PREFACE

This book has been written as a comprehensive, self-explanatory reference handbook for the benefit of all who have an interest in the design and application of radio receivers or audio amplifiers. Everything outside this field—television, radio transmission, radar, industrial electronics, test equipment and so on—has been excluded to limit the book to a reasonable size.

An effort has been made to produce a handbook which, in its own sphere, is as self-contained as possible. Extensive references to other sources of information have been included for the reader who might require additional detail.

The success of the previous edition, of which over 280,000 copies have been sold throughout the world, encouraged Amalgamated Wireless Valve Company Pty. Ltd., to undertake the compilation of the present up-to-date edition which is more complete, great pains having been taken to fill in many of the gaps in the data published hitherto. This has involved a considerable amount of both experimental and analytical work by the editor and by engineers assisting in the project. Some original work, previously unpublished, has been included.

Although the various chapters have been written by individual authors, all are truly the result of team work, each having been carefully and critically examined by several other engineers specializing in that particular field. In this way the accuracy of mathematical calculations and of individual statements was checked and re-checked to ensure that the reader would not be misinformed.

I wish to express my grateful thanks to Mr. R. Lambie, Manager, Mr. D. M. Sutherland, Works Manager, and to the following collaborating engineers—

J. E. Bailey, Dr. W. G. Baker, D. Barnett, J. D. G. Barrett, Dr. G. Builder, N. V. C. Cansick, W. N. Christiansen, Dr. E. R. Dalziel, K. G. Dean, H. L. Downing, J. Gilchrist, I. C. Hansen, R. Herbert, F. Holloway, I. Hood, D. G. Lindsay, W. S. McGuire, E. J. Packer, J. Pritchard, R. J. Rawlings, B. Sandel, J. Stacey, R. D. Stewart, J. E. Telfer, R. Vine, E. Watkinson.

I also wish to express my thanks to Mr. R. Ainsworth for his invaluable work in sub-editing and assistance in indexing and to Mr. R. H. Aston for compiling data.

F. LANGFORD-SMITH

Amalgamated Wireless Valve Company Pty. Ltd.

NOTES

References to valve types are to the prototype (e.g. 6J7) and include all equivalent types (e.g. 6J7-G, 6J7-GT etc.) unless otherwise indicated.

If any errors are noted, please write to the Editor, Radiotron Designer's Handbook, Amalgamated Wireless Valve Co. Pty. Ltd., 47 York Street, Sydney, Australia.

ACKNOWLEDGEMENTS

The editor wishes to acknowledge his indebtedness to the publishers of the following periodicals for permission to reproduce the diagrams listed below. In some cases the diagrams are based largely on the originals, although modified.

CONTENTS

PART 1 : THE RADIO VALVE

CHAPTER 1. INTRODUCTION TO THE RADIO VALVE

SECTION	PAGE
1. ELECTRICITY AND EMISSION	1
2. THE COMPONENT PARTS OF RADIO VALVES	4
(i) Filaments, cathodes and heaters	4
(ii) Grids	5
(iii) Plates	5
(iv) Bulbs	5
(v) Voltages with valve operation	5
3. TYPES OF RADIO VALVES	6
(i) Diodes	6
(ii) Triodes	7
(iii) Tetrodes	7
(iv) Pentodes	7
(v) Pentode power amplifiers	8
(vi) Combined valves	8
(vii) Pentagrid converters	8
4. MAXIMUM RATINGS AND TOLERANCES	9
(i) Maximum ratings and their interpretation	9
(ii) Tolerances	9
5. FILAMENT AND HEATER VOLTAGE/CURRENT CHARACTERISTICS	10
6. VALVE NUMBERING SYSTEMS	10
7. REFERENCES	12

CHAPTER 2. VALVE CHARACTERISTICS

1. VALVE COEFFICIENTS	13
2. CHARACTERISTIC CURVES	15
(i) Plate characteristics	15
(ii) Mutual characteristics	17
(iii) Grid current characteristics	18
(iv) Suppressor characteristics	21
(v) Constant current curves	22
(vi) "G" curves	23
(vii) Drift of characteristics during life	23
(viii) Effect of heater-voltage variation	24
3. RESISTANCE-LOADED AMPLIFIERS	24
(i) Triodes	24
(ii) Pentodes	26
4. TRANSFORMER-COUPLED AMPLIFIERS	27
(i) With resistive load	27
(ii) Effect of primary resistance	28
(iii) With i-f voltage amplifiers	28
(iv) R-F amplifiers with sliding screen	28

SECTION	CONTENTS	PAGE
	(v) Cathode loadlines	29
	(vi) With reactive loads	30
5. TRIODE OPERATION OF PENTODES		34
	(i) Triode operation of pentodes	34
	(ii) Examples of transconductance calculation	34
	(iii) Triode amplification factor	35
	(iv) Plate resistance	36
	(v) Connection of suppressor grid	36
6. CONVERSION FACTORS, AND THE CALCULATION OF CHARACTERISTICS OTHER THAN THOSE PUBLISHED		36
	(i) The basis of valve conversion factors	36
	(ii) The use of valve conversion factors	37
	(iii) The calculation of valve characteristics other than those published	40
	(iv) The effect of changes in operating conditions	42
7. VALVE EQUIVALENT CIRCUITS AND VECTORS		45
	(i) Constant voltage equivalent circuit	45
	(ii) Constant current equivalent circuit	46
	(iii) Valve vectors	47
8. VALVE ADMITTANCES		49
	(i) Grid input impedance and admittance	49
	(ii) Admittance coefficients	50
	(iii) The components of grid admittance-input resistance-input capacitance-grid input admittance	51
	(iv) Typical values of short-circuit input conductance	55
	(v) Change of short-circuit-input capacitance with transconductance	55
	(vi) Grid-cathode capacitance	56
	(vii) Input capacitances of pentodes (published values)	56
	(viii) Grid-plate capacitance	57
9. MATHEMATICAL RELATIONSHIPS		57
	(i) General	57
	(ii) Resistance load	58
	(iii) Power and efficiency	59
	(iv) Series expansion; resistance load	61
	(v) Series expansion; general case	63
	(vi) The equivalent plate circuit theorem	63
	(vii) Dynamic load line-general case-	64
	(viii) Valve networks-general case-	64
	(ix) Valve coefficients as partial differentials	64
	(x) Valve characteristics at low plate currents	65
10. REFERENCES		66

CHAPTER 3. THE TESTING OF OXIDE-COATED CATHODE HIGH-VACUUM RECEIVING VALVES

1. BASIS OF TESTING PRACTICE	68
(i) Fundamental physical properties	69
(ii) Basic functional characteristics	70
(iii) Fundamental characteristic tests	73
(iv) Valve ratings and their limiting effect on operation	75
(A) Limiting ratings	75
(B) Characteristics usually rated	75
(C) Rating systems	77
(D) Interpretation of maximum ratings	77
(E) Operating conditions	80
(v) Recommended practice and operation	80
(a) Mounting	80
(b) Ventilation	81

SECTION 1 : ELECTRICITY AND EMISSION

The proper understanding of the radio valve in its various applications requires some knowledge of the characteristics of the electron and its companion bodies which make up the complete structure of atoms and molecules.

All **matter** is composed of molecules which are the smallest particles preserving the individual characteristics of the substance. For example, water is made up of molecules that are bound together by the forces operating between them. Molecules are composed of atoms that are themselves made up of still smaller particles. According to the usual simplified theory, which is sufficient for this purpose, atoms may be pictured as having a central nucleus around which rotate one or more electrons in much the same manner as the planets move around the sun. In the case of the atom, however, there are frequently several electrons in each orbit. The innermost orbit may have up to 2, the second orbit up to 8, the third orbit up to 18, the fourth orbit up to 32, with decreasing numbers in the outermost orbits (which only occur with elements of high "atomic numbers"). We do not know the precise shape and positions of the orbits and modern theory speaks of them as "energy levels" or "shells." The electrons forming the innermost shell are closely bound to the nucleus but the forces become progressively less in the outer shells. Moreover, the number of electrons in the outermost shell may be less than the maximum number that this shell is capable of accommodating. In this case, the substance would be chemically active; examples of such are sodium and potassium.

In a **metal** the various atoms are situated in close proximity to one another, so that the electrons in the outermost shells have forces acting upon them both from their "parent" nucleus and their near neighbour. Some electrons are free to move about throughout the substance and are, therefore, called "free electrons." If an electric potential is applied between two points in the metal, the number of electrons moving from the negative to the positive point will be greater than those moving in the opposite direction. This constitutes an electric current, since each electron carries an electric charge. The charge on the electron is defined as unit negative charge and the accepted direction of current flow is opposite to the net electron movement.

