402
 Scales, musical, 873-874
 Schmitt phase inverter, 526, 670
 Scientific notation in arithmetic, 255
 Scott dynamic noise suppressor, 764
 Screen and bias stabilized amplifier, 214, 636, 655-658, 737-738, 746-751, 763
 Screen and cathode by-passing of r.c.c. pentode, incomplete, attenuation and phase shift characteristics, 498-500
 Screen by-pass r.c.c. pentode, 496-499
 Screen by-pass, r-f, series resonant, 944, 1289, 1291
 Screen by-passing, attenuation slope and phase angle, 360-361
 Screen by-passing of r.c.c. pentode, incomplete, attenuation characteristics, 496-497
 Screen by-passing of r.c.c. pentode, incomplete, phase shift/frequency characteristics, 489-499
 Screen characteristics of pentode, 16-17
 Screen circuit decoupling, 537
 Screen, concentric, effect on inductance of coils, 438-441, 444, 473
 Screen-coupled cathode follower, 326, 532
 Screen-coupled direct-coupled amplifier, 532
 Screen current, average, push-pull Class A, AB₁, pentodes, 584
 Screen current, Class A pentode, 562
 Screen current test, 103, 109, 113
 Screen dissipation, Class A pentode, 562
 Screen grid of tetrode or pentode, 7
 Screen loadlines, 513-514
 Screen regeneration in converters, 988-989
 Screen reflex superhet. receivers, design of, 1145-1146
 Screen series resistor, r.c.c. pentode, de-termination of, 505-506
 Screen source regulation, effect on power amplifiers, 562
 Screen stopper, type, 807, 563
 Screen stoppers, general, 91, 1283
 Screen supply from voltage divider, r.c.c. pentode, 506
 Screen supply, r.c.c. pentode, 496
 Screen to control grid amplification factor, 35
 Screen transconductance, 34
 Screen voltage, low, operation at, 84
 Screen voltage supply, valve ratings for, 79
 Screening, electrostatic, in power transformers, 233, 786, 1198, 1279
 Screening, electrostatic, to reduce hum, 784
 Screens around coils, design of, 466, 473
 Screw threads, 1388-1391
 American screw threads, 1388
 B.A. screw threads, 1389
 self-tapping screws, drill sizes for, 1391
 unified screw threads, 1390

- Screw threads (continued)
 Whitworth screw threads, 1389
 wood screws, 1391
- Scroggie's method for a.v.c. characteristics, 1114, 1232
- Secant of an angle, 272
- Second, measure of time, 1332
- Secondary emission, 2, 7, 8, 21, 39, 69, 71
- Sectionalized windings in transformers, 221-223
- Sector of circle, 273-274
- Selectivity,
 adjacent channel, F-M, 1040
 curves, universal, 421-422
 curves, universal, applications of, 1027,
 1031, 1035, 1055
 expanding, 455-456, 1048-1050, 1260, 1262
 graphical methods, 416-417
 single tuned circuit, 416-417
 two identical coupled tuned circuits, 417
 of aerial stages, 917-918, 920
 of A-M receivers, adequate, 1040-1041
 of coupled circuits of equal Q , 415-416, 426
 of coupled circuits of unequal Q , 416, 426
 of coupled circuits—tuned primary,
 tuned secondary, 414-415, 426
 of coupled circuits—tuned secondary,
 413-414, 425
 of identical tuned circuits in cascade, 421
 of i-f amplifiers, 1026-1028, 1031-1033,
 1035-1037
 of single tuned circuit (series and
 parallel), 412-413, 425
 of superregenerative receiver, measur-
 ing, 1087
 of variable bandwidth crystal filters,
 1055-1056
 tests in receivers, 1303-1305, 1318
 variable, i-f, 455-456, 1048-1050, 1260, 1262
- Selenium rectifiers, 1169
- Self-bias operation—*see under* Cathode
 bias.
- Self-rectifying vibrators, 1203, 1204
- Semi-infinite straight line, definition, 362
- Sensitivity, deviation, tests for, 1317
- Sensitivity, maximum-deviation, tests for, 1317
- Sensitivity of power amplifiers, definition, 545
- Sensitivity, power, Class A triode, 559
- Sensitivity, quieting-signal, test for, 1317
- Sensitivity tests on A-M receivers, 1302-1303
- Sensitivity tests on F-M receivers, 1317
- Series arm of network, definition, 159
- Series combinations of L , C and R , 144-147
- Series, condensers in, 135
- Series connection of batteries (cells), 129
- Series, definition, 1402
- Series expansion: general case, 63
- Series expansion: valve with resistance
 load, 61-62
- Series, Fourier, 299-302
- Series impedance of tuned circuit, 409
- Series in algebra, 266-267