It is interesting to note that the **total current flow**, equivalent to the total movements of all the free electrons, irrespective of their directions, is very much greater than that which occurs under any normal conditions of electric current flow. The directions of movement are such that the external effects of one are generally cancelled by those of another. Thus, in a metal, the oft-quoted picture of a flow of electrons from the negative to the positive terminal is only a partial truth and apt to be misleading. The velocity of the free electrons is very much less than that of the electric current being of the order of only a few centimetres per second. The electron current may be pictured as the successive impacts between one electron and another in the direction of the current. In an **insulator** the number of free electrons is practically zero, so that electric conduction does not take place. In a partial insulator the number of free electrons is quite small.

The **nucleus** is a very complex body, including one or more protons which may be combined with a number of neutrons*. The proton has a positive charge equal and opposite to the charge on an electron but its mass is very much greater than that of an electron. The simplest possible atom consists of one proton forming the nucleus with one electron in an orbit around it—this is the hydrogen atom. Helium consists of two protons and two neutrons in the nucleus, with two electrons rotating in orbits. The neutron has a mass slightly greater than that of a proton, but the neutron has no electric charge. An example of a more complicated atom is that of potassium which has 19 protons and 20 neutrons in the nucleus, thus having a positive charge of 19 units. The number of electrons in the orbits is 19, thus giving zero charge for the atom as a whole, this being the normal condition of any atom. The common form of uranium has 92 protons and 146 neutrons in the nucleus, with 92 electrons rotating in orbits.

Under normal circumstances no electrons leave the surface of a substance since the forces of attraction towards the centre of the body are too great. As the temperature of the substance is raised, the velocity of the free electrons increases and eventually, at a temperature which varies from one substance to another, some of the free electrons leave the surface and may be attracted to a positive electrode in a vacuum. This phenomenon is known as **thermionic emission** since its emission takes place under the influence of heating. There are other types of emission such as **photo emission** that occur when the surface of the substance is influenced by light, or **secondary emission** when the surface is bombarded by electrons.

The radio valve makes use of thermionic emission in conjunction with associated circuits for the purpose of producing amplification or oscillation. The most common types of radio valves have hot cathodes, either in the form of a filament or an indirectly-heated cathode. Many transmitting valves have filaments such as tungsten or thoriated-tungsten, but nearly all receiving valves have what is known as an **oxide coated filament or cathode**. The filament, or cathode sleeve, is usually made of nickel or an alloy containing a large percentage of nickel and this is coated with a mixture of barium and strontium carbonates that, during the manufacture of the valve, are turned into oxides. A valve having an oxide-coated cathode has a very high degree of emission as compared with other forms of emitters but requires very great care during manufacture since it is readily poisoned by certain impurities which may be present in the cathode itself or which may be driven out in the form of gas from the bulb or the other electrodes.

Oxide-coated cathodes are generally operated at an average temperature of about 1050° Kelvin (777° C) which looks a dull red. Temperatures much above 1100°K generally cause a short life, while those below 960°K are very susceptible to poisoning of the emission, and require careful attention to maintain a very high vacuum.

The thermionic valve is normally operated with its **anode† current** considerably less than the maximum emission produced by its cathode. In the case of one having a pure tungsten filament no damage is done to the filament if all the electrons emitted

*This is in accordance with the theory generally held at the time of writing; it is, however, subject to later modification.

†The anode (also called the plate) is the positive electrode; the cathode is the negative electrode.

are drawn away immediately to the anode. This is not so, however, with oxide coated cathodes and these, for a long life and satisfactory service, require a total emission very much greater than that drawn under operating conditions. In such a case a cloud of electrons accumulates a short distance from the surface of the cathode and supplies the electrons that go to the anode. This **space charge** as it is called, is like a reservoir of water that supplies varying requirements but is itself replenished at an average rate. The space charge forms a protection to the cathode coating against bombardment and high electrostatic fields, while it also limits the current which would otherwise be drawn by a positive voltage on the anode. If the electron emission from the cathode is insufficient to build up this "space charge," the cathode coating is called upon to supply high peak currents that may do permanent injury to the coating and in extreme cases may even cause sputtering or arcing.

In multi-grid valves, if one grid has a positive potential and the next succeeding grid (proceeding from cathode to plate) has a negative potential, there tends to be formed an additional space charge. This outer space charge behaves as a source of electrons for the outer electrodes, and is known as a **virtual cathode**.

An oxide-coated cathode, operated under proper conditions, is self-rejuvenating and may have an extremely long **working life**. The life is, therefore, largely governed by the excess emission over the peak current required in normal operation.

A valve having a large cathode area and small cathode current may have, under ideal conditions, a life of the order of 50 000 hours, whereas one having extremely limited surface area, such as a tiny battery valve, may have a working life of less than 1000 hours.

Under normal conditions a valve should be operated with its **filament or heater** at the recommended **voltage**; in the case of an oxide coated valve it is possible to have fluctuations of the order of 10% up or down without seriously affecting the life or characteristics of the valve [see Chapter 3 Sect. 1(iv)D]. The average voltage should, however, be maintained at the correct value. If the filament or cathode is operated continuously with a higher voltage than that recommended, some of the coating material is evaporated and permanently lost, thus reducing the life of the valve. Moreover, some of this vapour tends to deposit on the grid and give rise to what is known as **grid emission** when the grid itself emits electrons and draws current commonly known as **negative grid current** [for measurement see Chapter 3 Sect. 3 (iv)A].

If the filament or heater is operated for long periods at reduced voltages, the effect is a reduction in emission, but no damage is generally done to the valve unless the cathode currents are sufficient to exhaust the "space charge." Low cathode temperature is, therefore, permissible provided that the anode current is reduced in the proper proportion.

During the working life of the valve, its **emission** usually increases over the early period, reaches a maximum at an age which varies from valve to valve and from one manufacturer to another, and then begins to fall. The user does not generally suffer any detriment until the emission is insufficient to provide peak currents without distortion.

Tests for the measurement of the emission of an oxide-coated cathode are described in Chapter 3 Sect. 3(ii)f.

If a slight amount of **gas** is present some of the electrons will collide with atoms of the gas and may knock off one or more electrons, which will serve to increase the anode current, leaving atoms deficient in electrons. These are known as **positive ions** since they carry a positive charge (brought about by the loss of electrons), and the process is known as ionization. The positive ions are attracted by the negative cathode, and being comparatively massive, they tend to bombard the cathode coating in spite of the protection formed by the space charge.

Some types of rectifiers (e.g. OZ4) have no heaters, and the oxide-coated cathode is initially heated by ion bombardment; this flow of current is sufficient to raise the cathode temperature so as to enable it to emit electrons in the usual manner. The gas is an inert variety at reduced pressure. Although some types of gaseous thermionic

rectifiers will operate (once they have been thoroughly heated) without any filament or heater voltage, this is likely to cause early failure through loss of emission.

Most thermionic valves are **vacuum types** and operate under a very high degree of vacuum. This is produced during manufacture by a combination of vacuum pumps and is made permanent by the flashing of a small amount of "getter" which remains in the bulb ready to combine with any impurities which may be driven off during life. Valves coming through on the production line are all tested for gas by measuring the negative grid current under operating conditions; methods of testing are described in Chapter 3 Sect. 3(iv)A, where some values of maximum negative grid current are also given. If a valve has been on the shelf for a long time, it frequently shows a higher gas current, but this may usually be reduced to normal by operating the valve under normal conditions, with a low resistance connection between grid and cathode, for a short period. When a valve is slightly gassy, it usually shows a **blue glow** (ionization) between cathode and anode. In extreme cases this may extend outside the ends of the electrodes, but a valve in such condition should be regarded with suspicion and tested before being used in any equipment, as it might do serious damage. A slight crack may permit a very small amount of air to enter the bulb, giving rise to a pink/violet glow which may readily be identified by any one familiar with it; this is a sign of immediate end of life.

The anode current of a thermionic valve is not perfectly steady, since it is brought about by a flow of electrons from the cathode. When a valve is followed by very high gain amplifiers, the rushing noise heard in the loudspeaker is partly caused by the electrons in the valve, and partly by a somewhat similar effect (referred to as the "thermal agitation" or "Johnson noise") principally in the resistance in the grid circuit of the first valve—see Chapter 4 Sect. 9(i), and Chapter 18 Sect. 2(ii). This question of **valve noise** is dealt with in Chapter 18 Sect. 2(ii)c and Chapter 23 Sect. 6.

Some valves show a fluorescence on the inside of the bulb, which may fluctuate when the valve is operating. This is perfectly harmless and may be distinguished from blue glow by its position in the valve. In occasional cases fluorescence may also be observed on the surfaces of the mica supports inside the valve.

SECTION 2: THE COMPONENT PARTS OF RADIO VALVES

(i) *Filaments, cathodes and heaters* (ii) *Grids* (iii) *Plates* (iv) *Bulbs* (v) *Voltages with valve operation.*

(i) Filaments, Cathodes and Heaters

Cathodes are of two main types—directly heated and indirectly heated. Directly-heated cathodes are in the form of filaments which consists of a core of wire through which the filament current is passed, the wire being coated with the usual emissive coating. Filaments are the most economical form of cathodes so far as concerns the power necessary to heat the cathode. They are, therefore, used in most applications for operation from batteries, particularly dry batteries, and for special applications in which very quick heating is required. Filaments are also used in many types of power rectifiers and power triodes, where the special properties of the filament make it more suitable.

Valves having filaments should preferably be mounted with the filament vertical, but if it is necessary to mount them horizontally, they should be arranged so that the plane of the filament of V or W shaped filaments is vertical; this reduces the chance of the filament touching the grid.

All filament-type valves having close spacing between filament and grid have a filament tension spring, usually mounted at the top of the valve. Some typical filament arrangements are indicated in Fig. 1.1 where A shows a single "V" shape filament suspended by means of a top-hook at the apex, B shows a "W" shape with two top hooks and C a single strand filament with tension spring as used in 1.4 volt valves.

Indirectly-heated cathodes consist of a cathode sleeve surrounding a heater. The cathode sleeve may have a variety of shapes, including round (D), elliptical (E) and rectangular (F) cross section. They are usually fitted with a light ribbon tag for connection to the lead going to the base pin.

Fig. 1.1. A, B, C types of filaments ; D, E, F types of cathodes ; G, H types of heaters.

In an indirectly-heated valve, the function of the heater is solely to heat the cathode. No emission should take place from the heater and the insulation between heater and cathode should be good. The heater is generally made of tungsten or a tungsten alloy wire coated with a substance capable of providing the necessary insulation at high temperature, such as alundum. In all applications where hum is likely to be troublesome, the heater is preferably of the double helical type, as G in Fig. 1.1. Power valves and other types having elliptical or rectangular cathode sleeves, often employ a folded heater as in H. These are not generally suitable for use in very low level amplifiers whether for radio or audio frequencies.

(ii) Grids

Grids are constructed of very fine wire wound around one, two or four side rods—two being by far the most common. Some valves have two, three, four or five grids inside one another, but all of these are similar in general form although different in dimensions.

In the case of some grids it is necessary to take precautions to limit the grid temperature either to avoid grid emission, in the case of control grids, or to limit the grid temperature to prevent the formation of gas, in the case of screen grids. These may, for better heat radiation, be fitted with copper side rods and blackened radiators either above or below the other electrodes. Grids are numbered in order from the cathode outwards, so that No. 1 grid will be the one closest to the cathode, No. 2 grid the one adjacent to it, and No. 3 the one further out again.

(iii) Plates

The plate of a receiving valve is the anode or positive electrode. It may be in one of a great number of shapes, dependent on the particular application of the valve. The plates of power valves and rectifiers are frequently blackened to increase their heat radiation and thereby reduce their temperature.

(iv) Bulbs

The inside surfaces of glass bulbs are frequently blackened. This has the effects of making them more or less conductive, thereby reducing the tendency to develop static charges, and reducing the tendency towards secondary emission from the bulb.

(v) Voltages with valve operation

All voltages in radio valves are taken with respect to the cathode, in the case of indirectly-heated valves, and the negative end of the filament with directly-heated

valves. The cathode is usually earthed or is approximately at earth potential, so that this convention is easy to follow under normal conditions. In some cases, as for example phase splitters or cathode followers, the cathode is at a potential considerably above earth and care should be taken to avoid errors.

Some directly-heated valves may be operated with their filaments on a.c. supply, usually with the centre tap of the filament circuit treated as a cathode. In all such cases the valve data emphasize the fact that the filament is intended for operation on a.c. The plate characteristics are usually drawn with d.c. on the filament and these curves may be applied to a.c. operation by increasing the bias voltage by half the filament voltage.

In cases where resistors or other impedances are connected between the positive electrodes and the supply voltages, the electrode voltages (e.g. E_b , E_{c2}) are the voltages existing between those electrodes and cathode under operating conditions. The supply voltages are distinguished by the symbols E_{bb} , E_{cc2} etc. See the list of symbols in Chapter 38 Sect. 6.

For further information on valve operation see Chapter 3 Sect. 1.

SECTION 3 : TYPES OF RADIO VALVES

(i) *Diodes* (ii) *Triodes* (iii) *Tetrodes* (iv) *Pentodes* (v) *Pentode power amplifiers*
(vi) *Combined valves* (vii) *Pentagrid converters.*

(i) Diodes

A diode is the simplest type of radio valve consisting of two electrodes only, the cathode and anode (or plate). The cathode may be either directly or indirectly heated and the valve may be either very small, as for a signal detector, large as for a power rectifier, or any intermediate size. One or two diodes are frequently used in combination with a triode or pentode a-f amplifier as the second detector in receivers ; in most of these cases, a common cathode is used. For some purposes it is necessary to have two diode units with separate cathodes, as in type 6H6. Amplifier types with three diodes, some with a common cathode and others with separate cathodes, have

Fig. 1.2. Fundamental circuit including diode, A and B batteries and load resistor.

also been manufactured for special purposes. Fig. 1.2 shows the circuit of a diode valve in which battery A is used to heat the filament or heater, and battery B to apply a positive potential to the anode through the load resistor. The plate current is measured by a milliammeter connected as shown, and the direction of current flow is from the positive end of battery B towards the anode, this being the opposite of the electron current flow. It should be noted that the negative end of battery B is returned to the negative end of battery A in accordance with the usual convention. It would be quite permissible to connect the negative end of the battery B to the positive end of battery A so as to get the benefit of the voltage A applied to the anode, but in this case, the total voltage applied to the anode would be $A + B$. If voltage of battery B is reversed, it will be noted that the plate current is zero, thus indicating the rectification that takes place in a diode. If an alternating voltage is applied, current will only flow during the half-cycles when the anode is positive. This is called a half-wave rectifier since it is only capable of rectifying one half of the cycle.

Full wave* rectifiers are manufactured with two anodes and a common cathode and these are arranged in the circuit so that one diode conducts during one half-cycle and the other during the other half-cycle.

(ii) Triodes

A triode is a three electrode valve, the electrodes being the cathode, grid and anode (or plate). The grid serves to control the plate current flow, and if the grid is made sufficiently negative the plate current is reduced to zero. The voltage on the grid is controlled by battery C in Fig. 1.3, the other part of the circuit being as for the diode in Fig. 1.2. When the grid is negative with respect to the cathode, it does not draw appreciable current; this is the normal condition as a class A_1 amplifier. Although an indirectly heated cathode has been shown in this instance, a directly heated valve could equally well have been used. The heater in Fig. 1.3 may be supplied either from an a.c. or d.c. source, which should preferably be connected to the cathode or as close as possible to cathode potential.

As the grid is made more negative, so the plate current is decreased and when the grid is made more positive the plate current is increased. A triode is, therefore, capable of converting a voltage change at the grid into a change of power in the load resistor. It may also be used as a voltage amplifier or oscillator.

FIG. 1.3

Fig. 1.3. Fundamental circuit including indirectly-heated triode, B and C batteries, and load resistor in plate circuit.

(iii) Tetrodes

The capacitance between the grid and plate can be reduced by mounting an additional electrode, generally called the screen or screen grid, between the grid and plate. The valve thus has four electrodes, hence the name tetrode. The function of the screen is to act as an electrostatic shield between grid and plate, thus reducing the grid-to-plate capacitance. The screen is connected to a positive potential (although less than that of the plate) in order to counteract the blocking effect which it would otherwise have on the plate current—see Fig. 1.4. Owing to the comparatively large spaces between the wires in the screen, most of the electrons from the cathode pass through the screen to the plate. So long as the plate voltage is higher than the screen voltage, the plate current depends primarily on the screen voltage and only to a slight extent on the plate voltage. This construction makes possible a much higher amplification than with a triode, and the lower grid-to-plate capacitance makes the high gain practicable at radio frequencies without instability.

Fig. 1.4. Fundamental circuit including indirectly-heated tetrode, B and C batteries, and load resistor in plate circuit.