- Series, infinite, 268-269
- Series, Maclaurin's, 299
- Series-parallel combinations of L , C and
 R , 149-153
- Series, reactance and resistance in, im-
 pedance of—tables and charts 1382-1385
- Series, resistances in, 131-132
- Series resistors, electrode voltages sup-
 plied through, 70
- Series resistors to limit rectifier current,
 1165, 1173
- Series resonance, 145, 409, 412, 424
- Series, Taylor's, 298
- Series to parallel impedance, conversion
 from, 157-158
- Service tester practice, 121-125
- Service testers
 a.c. versus d.c. test voltages, 124
 characteristics which should be tested,
 methods of testing in, 123-125
 types of commercial, 122-123
 Service testing of valves, 121-125
- Sheet metal gauges, 1393
- Shellac pressings, 701, 704-708
- Shielding a-f transformers to reduce hum,
 207, 210-211, 781, 784, 1198
- Shielding of leads, magnetic, in pre-ampli-
 fiers, 786
- Short-circuit, definition, 1402
- Short-circuit feedback admittance, 50-55
 tests for, 117
- Short-circuit feedback admittance,
 methods of increasing in i-f amplifiers, 1064
- Short-circuit forward admittance, 50-55
 tests for, 117
- Short-circuit interelectrode admittances, 69
- Short-circuit input admittance, 50-55
 tests for, 113-117
- Short-circuit input capacitance, change of,
 with transconductance, 55
- Short-circuit input conductance, typical
 values of, 55
- Short-circuit output admittance, 50-55
 tests for, 117
- Short-circuits, interelectrode, tests for,
 73, 91-93, 123
- Short-wave coils, design of, 463-468
 charts, 466-473
- Short-wave communication, long dis-
 tance, 404, 901
 forecasting frequencies for, 404, 901
- Shorter's method of testing for loud-
 speaker transients, 870-871
- Shot effect noise, 783, 787, 936-938, 1230
- Shunt arm of network, definition, 159
- Shunt capacitance coupling in i-f trans-
 formers, 1023-1024
- Shunt, definition, 1402
- Shunt diode bias supplies, 1188-1191
- Sibilant speech sounds, distortion of,
 with volume compression, 683
- Sideband cutting in receiver, equalization
 of, 654
- Sideband, definition, 1402
- Side-chain amplifier in volume expansion,
 686
- Side frequency, definition, 1402
- Side-thrust on grooves of record, 723, 726-727
- Siemens, 1332
- Signal circuits, padded, 1013-1017
- Signal generator, standard, 1298-1299,
 1315-1316
- Signal strength meter, 1263
- Signal to noise ratio in microphone pre-
 amplifiers, 788, 793
 maximum possible, 788
 standard, in pre-amplifiers for broad-
 casting, 793
 with crystal microphones, 788
- Signal to noise ratio in record reproduc-
 tion, maximum, 704-705, 766, 770
- Signal voltage, definition, 1402
- Silicon crystal detectors, 1137
- Silvered mica dielectric condensers, 196
- Simple harmonic motion, 278-279, 702
- Sine of an angle, 272, 275
- Sine wave alternating current, 129, 130, 278
- Sine wave, average (r.m.s.) by definite
 integrals, 298
- Sine wave, derivative and integral of,
 130
- Sine wave, distorted, 130
- Sine wave, fundamental, 130, 299-300
- Sine wave, harmonic frequency, 130, 300
- Sine wave, rectified, 130, 302
- Single channel sound system vs. dual
 channel, 627
- Single time constant circuit, 359
- Sinking diode circuit, 1108, 1117, 1257, 1295
- Sinusoidal, definition, 1402
- Skating, groove, 710, 713
- Sky (space) wave, 404, 896, 897
- Slide rule, 257-258
- Slide rule, special calculations on, 258, 822-823
- Sliding screen, effect on gain, 28-29
- Slope, negative, 25, 289
- Slope of bass boosting frequency charac-
 teristics, maximum, 642
- Slope of curve, 280, 289-291
- Slope of dynamic characteristic, r.c.c.
 pentode, 506, 507-508