FIG. 1.4

(iv) Pentodes

Electrons striking the plate with sufficient velocities may dislodge other electrons and so cause what is known as "secondary emission." In the case of tetrodes, when

*These are sometimes called biphase half-wave rectifiers.

the plate voltage swings down to a low value under working conditions, the screen may be instantaneously at a higher positive potential than the plate, and hence the secondary electrons are attracted to the screen. This has the effect of lowering the plate current over the region of low plate voltage and thus limits the permissible plate voltage swing. This effect is avoided when a suppressor is inserted between screen and plate. The suppressor is normally connected to the cathode as in Fig. 1.5. Owing to its negative potential with respect to the plate, the suppressor retards the movements of secondary electrons and diverts them back to the plate.

A valve with three grids is known as a pentode because it has five electrodes. Pentodes are commonly used as radio frequency amplifiers and as power amplifiers. Pentode r-f amplifiers are of two main varieties, those having a sharp cut-off* characteristic and those having a remote cut-off*. Valves having sharp cut-off characteristics are generally used as audio frequency voltage amplifiers and anode bend detectors, while remote cut-off valves are used as r-f and i-f amplifiers. The

Fig. 1.5. Fundamental circuit including indirectly-heated pentode, B and C batteries, and load resistor in plate circuit,

FIG. 1.5

remote cut-off characteristic permits the application of automatic volume control with a minimum of distortion; this subject is treated in detail in Chapter 27 Sect. 3.

(v) Pentode power amplifiers

Pentode power amplifiers are commonly used in receiving sets to produce a-f power outputs from about 1 watt up to about 5 watts. They differ from r-f amplifiers in that no particular precautions are made to provide screening, and they are designed for handling higher plate currents and screen voltages. In principle, however, both types are identical and any r-f pentode may be used as a low-power a-f amplifier.

Beam power valves with "aligned" grids do not require a third grid to give characteristics resembling those of a power pentode; a typical structure is shown in Fig. 1.6. Some "kinkless" tetrodes are also used as r-f and i-f amplifiers. All of these may be treated as being, in most respects, equivalent to pentodes.

(vi) Combined valves

Many combinations of valves have been made. Two triodes are frequently mounted in one envelope to form a "twin triode." One or more diodes are frequently combined with triodes and pentodes to form second detectors. A combination of triode and pentode in one envelope is also fairly common, one application being as a frequency changer. Other combinations are triode-hexodes and triode-heptodes, all of which are primarily intended for use as frequency changers or "converters." In these, the triode grid is generally connected internally to No. 3 grid in the hexode or heptode to provide the necessary mixing of the oscillator and signal voltages. A hexode has four grids while the heptode has five, the outermost of which is a suppressor functioning in the same manner as in a pentode.

In addition to this wide range of combinations, entirely different valves may be combined in one envelope to save space in very small receivers. This is a practice which appears to be dying out, particularly as the envelope size becomes smaller.

(vii) Pentagrid converters

Pentagrids are valves having 5 grids, so that they are really heptodes, but the name pentagrid appears to make a convenient distinction between valves in this group

*Sharp cut-off indicates that the plate-current characteristic is as straight as it can be made. A remote cut-off characteristic indicates that the plate current does not become zero until the grid voltage is made very much negative (usually over 30 volts).

ELECTRON BEAM SHEETS FORMED BY GRID WIRES

Fig. 1.6. Internal structure of type 6L6 or 807 aligned grid beam power valve (diagram by courtesy of R.C.A.).

(which do not normally require external oscillators) and those of the hexode or heptode "mixer" type which are used with separate oscillators. Pentagrid converters are of two main groups, the first of these being the 6A8 type of construction which incorporates an oscillator grid and oscillator anode ("anode grid") as part of the main cathode stream. The other group comprises the 6SA7, 6BE6 and 1R5 type of construction which has no separate oscillator anode, the screen grid serving a dual purpose. The various types of pentagrid converters are described in detail in Chapter 25.

SECTION 4 : MAXIMUM RATINGS AND TOLERANCES

(i) *Maximum ratings and their interpretation* (ii) *Tolerances.*

(i) Maximum ratings and their interpretation

Maximum ratings are of two types—the Absolute Maximum system and the Design Centre system. These are described in detail in Chapter 3 Sect. 1(iv).

(ii) Tolerances

All valves are tested in the factory for a number of characteristics, these usually including plate current, screen current, negative grid current, mutual conductance, noise and microphony, as well as having to pass visual inspection tests for appearance. For methods of testing see Chapter 3. As with any other components such as resistors or capacitors, the characteristics can only be maintained within certain tolerances. For example, a resistor may be bought with a tolerance of plus or minus 10% or 20% ; closer tolerances may be purchased at a higher price.

The subject of tolerances in valve characteristics is covered in detail in Chapter 3 Sect. 2(iii).

Special care should be taken in the screen circuits of beam power amplifiers since in these the screen currents may vary from zero to twice the average figure. Any

screen voltage dropping resistor is undesirable with such valves and if the screen is required to be operated at a lower voltage than the plate, it should be supplied from a voltage divider having a bleed current of preferably 5 times the nominal screen current. Alternatively, the screen voltage should be determined for the extreme cases of zero and twice nominal screen current.

Fig. 1.7. Filament current versus filament voltage for a valve having a 1.4 volt 50 milliamper filament.

The heater voltage should be maintained at an average voltage equal to the recommended voltage, thus leaving a margin of plus or minus 10% for line fluctuations under normal conditions—see Chapter 3 Sect. 1(iv)D. If any wider variation is required, this will involve decreased maximum grid circuit resistance for a higher heater voltage and decreased plate current for lower heater voltage.

SECTION 5 : FILAMENT AND HEATER VOLTAGE/CURRENT CHARACTERISTICS

A valve filament or heater operates at such a temperature that its resistance when hot is much greater than its resistance when cold. The current/voltage characteristic is curved and does not follow Ohm's Law. Two typical examples are Fig. 1.7 for a battery valve and Fig. 35.14 for an indirectly-heated valve. Approximate curves for general use, on a percentage basis, are given in Fig. 1.8 including also dissipation in watts and temperature (Ref. 7). Filament and heater ratings are covered in Chapter 3 Sect. 1.

SECTION 6 : VALVE NUMBERING SYSTEMS

Receiving valves having the American numbering follow two main systems. The first of these is the numerical system, which is the older, and the second the R.M.A. system. Originally various manufacturers produced the same valve under different type numbers such as 135, 235, 335, 435 etc. This was improved upon by dropping the first figure and using only the two latter figures, e.g. 35.

All the more recent American releases follow the R.M.A. system (Ref. 8) of which a typical example is 6A8-GT. In this system the first figure indicates the approximate filament or heater voltage—6 indicates a voltage between 5.6 and 6.6 volts, while 5 indicates a voltage between 4.6 and 5.6 volts; 1 indicates a voltage in excess of 0 and including 1.6 volts, while 0 indicates a cold cathode. Lock-in types in the 6.3 volt range are given the first figure 7 (this being the "nominal" voltage), but

the normal operating voltages remain at 6.3 volts. In the case of tapped filaments or heaters the first figure indicates the total voltage with both sections in series.

The second symbol is a letter which is allotted in sequence commencing with A, except that I and O are not used; rectifiers follow the sequence backwards commencing at Z. When all the single letters of a group are exhausted, the system then proceeds with two letters commencing with AB; combinations of identical letters are not normally used. The single-ended a.c. range has a first letter S while the second letter may be that of the nearest equivalent in the double-ended range—e.g. type 6SK7 is the nearest single-ended equivalent to type 6K7. Another special case is the first letter L which is used for lock-in types in the battery range.

Fig. 1.8. Filament or heater current, dissipation and temperature plotted against filament or heater voltage, per cent (Ref. 7).

The final figure denotes the number of "useful elements" brought out to an external connection.

The envelope of a metal valve, the metal base of a lock-in valve, and internal shielding having its separate and exclusive terminal(s) are counted as useful elements. A filament or heater counts as one useful element, except that a tapped filament or heater of two or more sections of unequal rated section voltages or currents counts as two useful elements. An octal-based glass valve having n useful elements exclusive of those connected to Pin No. 1 is counted as having $n + 1$ useful elements. Elements connected to terminals identified as "internal connection, do not use" do not count as useful elements. Combinations of one or more elements connected to the same terminal or terminals are counted as one useful element. For example a directly heated triode with a non-octal base is denoted by 3; an indirectly-heated triode, with a non-octal base is designated by 4; a directly-heated tetrode with a non-octal base is designated by 4. A pentode with the suppressor internally connected to filament or cathode is numbered as a tetrode. A metal envelope or octal-based glass triode with an indirectly-heated cathode is designated by 5, a tetrode (or pentode with the suppressor internally connected) by 6, and a triode-hexode converter usually by 8.