- Slope of mutual characteristic, 17
 Slope, rate of change of, 289-291
 Small compared with, definition, 1402
 Sockets, octal, use of pin No. 1, 81
 Sockets, valve, connections to, 80, 81
 Soft valve, definition, 1402
 Soldering, effect on composition resistors, 188, 1345, 1346
 Soldering valves into wiring, 81
 Solenoids, multilayer, design of, 443-444
 Solenoids, multilayer, inductance of, 441-444
 Solenoids, single layer, calculation of self-capacitance, 451-452
 Solenoids, single layer, design of, 443-445
 Solenoids, single layer, inductance of, 429-441
 Solids, surfaces and volumes of, 275
 Sound chamber in horn loudspeakers, 854-855
 Sound, critical frequency bands, 621-622
 Sound equipment, loudspeakers, standards for, 874-876
 Sound level and noise, measurement of, 827-880
 acoustical noise measurement, 827
 electrical noise measurement, 827
 noise in amplifiers, measurement of, 829-830
 broadcast systems, 829
 sound equipment, 829
 noise level, definition, 829
 noise level, weighted, standard, 829
 objective noise meter, 828
 radio noise, measurement of, 829-830
 radio noise meter, 829-830
 references, 830
 sound level meter, American standard, 828
 sound levels, typical—table, 828-829
 weighting network for measurements, 827-828
 Sound level and peak acoustical power, difference between, 623
 Sound level—*see also under* Volume level.
 Sound levels, nomogram for adding two component, 821-822
 Sound levels, preferred listening, 623
 Sound or film, 701
 Sound pressure with conversational speech, 775
 Sound reinforcing system, 866-867
 Sound, reproduced, imagery for describing, 604-605
 Sound system, complete, 810, 812-813
 Sound system rating, 812-813
 Sound system, single channel vs. dual channel or stereophonic, 627
 Sound systems, constant line voltage, 874, 883
 Sound, velocity and wavelength of, 872
 Sound waves, 403
 Source impedance, effect of zero or negative, on loudspeakers, 841
 Source impedance for pre-amplifiers, standard, 793
 Source impedance, loudspeaker measurement, 841
 Space charge, 3, 71
 Space charge, coupling in converters, 963, 975-977, 980
 Space charge, effect on input capacitance, 51
 Space charge tetrodes as power amplifiers, 569
 Space current, 70
 see also Cathode current.
 Space current, definition, 1402
 Space, intrinsic resistance of, 897
 Space (sky) wave, 404, 896, 897
 Spark plates in car radio, 1277
 Specification for power transformers, 241
 Specifications for a-f transformers, 228
 Specifications for motor and turntable unit, 705
 Speech and noise, references, 634
 Speech articulation, 628-629, 630
 Speech clippers, 693-694
 Speech, compression of, 684
 Speech, conversational, sound pressure with, 629
 Speech, declamatory, 629
 Speech, masking by noise, 628
 Speech peak dynamic range, 628
 Speech power, 628
 Speech reproduction, 628-630
 Speech reproduction, distortion in, 629
 Speech reproduction, frequency ranges for, 630
 Sphere, 275
 Spider cone suspension, 835
 Spirals, flat, inductance of, 445-446
 Split-reed synchronous vibrators, 1204
 Spurious frequencies
 formed by intermodulation distortion, 62
 from converters, 62, 987, 995, 1247
 in A-M receivers, 1116, 1278-1279
 tests for, 1310
 spurious response ratio, 1310
 image response, tests for, 1310
 image ratio, tests for, 1310
 in F-M receivers, 1112, 1294, 1295, 1310, 1319
 Spurious radiation in F-M receivers, open field method of measurement of, 1320
 Spurious-response ratio, 1310
 Spurious responses—*see under* Spurious frequencies.
 Sputter in rectifier valves, 100
 Sputtering, 3
 Square wave testing for loudspeaker transients, 870
 Square wave testing of a-f amplifiers, 1324
 Square waves, 130, 301, 870, 1324
 Squeals (squeaks) in A-M receivers, 1246, 1312
 Squegging, 958, 992, 1
 Squelch systems, 1125-1130
 Stability factor (Becker), 388
 Stability in a-f amplifiers, tests for, 1324
 Stability in feedback amplifiers, 356-378
 see also under Feedback.
 Stability in i-f amplifiers, 1065-1067
 Stability in r-f amplifiers, 942-944
 Stability in voltage amplifiers, 535-538
 Stability margin in feedback amplifiers, 359, 367, 368, 372
 Stability of composition resistors, 186
 Stability of electrical characteristics of valves, 69, 70
 Stabilization, frequency, 957-958, 992-996
 Stabilized amplifier, bias and screen, 593-594
 Stacking factor in power transformers, 235
 Stage gain, test for, 74, 108
 Stagger tuning of i-f transformers, 1026
 Staggering attenuation characteristics of feedback amplifiers, 364-365, 367, 382-385
 Stand-by operation of valves, 84
 Standard a.c. waveform, 130
 Standard distribution lines, loudspeaker power rating, 874
 Standard test signals, loudspeaker, 874-875
 Standards, American recording, 702
 Standards for loudspeakers, 874-876
 Standards for microphones, 781-782
 Standards for pre-amplifiers, 793
 Standards for vibrator power transformers, 1207
 Standards for vibrators for auto-radio, 1205
 Standing-wave ratio of transmission lines, 891
 Standing waves in enclosed cabinets, 843
 Statampere, 1332, 1333