The suffix after the hyphen denotes the type of construction used. In general, metal valves, lock-in types and miniature types have no suffixes, but octal-based glass valves types are given the suffix G for the larger glass bulb or GT for the smaller parallel-sided T9 bulb. The letter M indicates a metal-coated glass envelope and octal base. X indicates a "low loss" base composed of material having a loss factor of 0.035 maximum (determination of loss factor to be in accordance with ASTM Designation D-150-41T). The letter Y indicates an intermediate-loss base composed of material having a loss factor of 0.1 maximum. The letter W indicates a military type. The letters, A, B, C, D, E and F assigned in that order indicate a later and modified version which can be substituted for any previous version but not vice versa.

SECTION 1 : VALVE COEFFICIENTS

(Otherwise known as Constants, Parameters or Factors)

The triode or multigrid radio valve is a device which allows, under certain operating conditions, an amplified replica of a voltage applied between grid and cathode to appear across an impedance placed between plate and cathode.

A valve, in itself, does not provide amplification of the applied grid-to-cathode voltage. The amplified voltage across the load impedance is due to the action of the valve in controlling the power available from the power supply. The amount of power which can be so controlled is determined by the operating conditions and the characteristics of the valve and of its associated circuits.

The maximum voltage amplification which a valve is capable of giving under ideal conditions is called the amplification factor, generally designated by the Greek symbol μ (mu). This is not truly constant under all conditions (except for an imaginary "ideal valve") and varies slightly with grid bias and plate voltage in the case of a triode, and is very far from being constant with most multi-electrode valves.

The **amplification factor** (μ) is the ratio of the incremental* change in plate voltage to the incremental change in control grid voltage in the opposite direction, under the conditions that the plate current remains unchanged, and all other electrode voltages are maintained constant.

There are two other principal Valve Coefficients, known as the mutual conductance and the plate resistance (or anode resistance), the values of these also being somewhat dependent upon the applied voltages.

*An incremental change of voltage applied to an electrode may be taken as indicating a change so small that the curvature of the characteristics may be neglected. For the mathematical treatment of rate of change, see Chapter 6 Sect. 7(i) and (ii). For treatment of valve coefficients as partial differentials see Chapter 2 Sect. 9(ix).

The **mutual conductance** (or grid-plate transconductance) is the incremental change in plate current divided by the incremental change in the control-grid voltage producing it, under the condition that all other voltages remain unchanged.

The **plate resistance**† is the incremental change in plate voltage divided by the incremental change in plate current which it produces, the other voltages remaining constant.

There is a relationship between these three principal valve coefficients, which is exact provided that all have been measured at the same operating point,

$$\begin{aligned}\mu &= g_m \cdot r_p, \\ \text{or } g_m &= \frac{\mu}{r_p}, \\ \text{or } r_p &= \frac{\mu}{g_m}.\end{aligned}$$

The calculation of these "valve coefficients" from the characteristic curves is given in Section 2 of this Chapter, while their direct measurement is described in Chapter 3 Sect. 3. The mathematical derivation of these coefficients and their relationship to one another are given in Section 9 of this Chapter, as is also the representation of valve coefficients in the form of partial differentials.

The reciprocals of two of these coefficients are occasionally used—

$\frac{1}{\mu} = D$ where D is called the **Durchgriff** (or **Penetration Factor**) and which may be expressed as a percentage.

$\frac{1}{r_p} = g_p$ where g_p is called the **Plate Conductance** (see also below).

Other valve coefficients are described below:—

The **Mu-Factor**, of which the amplification factor is a special case, is the ratio of the incremental change in any one electrode voltage to the incremental change in any other electrode voltage, under the conditions that a specified current remains unchanged and that all other electrode voltages are maintained constant. Examples are

$$\mu_{g1 \cdot g2}, \mu_{g2 \cdot g}.$$

The **Conductance** (g) is the incremental change in current to any electrode divided by the incremental change in voltage to the same electrode, all other voltages remaining unchanged.

Examples are grid conductance (g_g), plate conductance (g_p).

Transconductance is the incremental change in current to any electrode divided by the incremental change in voltage to another electrode, under the condition that all other voltages remain unchanged. A special case is the grid-plate transconductance which is known as the mutual conductance. Another example is the plate-grid transconductance (g_n).

Conversion transconductance (S_c) is associated with mixer (frequency changing) valves, and is the incremental change in intermediate-frequency plate current divided by the incremental change in radio-frequency signal-grid voltage producing it.

The **Resistance** (r) of any electrode is the reciprocal of the conductance; for example plate resistance is the reciprocal of plate conductance,

$$r_p = 1/g_p.$$

Perveance (G) is the relation between the space-charge-limited cathode current and the three-halves power of the anode voltage. It is independent of the electrode voltages and currents, so long as the three-halves law holds:

$$G = \frac{i_k}{e_v^{3/2}}$$

The measurement of perveance is covered in Chapter 3 Sect. 3(vi)E.

†This is strictly the "variational plate resistance" and must be distinguished from the d.c. plate resistance.

SECTION 2 : CHARACTERISTIC CURVES

(i) Plate characteristics (ii) Mutual characteristics (iii) Grid current characteristics
(iv) Suppressor characteristics (v) Constant current curves (vi) "G" curves (vii) Drift of characteristics during life (viii) Effect of heater-voltage variation.

It is convenient to set down the measured characteristics of a valve in the form of curves. These are thus a record of the actual currents which flow in a given valve when the specified voltages are applied.

The curves published by the valve manufacturers are those of an "average" valve, and any one valve may differ from them within the limits of the manufacturing tolerances.

FIG. 2.1

Fig. 2.1. Method of measuring the plate and grid currents of a triode valve.

The method of measuring the plate and grid currents of a triode valve is shown in Fig. 2.1 in which a tapping on the grid bias battery is returned to the cathode so as to permit either positive or negative voltages to be connected to the grid. The grid microammeter and voltmeter should be of the centre-zero type, or provision made for reversal of polarity. For more elaborate testing see Chapter 3 Sect. 3.

(i) Plate characteristics

The Plate Characteristic may be drawn by maintaining the grid at some constant voltage, varying the plate voltage step-by-step from zero up to the maximum available, and noting the plate current for each step of plate voltage. These readings may then be plotted on graph paper with the plate voltage horizontal and plate current vertical. This procedure may be repeated for other values of grid voltage to complete the Plate Characteristic Family.

The Plate Characteristic Family for a typical triode is shown in Fig. 2.2. It is assumed that the plate voltage has been selected as 180 volts, and the grid bias -4 volts. By drawing a vertical line from 180 volts on the E_p axis (point K), the quiescent operating point Q will be determined by its intersection with the " $E_g = -4$ " curve. By referring Q to the vertical scale (I_p) the plate current is found to be 6mA. The plate resistance at the point Q is found by drawing a tangent (EF) to the curve for $E_g = -4$ so that it touches the curve at Q.

The plate resistance (r_p) at the point Q is then EK in volts (65) divided by QK in amperes (6 mA = 0.006 A) or 10 800 ohms.

The amplification factor (μ) is the change of plate voltage divided by the change of grid voltage for constant plate current. Line CD is drawn horizontally through Q, and represents a line of constant plate current. Points C and D represent grid voltages of -2 and -6 , and correspond to plate voltages of 142 and 218 respectively. The value of μ^* is therefore (218 - 142) plate volts divided by a change of 4 grid volts, this being 76/4 or 19.

The mutual conductance (g_m) is the change of plate current divided by the change of grid voltage for constant plate voltage. Line AB, which is drawn vertically through Q, represents constant plate voltage. Point A corresponds to 9.6 mA, while point B corresponds to 2.6 mA, giving a difference of 7 mA. Since points A and B also differ by 4 volts grid bias, the mutual conductance* is 7 mA divided by 4 volts, which is 1.75 mA/volt or 1750 micromhos.

*The value so determined is not exactly the value which would be obtained with a very small swing, but is sufficiently accurate for most practical purposes.

In these calculations it is important to work with points equidistant on each side of Q to reduce to a minimum errors due to curvature.

Fig. 2.2. Plate characteristic family of curves for a typical triode.

Fig. 2.3. Plate characteristics of a pentode, for one fixed screen voltage.

The plate characteristics of a pentode for one fixed screen voltage are shown in Fig. 2.3. Owing to the high plate resistance of a pentode the slope of the portion of the curves above the "knee" is frequently so flat that it is necessary to draw extended tangents to the curves as at A, B and Q. A horizontal line may be drawn through Q to intersect the tangents at A and B at points C and D. As with a triode, points A and B are vertically above and below Q. The mutual conductance is AB (4.1 mA) divided by 4 volts change of grid bias, that is 1.025 mA/V or 1025 micromhos. The amplification factor is the change of plate voltage ($CD = 447$ volts) divided by the change of grid voltage (4 volts) or 111.7. The plate resistance is EK/QK , i.e. $180/0.00165$ or 109 000 ohms.