 transfer characteristics, 17
 with feedback, 390-399
 Valve characteristics (Chapter 2), 8, 13-67
 activation of cathode, 69
 amplification factor, 13, 72
 effective, with feedback, 311, 313, 314, 315, 316
 graphical determination, 15, 16, 18
 arcing in rectifier valves, 100
 calculation of, other than published, 40-42
 capacitance grid-plate, 7
 capacitances, interelectrode, 73
 cathode current, total available average, 73
 cathode current, total available peak, 73
 cathode current—*see also under* Space current.
 cathode follower, equivalent characteristics, 318
 change in operating conditions, effect of, 42-44
 characteristic parameters, derived, 72
 conductance, definition, 14
 contact potential, general—*see under* Contact potential.
 contact potential (grid-cathode), 18, 20, 39, 69, 70, 85-89
 control during manufacture, 36-40, 57, 493, 511, 568
 conversion factors, 36-40, 57, 493, 511, 568
 conversion transconductance, definitions and basis of, 14, 109, 964-967
 distortion in—*see under* Distortion.
 drift of characteristics during life, 23-24, 70, 84, 530, 533
 durchgriff, definition, 14
 dynamic characteristics of pentode, 26-27, 72, 503-506
 dynamic characteristics of triode, 25-26, 72, 491
 effect of heater voltage on characteristics, 24
 emission, thermionic, 2, 3, 69
 equivalent electrode voltage, 71
 figure of merit for r-f amplifier valves, 927
 filament dissipation and temperature characteristic, 10, 11
 filament voltage/current characteristic, 10, 11
 filaments on a.c. supply, 6
 functional characteristics, basic, 70-73
 fundamental physical properties, 69-70
 gas current, 3, 19, 51
 gas pressure, 73
 grid blocking, 21, 84
 grid circuit resistance, maximum—*see under* Grid circuit resistance, maximum.
 grid current characteristics, 18-21
 grid current cross-over point, 19, 20
 grid current commencement point, 19, 84
 grid current, maximum negative, typical values, 101-102

- Valve characteristics (continued)
- grid current, negative, 3, 19, 21, 51, 101-102, 484, 488
 - grid current, positive, 18, 21, 51, 484, 489
 - grid current, positive, damping due to, 489
 - grid emission, 3, 5, 20, 21, 51
 - grid input admittance, 49-53

 - ratings for storage battery operation, 78, 79

Valve ratings and limiting effect on operation (continued)
 screen voltage supply, 79
 specific additional electrical ratings applied to particular types, 76-77
 tolerances in characteristics, 9, 15, 88
 typical operating conditions, 80
 Valve sockets, connections to, 80, 81
 Valve test specifications
 basic manufacturing test specification, 85
 characteristics, 75-77, 85, 86
see also under Valve ratings.
 grid current, negative, typical values, 101-102
 life test, 75, 85
 mechanical and electrical tests, 85
 quality control, 85
 ratings—*see under* Valve ratings.
 Valve vectors, 47-49
 Valve wiring jig, 80
 Valves for use in pre-amplifiers, 786-788
 Valves, fundamental physical properties of, 69-70
 Valves, glass-based, sockets and connections for, 80, 81
 Valves, hum due to conditions within, 81, 84, 540, 1196-1198
 Valves, in magnetic field, hum with, 785, 786, 788, 1198
 Valves in receiver, position of, 957
 Valves, low noise types, 786-788
 Valves, mounting position for, 4, 80
 Valves, recommended practice and operation, 80-84
 Valves, soldering into wiring, 81
 Valves, stand-by operation of, 84
 Valves, testing of (Chapter 3), 68-127
 acceptance testing, 120
 admittance, short-circuit feedback, 117
 admittance, short-circuit forward, 117
 admittance, short-circuit input, 113-117
 admittance, short-circuit output, 117
 amplification, a.c., 74, 105, 124
 amplification factor, 74, 104, 113
 back emission, 74, 100
 basis of testing practice, 68, 84
 beam tetrode characteristics, specific, 101-108
 blocking, 107-108, 113
 capacitances, interelectrode, tests for, 73, 95-99
 characteristics by curve tracer methods, 119-120
 characteristics by display, 120
 characteristics by pulse methods, 118-119
 control of characteristics during manufacture, 85-89
 conversion stage gain, 74
 conversion transconductance (mixer), 74, 109-111, 124
 converter characteristics, specific, 108-113
 methods of operation, 108-109
 oscillator driven, 109
 oscillator self-excited, 108-109
 static operation, 109
 dimensions, physical, 91
 diode characteristics, specific, 99-101
 diode plate current, zero signal, 100
 display of valve characteristics, 120
 dissipation of electrodes, 108
 distortion in power amplifier valve, 106-107
 electrode continuity, 73, 91-93, 123
 emission, 73, 94-95, 123
 emission-dependent dynamic test, 73
 filament voltages, lowest used for testing battery valves, 1313
 fundamental characteristic tests, 73-75
 fundamental physical properties, 69-70
 gas current, 101, 102
 grid current, commencement voltage, test for, 73, 102, 109
 grid current, negative (reverse) tests for, 73, 101-102, 109, 124
 typical maximum values in new valves, 101-102
 grid current, positive, tests for, 73, 102
 grid emission (primary), 101, 102
 grid emission (secondary), 102