The plate characteristics of a beam tetrode are somewhat similar to those of a pentode except that the "knee" tends to be more pronounced at high values of plate current.

The plate characteristics of a screen-grid or tetrode are in the upper portion similar to a pentode, but the "knee" occurs at a plate voltage slightly greater than the screen voltage and operation below the "knee" is normally inadvisable due to instability.

The plate and screen characteristics of a pentode are shown in Fig. 2.4, from which it will be seen that the total cathode (plate + screen) current for any fixed grid bias is nearly constant, except at low plate voltages, and that the plate current increases at the expense of the screen, and vice versa. A pentode is frequently described as a "constant-current device," but the plate current is not so nearly con-

stant as the combination of plate and screen currents, with fixed grid bias and screen voltage.

(ii) Mutual characteristics†

The Mutual Characteristics may be drawn by maintaining the plate voltage constant, and varying the grid from the extreme negative to the extreme positive voltage desired. For any particular plate voltage, there is a negative grid voltage at which the plate current becomes zero; this is called the point of plate current cut-off, and any increase of grid voltage in the negative direction has no effect on the plate current, which remains zero. If the mutual characteristic were perfectly straight, the point of plate current cut-off would be at a grid voltage of E_b/μ ; in reality, it occurs at a point slightly more negative, owing to the curved foot of the characteristic.

Fig. 2.4. Plate and screen characteristics for a pentode, with fixed screen and grid voltages, showing also the cathode current curve which is the sum of the plate and screen currents at all plate voltages.

Fig. 2.5. Mutual characteristics of a triode, with one curve for each of five fixed plate voltages.

The Mutual Characteristics of a triode are shown in Fig. 2.5. Each curve corresponds to a constant plate voltage. Let P be a point on the $E_b = 250$ curve, and let us endeavour to find out what information is available from the curves. The bias corresponding to P is given by R (-6 volts) and the plate current is given by S (6 mA). Let now a triangle ABC be constructed so that AP = PC, AB is vertical, CB is horizontal and point B comes on the $E_b = 200$ curve.

The mutual conductance is given by AB/BC or 2.32 mA/4 volts, which is 0.580 mA/volt or 580 micromhos. Thus the slope of the characteristic is the mutual conductance.**

†Also known as Transfer Characteristics.

**This simple construction assumes that APC is a straight line. In practice it is slightly curved but the construction gives a very close approximation to the slope at point P because the slope of the tangent at P is approximately the slope of the chord joining A and C.

The amplification factor is given by the change of plate voltage divided by the change of grid voltage for constant plate current, that is

$$\mu = \frac{E_{b1} - E_{b2}}{CB} = \frac{E_{b1} - E_{b2}}{\Delta E_c} = \frac{250 - 200}{4} = 12.5.$$

The plate resistance is given by the change of plate voltage divided by the change of plate current for constant grid voltage; that is

$$r_p = \frac{E_{b1} - E_{b2}}{AB} = \frac{E_{b1} - E_{b2}}{\Delta I_b} = \frac{250 - 200}{2.32 \times 10^{-3}} = 21\,600 \text{ ohms}.$$

These curves hold only if there is no series resistance in the plate circuit. They could therefore be used for a transformer-coupled amplifier provided that the primary of the transformer had negligible resistance. In the present form they could not be used to predict the operation under dynamic conditions. The static operation point P may, however, be located by their use.

The mutual characteristics of a pentode, for a fixed screen voltage, are very similar to those of a triode except that each curve applies to a different value of screen (instead of plate) voltage. The plate voltage of pentodes having high plate resistance has only a very minor effect on the plate current, provided that it does not come below the screen voltage.

FIG. 2.7

FIG. 2.8

Fig. 2.7. Mutual characteristics of a pentode, with constant plate voltage, and five fixed screen voltages.

Fig. 2.8. Screen current mutual characteristics of a pentode (same as for Fig. 2.7).

The Mutual Characteristic Family for a typical pentode is shown in Fig. 2.7, and the corresponding screen current characteristics in Fig. 2.8.

The resemblance between the shapes of the plate and screen characteristics is very close, and there is an almost constant ratio between the plate and screen currents along each curve.

(iii) Grid current characteristics

Positive grid current in a perfectly hard indirectly-heated valve usually commences to flow when the grid is slightly negative (point Y in Fig. 2.9) and increases rapidly as the grid is made more positive (Curve A). The position of point Y is affected both by the contact potential between grid and cathode and also by the initial electron velocity of emission; the latter is a function of the plate and grid voltages and the amplification factor of the valve, and will therefore vary slightly as the electrode

voltages are changed. The grid current commencement point in perfectly hard battery valves is usually slightly positive, so that they may be operated at zero bias with negligible positive grid current (Curve B).

A typical valve at its normal negative bias will have negative (or reverse) grid current which is the sum of gas (ionization) current, leakage current and grid primary emission current. If the two latter are negligibly small, negative grid current (i.e. *gas current*) will be roughly proportional to the plate current, and will increase with the pressure of gas in the valve. If the plate current is maintained constant, the gas current varies approximately as the square of the plate voltage; reduced cathode temperature has little effect on this relationship (Ref. A12). See Chapter 1 Sect. 1 for general information regarding gas current and Chapter 3 Sect. 3(iv)A for the measurement of reverse grid current.

FIG. 2.9

Fig. 2.9. Grid current characteristics of a triode or pentode.

Curve C shows the gas (ionization) current alone, and the solid line D is the combination of curves A and C, this being the grid current characteristic of a typical indirectly heated valve with a slight amount of gas. The maximum negative grid current occurs at a value of grid bias approximately equal to that of the grid current commencement point of the same valve if it could be made perfectly hard (point Y). The point of zero grid current (X) differs from the point of grid current commencement in a perfectly hard valve (Y).

The grid current cross-over point (X) in a new indirectly heated valve is usually between zero and -1.0 volt, and some slight variations in the value are to be expected during life. Change of contact potential between grid and cathode results in a corresponding shift of the mutual characteristics; a change of contact potential in the direction which makes the grid current cross-over point move in the positive direction during the life of the valve will result in decreased plate current, which may be quite serious in a high- μ triode operating on a low plate supply voltage. This is one reason why grid leak bias (with a grid resistor of about 5 or 10 megohms) is often used with such valves, so that the operating point is maintained in the same relation to the mutual characteristic.

In battery type valves the grid current cross-over point may be either positive or negative and designers should allow for some valves with negative values, particularly in cases of low screen voltage operation.

If valve is operated with its grid completely open-circuited, the operating point will be at D, since this is the only point corresponding to zero grid current, unless the grid characteristic has a second point of zero grid current at a positive grid voltage (see under grid blocking).

If the valve is operated with zero bias, that is with the grid resistor returned to cathode, the grid static operating point will be at E, the intersection of the grid current characteristic and the grid loadline through O. If the valve is one with positive cross-over point, operating at zero bias, the grid static operating point will occur at F.

In all cases considered above, the operating points are for static conditions, and any large signal voltages applied to the grid may have an effect in shifting the operating point. If the signal voltage swings the grid sufficiently to draw positive grid current, the operating point will shift as the result of rectified current flowing through R_g .

The effect of negative grid current on the maximum grid circuit resistance and the operation of a-f amplifiers is described in Chapter 12 Sect. 2(iii) and (iv); Sect. 3(iv)C and (v); also Chapter 13 Sect. 10(i).

Fig. 2.11. Grid current characteristics indicating the possibility of "grid blocking" with a valve operating at zero bias.

FIG. 2.11

Positive grid voltages and grid blocking

When the grid is made positive, it is bombarded by electrons which cause it to increase in temperature, and it may have both **primary and secondary electron emission**. This current is in a direction opposite to that of positive grid current flow, and may result in a slight kink in the grid characteristic, or may be severe enough to cause the grid current in this region to become negative. A typical case of the severe type is shown in Fig. 2.11, in which the greatest negative grid current occurs at a positive grid voltage of 70 or 80 volts. Such a valve is capable of "grid blocking" if the grid is swung sufficiently positive, and if the grid circuit resistance is high enough. Grid blocking can only occur if the grid loadline cuts the negative loop of grid current. In Fig. 2.11 the 0.1 megohm loadline cuts it at points A and B, but point A is unstable and the grid will jump on to point B and remain there until the valve is switched off, or the grid circuit resistance decreased until the grid loadline no longer cuts the curve (e.g. 0.04 megohm in Fig. 2.11).