Valves, testing of (continued)
 grid leakage current, hot and cold, 101, 102
 heater or filament current, 93-94
 heater to cathode leakage, 73, 94, 123
 hexaphase shorts and continuity test, 91-93
 interelectrode insulation resistance, 73, 94, 102
 life test end points, 88-89
 life tests, 75, 85, 87-88
 methods of testing characteristics, 89-120
 general conventions, 90-91
 microphony, 74, 107, 113, 121
 mixers (frequency changers), 109-113
 mixer conversion transconductance, 74, 109-111, 124
 mixer plate resistance, 111
 mixer transconductance, 111
 mutual conductance (transconductance grid-plate), 74, 103-104, 113, 123, 124
 noise, valve, 74, 107, 113, 124
 open-circuited electrodes, 73, 91-93, 123
 oscillator characteristics, 113
 oscillator grid current, 74, 111-112
 oscillator performance, 111-112
 oscillator transconductance, 74
 pentode characteristics, specific, 101-108
 permeance of diode, 117-118
 permeance of triode, 118
 physical dimensions, 91
 plate conductance, 124
 plate current commencement, 74
 plate resistance, 74, 104-105, 111, 113

CHAPTER 7

NEGATIVE FEEDBACK

SECTION 7: OVERLOADING OF FEEDBACK AMPLIFIERS ON TRANSIENTS

Negative-feedback amplifiers often distort a signal, such as a pulse, which changes rapidly with time, although the amplitude of the signal is less than that required to overload the amplifier when the rate of change of the signal is small. This is because the feedback voltage changes more slowly than the input voltage, with the result that the voltage applied to the grid of one of the valves becomes large enough to drive it into grid current or beyond cut-off.

The case of a cathode follower with a capacitive load has been covered in Sect. 2(i)(Y) page 327.

The design of single-stage, two- and three-stage resistance-coupled amplifiers is covered in Ref. J3, with curves, of which the following is a summary. In single stage amplifiers the magnitude of signal required to overload the valve decreases as the rise-time of the signal is reduced. In two-stage amplifiers, the voltage applied to the first valve increases as the rise-time of the signal is reduced, but only if the gain of the amplifier is very small is it possible for the first valve to be overloaded by a signal which does not also overload the second valve. The second valve is, therefore, normally the first to overload. If the time-constant of the first stage is sufficiently large compared with that of the second stage, the input signal required to overload the second valve does not decrease as the rise-time of the signal is reduced. In three-stage amplifiers, the voltage applied to the third stage is never greater for a quick change than for a slow change. Therefore, if the first two stages are designed not to overload, the signal required to overload the amplifier is as large when it changes quickly as when it changes slowly.

See also Ref. J10.

CHAPTER 15

TONE COMPENSATION AND TONE CONTROL

Additional Tone Control Circuit

(see page 669)

FIG. 15.57 C

Fig. 15.57C. Tone control circuit. Tolerances $R_1, R_2, C_1, C_2, R_3, C_3 \pm 5\%$. P_1 and P_2 are linear potentiometers, P_2 having a fixed tapping at 50% rotation. The source impedance should not be more than 10,000 ohms. C_4 should normally be $0.05\mu\text{F}$ if following stage has $0.25\text{ M}\Omega$ grid leak (Ref. 91). Type 6AU6 could be used as substitute for the type shown, with suitable values of cathode and screen resistors, to give an output of about 2 V r.m.s.

FIG. 15.57 D

Fig. 15.57D. Measured frequency response curves of circuit of Fig. 15.57C. Labels on curves are resistance values between potentiometer slider and centre of element. Dotted curves are with P_2 centre-tap disconnected from earth and with one $0.33\text{ M}\Omega$ resistor connected from each end of P_2 to earth (Ref. 91).

CHAPTER 17

REPRODUCTION FROM RECORDS

DISCS AND STYLII (Continued from page 709)

(D) R.C.A. 45 r.p.m. Extended Play (EP) records

These records have a maximum playing time of 7.9 minutes and the following characteristics:

Grooves per inch, normal max.	300
Peak recording velocity	14 cm/sec.
Diameter innermost music groove	4½ in. min.
Groove width	2.5 to 3.0 mils
Minimum permissible groove width	2.2 mils

The lead-out groove is reduced in length due to the smaller ending diameters. All other factors (except intermodulation distortion and groove velocity) as shown on pages 708 and 709. For shorter selections (3 to 4 minutes or so) the number of grooves per inch is selected to bring the last music groove to 4.875 inches, and the lead-out groove is as described on pages 708 and 709. For longer selections the number of grooves per inch is gradually increased and minimum recording diameter decreased simultaneously to the limiting values stated above.

SECTION 5 (i) Standard Playback Curve

(Continued from pages 731-732)

The original AES Standard Playback Curve (Fig. 17.15A) has now been revised, and the new curve (Fig. 17.15D Curve B) has been adopted by the RIAA, AES, NARTB (transcriptions) and leading American phonograph manufacturers. The original curve is also shown as Curve A in Fig. 17.15D to enable a direct comparison to be made.

This curve may be duplicated on a flat amplifier by the RC network of Fig. 17.15E following a triode, or that of Fig. 17.15F following a pentode.

The history and details of the new curve are given by Moyer (Ref. 346).

Fig. 17.15D. (A) Old AES Standard Playback Curve ; (B) New RIAA—AES—NARTB—RCA New Orthophonic Standard Playback Curve (RT14).

Fig. 17.15E. Equalizing circuit following a triode (RT15).

Fig. 17.15F. Equalizing circuit following a pentode (RT16).

ADDITIONAL STANDARD FREQUENCY TEST RECORDS

(Continued from pages 753-757)

LXT 2695 Decca Microgroove Frequency Test Record

This record has been cut at 33-1/3 r.p.m. with the groove width, at the top, of 0.0037 of an inch (0.95mm) with an included angle of $90^\circ \pm 1^\circ$ and a radius at the bottom of the groove of less than 0.0003. The recording is from outside to inside in bands of constant frequency and in the following order :—

15 Kc/s (+ 12.5 db); 14 Kc/s (+ 13.1 db); 13 Kc/s (+ 12.9 db); 12 Kc/s (+ 12.0 db); 11 Kc/s (+ 11.5 db); 10 Kc/s (+ 10.5 db); 9 Kc/s (+ 10.1 db); 8 Kc/s (+ 9.2 db); 7 Kc/s (+ 8.5 db); 6 Kc/s (+ 7.3 db); 5 Kc/s (+ 5.9 db); 4 Kc/s (+ 4.6 db); 3 Kc/s (+ 3.6 db); 2 Kc/s (+ 1.9 db); 1 Kc/s (0 db); 500 c/s (- 2.3 db); 250 c/s (- 6.6 db); 125 c/s (- 9.0 db); 60 c/s (- 11.7 db); 40 c/s (- 13.9 db).

The recorded velocity at 1,000 cps is 1.2 cm per sec. r.m.s. These levels are accurate to within + or - 0.5 db.

This record should be played with a pickup using a point radius of 0.001 of an inch and with a vertical force of not greater than 10 grams.

CHAPTER 19

UNITS FOR THE MEASUREMENT OF GAIN AND NOISE

(iii) Loudness Units (Continued from page 827)

The **sone** is commonly used as an alternative to the loudness unit, 1 sone being equal to 1000 loudness units. The solid curve in Fig. 19.9 is the A.S.A. Standard, as in Fig. 19.8. The broken curve is the relationship between subjective loudness

and loudness level in phons as determined by Garner (Ref. 46) and is scaled in lambda (λ) units to distinguish it from the present standard system. The difference between the two curves is very great.

RT17

Fig. 19.9. Relationship between loudness in sones (solid curve) or in lambda units (broken curve) and loudness level in phons (RT17).