(iv) Suppressor characteristics

In some pentodes, the suppressor is brought out to a separate pin, and may be used for some special purposes. Fig. 2.12 shows the mutual characteristics of a pentode suitable for suppressor modulation, although typical of any pentode. The curves

are in the shape of a fan pivoted at the cut-off point, with the slope controlled by the suppressor voltage. The curves of electrode currents versus suppressor voltage are given in Fig. 2.13, and indicate that the plate current curve rises fairly steadily from the point of cut-off at a high negative voltage but flattens out while still at a negative suppressor voltage. The screen current falls as the plate current rises, as would be expected, and the suppressor current commences at a slight positive voltage, although in this case it becomes negative at high voltages due to secondary emission.

The suppressor is occasionally used as a detector in receivers, instead of a diode, but its rectification efficiency is low, since the internal resistance is of the order of 20 000 ohms.

In remote cut-off r-f pentodes the suppressor is sometimes used to provide a more rapid cut-off characteristic. A family of mutual conductance and plate resistance curves for a typical remote cut-off pentode are given in Fig. 2.14.

It will be seen the mutual conductance for any fixed control grid voltage (say $E_{c1} = -3$) may be reduced by making the suppressor voltage negative. This has the additional effect, however of decreasing the plate resistance from 0.8 megohm (at $E_{c3} = 0$) to 35 000 ohms at $E_{c3} = -37$, for $E_{c1} = -3$ volts. The initial rate of reduction is very steep, and occurs with all values of control grid voltage.

Fig. 2.13. Suppressor characteristics of a pentode (6SJ7) for fixed control grid, screen and plate voltages.

FIG. 2.12

Fig. 2.12. Mutual characteristics of a pentode (6SJ7) for various suppressor voltages.

If the suppressor grid has the same bias control voltage as the control grid, the control characteristic will be as shown by the curve marked " $E_{c1} = E_{c3}$," but in this case the plate resistance, although initially slightly lower for $E_{c3} = -3$ than for $E_{c3} = 0$, rises rapidly as $E_{c1} = E_{c3}$ is made more negative.

(v) Constant current curves

The third principal type of valve characteristic is known as the "Constant Current" Characteristic. A

typical family of Constant Current Curves is shown in Fig. 2.15, these being for a typical triode (type 801). The slope of the curves indicates the amplification factor, and the slope of the loadline indicates the stage voltage gain. The operating point is fixed definitely by a knowledge of plate and grid supply voltages, but the loadline is only straight when both plate and grid voltages follow the same law (e.g., both sine wave). Distortion results in curved characteristics, so that this form of representation is not very useful except for tuned-grid tuned-plate or "tank-circuit" coupled r-f amplifiers. Constant Current Curves may be drawn by transferring points from the other published characteristics. For a full treatment the reader is referred to

(vi) "G" curves

Curves of constant g_m and g_p are plotted for a typical triode in Fig. 13.9B. These are helpful in calculating the voltage gain of resistance-coupled triodes and, to a less extent, pentodes, and in other applications. (Refs. B14, B22, B31, B32).

(vii) Drift of characteristics during life

During the life of a valve there is always a slow drift which is particularly apparent in the plate and screen currents, mutual conductance, negative grid current and the contact potential point. The direction of drift sometimes reverses one or more times during life. It is assumed here that the valve is operated at constant applied voltages throughout its life.

In general, the grid current crossover point (Fig. 2.9) tends to drift in the positive direction during life. The movement of the contact potential point results in a shift of the mutual characteristics which in turn has the effect of reducing the plate current which flows at a fixed grid bias.

Life tests have been carried out (Ref. A12) for a period of 3200 hours on type 6SL7 high- μ twin triodes. The recorded characteristic was the grid voltage to give a plate current of 0.1 mA with a plate voltage of 75 volts. The maximum drift was 0.6 volt (from -1.65 to -1.05 volts), but the majority of the valves did not go outside the limits -1.5 to -1.1 volt (0.4 volt drift). In most cases the drift was generally in a positive direction, but there were two exceptions (out of a total of twelve units) which showed a general tendency to drift in the negative direction for the first hundred hours or so and then to drift in the positive direction, ending up at approximately the same values where they began. However, even those having a positive

Fig. 2.14. Suppressor characteristics of a remote cut-off pentode (6U7-G) for fixed screen and plate voltages.

general direction showed rapid changes in the rate of change, and usually at least one temporary reversal of direction.

It was found that minimum drift occurred for plate currents between 0.1 and 1.0 mA for indirectly-heated types, or between 10 and 100 μ A for small filament types.

This drift occurs in diodes and all types of amplifying valves, being particularly noticeable in its effects on high- μ triodes (on account of the short grid base) and on power amplifiers (on account of the decrease in maximum power output). In direct-coupled amplifiers this drift becomes serious, the first stage being the one most affected.

Most of the drift usually occurs during the first hundred hours of operation. If stability is required it is advisable to age the valves for at least 2 days, but in some cases this does not cure the rapid drift. Reference A12, pp. 730-733.

FIG. 2-15

FIG. 2-16

Fig. 2.15. Constant current characteristics for a typical small transmitting triode (801).

Fig. 2.16. Triode plate characteristics with loadlines for five values of load resistance.

(viii) Effect of heater-voltage variation

When a valve is being operated so that the plate current is small compared with the total cathode emission, an increase in heater voltage normally causes an increase in plate current, which may be brought back to its original value by an increased negative bias. With indirectly-heated cathodes the increase in negative bias is approximately 0.2 volt for a 20% increase in heater voltage, whether the valve is a diode, triode or multi-grid valve (Ref. A12, p. 421).

This effect is serious in d-c amplifiers; there are methods for cancelling the effect (Ref. A12, p. 458).

SECTION 3 : RESISTANCE-LOADED AMPLIFIERS

(i) Triodes (ii) Pentodes.

(i) Triodes

When there is a resistance load in the plate circuit, the voltage actually on the plate is less than that of the supply voltage by the drop in the load resistor,

$$E_b = E_{bb} - R_L I_b.$$

This equation may be represented by what is known as a **Load Line** on the plate characteristics. Since the load is a pure resistance it will obey Ohm's Law, and the relationship between current and voltage will be a straight line; the loadline will therefore be a straight line.

The static operating point is the intersection of the loadline and the appropriate characteristic curve. Fig. 2.16 shows several loadlines, corresponding to different load resistors, drawn on a plate characteristic family. Zero load resistance is indicated by a vertical loadline, while a horizontal line indicates infinite resistance.

A loadline may be drawn quite independently of the plate characteristics, as in Fig. 2.17. The point B is the plate supply voltage E_{bb} (in this case 300 V); the slope* of the loadline $AB = -1/R_L$ and therefore $AO = E_{bb}/R_L$ (in this case $300/50\,000 = 0.006\text{ A} = 6\text{ mA}$). The voltage actually on the plate can only be equal to E_{bb} when the current is zero (point B). At point A the voltage across the valve is zero and the whole supply voltage is across R_L ; this is what happens when the valve is short-circuited from plate to cathode. The plate current (E_{bb}/R_L) which flows under these conditions is used as a reference basis for the correct operation of a resistance coupled amplifier (Chapter 12). As the plate voltage, under high level dynamic conditions, must swing about the operating point, the latter must be somewhere in the region of the middle of AB; the plate current would then be in the region of $0.5 E_{bb}/R_L$ and the plate voltage $0.5 E_{bb}$ —in other words, the supply voltage is roughly divided equally between the valve and the load resistance. Actually, the operating point may be anywhere within the limits 0.4 and 0.85 times E_{bb}/R_L —see Chapter 12 Sect. 2(vi) and Sect. 3(vi).

In most resistance-loaded amplifiers, the plate is coupled by a capacitor to the grid of the following valve, which has a grid resistor R_g to earth. This resistor acts as a load on the previous valve, but only under dynamic conditions. In Fig. 2.18 the loadline AB is drawn, as in Fig. 2.17, and the operating point Q is fixed by selecting the grid bias (here -6 volts). Through Q is then drawn another line CD having a slope of $-(1/R_L + 1/R_g)$; this is the dynamic loadline, and is used for determining the voltage gain, maximum output voltage and distortion (Chapter 12).

Fig. 2.17. Loadline is independent of valve curves.

Fig. 2.18. Loadlines of resistance loaded triode; AQB is without any following grid resistor, CQD allows for the grid resistor.