CHAPTER 20 LOUDSPEAKERS

SECTION 3 : BAFFLES AND ENCLOSURES

(Continued from page 850)

(C) Special types of vented baffle loudspeakers

(1) The Baruch and Lang loudspeaker

The Baruch and Lang loudspeaker employs four 5 inch loudspeakers in an enclosure with a volume of only half a cubic foot and is claimed to radiate 0.1 acoustic watt at 3% distortion, with an input of 2 watts and an efficiency about 5%. The response is claimed to be flat ± 3 db from 40 to 12,000 c/s, and the high frequency angular

dispersion is 75° . It is a modified acoustical phase inverter (vented baffle) with an array of small holes on one side to provide the requisite port area—15 holes each $15/32$ inch diameter spaced $2\frac{1}{4}$ inches apart. There is an internal baffle with 21 holes spaced 2 inches apart. These holes provide acoustical resistance to damp down the system resonance to the most desirable degree. In addition, it is claimed that, because the holes are distributed over a large area, the radiation impedance of the array is equivalent to that of a 21 inch cone.

The speakers employed are standard low-cost replacement units, modified to meet the requirements of the system. The optimum dimensions of cabinet and holes, as well as the configuration of holes and the speaker array, are determined by the characteristics of the particular speakers used.

This is a most interesting high-fidelity loudspeaker and enclosure which has been designed to bring the cost within reach of those with limited means—a commercial model is now selling in U.S.A. for less than 20 dollars.

Refs. 202, 311, 316.

(2) Additional Notes on the R-J loudspeaker (from page 850)

When one speaker is intended to handle a wide frequency range, the central portion of the cone must not be obstructed by the frontal board; an oval or lemon-shaped opening may be used. The loudspeaker is mounted on a "speaker board" which is mounted a short distance behind the frontal board. By decreasing the spacing between these two boards, it is possible to lower the Q of the system. Usually apertures are provided between the speaker board and the frontal board on two sides only, the remaining two sides being blocked up. These two apertures should feed in where the frontal board projects furthest over the cone, thus giving maximum front loading on the cone. One effect is to reduce the resonance of the system considerably below the speaker resonant frequency. When properly designed and adjusted, the system is well damped and remarkably free from frequency doubling, even below the system resonance.

Refs. 189, 190, 219, 234, 246, 247.

(3) The Karlson Exponential Slot enclosure

This is totally enclosed except for an exponential form of slot in front. The enclosure is divided into two chambers by a partition on which the loudspeaker is mounted and which includes a port joining the two chambers. The front chamber includes the exponential slot, with the smaller dimension near the top of the cabinet, while the back chamber is enclosed and has some acoustical padding.

Refs. 214, 288 (latter gives dimensions).

CHAPTER 27

DETECTION AND AUTOMATIC VOLUME CONTROL

LOW DISTORTION A-M DETECTOR

A low-distortion A-M detector has been developed by W. T. Selsted and B. H. Smith (Fig. 27.56). This consists of a conventional diode rectifier direct-coupled to a cathode follower which is in turn connected to an r-f filter to reduce the carrier signal output. The excellent performance of this circuit is due to two facts:

1. That the load on the diode for normal A-M carrier frequencies is essentially resistive, and the normal effects of excessive shunting capacitance are eliminated.

2. That, since the coupling to the cathode follower is direct, there is no effect of biasing currents which are normally developed in a diode loading circuit using coupling condensers. The distortion for 100% modulation, as shown in Fig. 27.57, is claimed to be 0.3% at a modulating frequency of 420 c/s and 0.8% at 4000 c/s. The carrier input voltage and frequency are not stated.

TABLES, CHARTS AND SUNDRY DATA

Sect. 3 (xi) (F) British Radio Industry Council (page 1360) add after F5 :—
F5a.RIC/131/B. Capacitors, fixed, paper dielectric, foil, in rectangular metal cases.

Additional definition

Maximum output (in receivers). The greatest average output power into the rated load regardless of distortion.

ADDITIONAL ITEMS

Neutralizing circuits (reference to page 1065)

These circuits in Figs. 26.19 and 26.21 are strictly not neutralizing circuits, but the effect achieved by using C_v is similar to that achieved by true neutralization as it allows the effect of feedback due to grid-to-plate capacitance to be reduced to negligible proportions, although it does not completely eliminate it.