The dynamic characteristic is the effective mutual characteristic when the valve has a resistive load in the plate circuit†. While the slope of the mutual characteristic is g_m or μ/r_p , the slope of the dynamic characteristic is $\mu/(r_p + R_L)$. Owing to $(r_p + R_L)$ being more nearly constant than r_p , the dynamic characteristic is more nearly straight than the mutual characteristic.

*The slope of AB is negative since the plate voltage is the difference between the supply voltage and the voltage drop in R_L , and the inverted form $(1/R_L)$ is due to the way in which the valve characteristics are drawn with current vertically and voltage horizontally. The slope of AB is often loosely spoken of as being the resistance of R_L , the negative sign and inverted form being understood.

†It does not make allowance for the following grid resistor, and does not therefore correspond to the dynamic loadline. It is, of course, possible to derive from the dynamic loadline a modified dynamic characteristic which does make allowance for the grid resistor.

A typical dynamic characteristic is shown in Fig. 2.19 applying to a supply voltage of 250 volts and load resistance 0.1 megohm; the mutual characteristics are shown with dashed lines.

The dynamic characteristic may be drawn by transferring points from along the loadline in the plate characteristic to the mutual characteristic. An alternative method making use of the mutual characteristic is as follows—

When the plate current is zero, the voltage drop in the load resistance is zero, and the plate voltage is equal to the supply voltage (250). For the plate voltage to be 200 volts, there must be a drop of 50 volts in the load resistor (100 000 ohms) and the plate current must therefore be 50/100 000 or 0.5 mA, and so on. A table may be prepared for ease of calculation:

Plate Voltage	Voltage Drop in Load Resistor	Plate Current (= volts drop/ R_L)
250	0	0
200	50	0.5 mA.
150	100	1.0 mA.
100	150	1.5 mA.
50	200	2.0 mA.

It will be seen that this table is not affected by the shape of the valve characteristics. The dynamic characteristic may then be plotted by taking the intersections of the various plate voltage curves with the plate current values given in the table.

The dynamic characteristic of a triode is very nearly straight along the central portion, with curves at both ends, the "upper bend" being always in the positive grid current region.

Fig. 2.19. Triode dynamic characteristic (solid line) for resistance loading.

Fig. 2.20. Illustrating power dissipation in a resistance-loaded triode.

Refer to Chapter 12 for further information on resistance coupled amplifiers.

When a resistance-loaded triode is operated under steady conditions, the **power dissipation** is indicated by Fig. 2.20. The area of the rectangle OCDB represents the total power ($E_{bb} I_{b0}$) drawn from the plate supply. The area of the rectangle OCQK represents the plate dissipation of the valve ($E_{bb} I_{b0}$) and the area of the rectangle KQDB represents the dissipation in the load resistor ($E_{bb} - E_{b0}$) $I_{b0} = I_{b0} R_L$. Under dynamic conditions the plate dissipation decreases by the amount of power output, and the load resistor dissipation increases by the same amount, provided that there is no a.c. shunt load and that there is no distortion. The case of transformer-coupled loads is treated in Chapter 13.

(ii) Pentodes

Pentodes with resistive loads are treated in the same manner as triodes, the only complication being the screen voltage which must be selected at some suitable value

and maintained constant (Fig. 2.21). The operating point as an amplifier will normally, as with a triode, be in the region of the middle of the loadline so that the voltage across the valve and that across R_L will be approximately the same. The only special case is with very low values of R_L (e.g. 20 000 ohms) where grid current occurs at approximately $E_{c1} = 0$, thereby limiting the useful part of the loadline.

FIG. 2.21

FIG. 2.22

Fig. 2.21. Loadlines of resistance-loaded pentode.

Fig. 2.22. Triode plate characteristics and loadline with transformer-coupled load.

With any value of screen voltage, and any value of load resistance, it is possible to select a grid bias voltage which will give normal operation as an amplifier. With load resistance of 0.1 megohm and above, pentodes give dynamic characteristics which closely resemble the shape of triode dynamic characteristics with slightly greater curvature at the lower end; at the upper end, provided that the screen voltage is not too low, the pentode has a curved portion where the triode runs into grid current. The top bend of the pentode dynamic characteristic is often used in preference to the bottom bend for plate detection—see Chapter 27 Sect. 1(ii)C.

For further information on resistance coupled pentode amplifiers, reference should be made to Chapter 12 Sect. 3.

SECTION 4 : TRANSFORMER-COUPLED AMPLIFIERS

- (i) With resistive load. (ii) Effect of primary resistance (iii) With i-f voltage amplifiers (iv) R-F amplifiers with sliding screen (v) Cathode loadlines (vi) With reactive loads.

(i) With resistive load

When the load resistance is coupled to the valve by an ideal transformer, there is no direct voltage drop between the supply voltage and the plate. The slope of the loadline, as before, is $-1/R_L$ but the loadline must be lifted so that it passes through the operating point. Fig. 2.22 shows a typical triode with $E_b = 250$ volts, and $E_c = -10$ volts, thus determining the static operating point Q. The loadline AQB is then drawn through Q with a slope corresponding to a resistance of 30 000 ohms. It is not taken beyond point A ($E_c = 0$) because in this case it is intended to be a Class A amplifier, operating without grid current. It is not taken beyond B because this is the limit of swing in the downward direction corresponding to A in the upward direction and having twice the bias of point Q (i.e. -20 volts). Of course, AB could be projected upwards and downwards if it were desired to increase the grid swing without regard to grid current or distortion.

(ii) Effect of primary resistance

If the primary circuit includes resistance, the point Q must be determined by drawing through E_b a straight line with a slope of $-1/R'$, where R' includes all resistances in the primary circuit other than the plate resistance of the valve. R' will include the d.c. resistance of the transformer primary winding and any equivalent internal resistance of the plate supply source. Fig. 2.23 is a typical example, with $R' = 1500$ ohms, from which point Q can be determined as previously. The total a.c. load on the valve is then $(R_L + R')$, in this case 31 500 ohms, which will give the slope of AQB. In these examples it is assumed that fixed bias is used, and that the negative side of the supply voltage is applied directly to the cathode of the valve.

(iii) With i-f voltage amplifiers

I-F amplifiers, when correctly tuned, operate with the valve working into practically a resistive load. I-F and r-f amplifier valves are in two principal groups—sharp cut-off and remote cut-off.

Sharp cut-off r-f pentodes operate in much the same manner as a-f pentodes, and the tuned transformer in the plate circuit reduces any distortion which might occur through non-linearity of the characteristics. The d.c. resistance of the transformer is usually so small that it may be neglected and the loadline drawn through Q with a slope corresponding to the dynamic load resistance of the transformer (including its secondary load, if any, referred to the primary).

FIG. 2-23

FIG. 2-24

Fig. 2.23. Triode plate characteristics and loadlines with transformer-coupled load, allowing for the resistance of the primary winding.

Fig. 2.24. Plate characteristics of typical remote cut-off pentode with fixed screen and suppressor voltages.

Remote cut-off r-f pentodes are similar, except that the mutual characteristics are curved, and the distortion is greater. Fig. 2.24 shows the plate characteristics of a typical remote cut-off pentode, with $E_b = 250$ volts. Two loadlines (AQB, A'Q'B') have been drawn for grid bias voltages of -3 and -12 volts respectively, with a slope corresponding to a load resistance of 200 000 ohms, as for an i-f amplifier. This application of the loadline is not entirely valid, although it gives some useful information, since the tuned plate circuit acts as a "flywheel" to improve the linearity and reduce the distortion. This is a case in which constant current curves could be used with advantage. However, the ordinary plate characteristics at least indicate the importance of a high Q (high dynamic resistance) second i-f transformer if it is desired to obtain high output voltages at even moderately high negative bias voltages; a steeper loadline would reach plate current cut-off at the high voltage peak.

(iv) R-F Amplifiers with sliding screen

Remote cut-off pentodes may have their cut-off points made even more remote by supplying the screen from a higher voltage (generally the plate supply) through a

Fig. 2.25. Plate current characteristic of remote cut-off pentode with "sliding screen." The straight lines indicate the mutual conductances at several points.

resistor designed to provide the correct screen voltage for the normal (minimum bias) operating condition. The screen requires to be by-passed to the cathode.

The same method may be used with a sharp cut-off pentode to provide a longer grid base. This does not make it possible to obtain the same results as with a properly designed remote cut-off pentode, although it does increase the maximum input voltage which can be handled with a limited distortion. It is important to remember that the extended plate current characteristic curve obtained by this method cannot be used to determine the dynamic slope, since the latter is higher than would be calculated from the characteristic. This is demonstrated in Fig. 2.25 which shows the "sliding screen" plate current characteristic, with straight lines drawn to indicate the mutual conductance at several points.

The procedure for deriving the "sliding screen" plate current characteristic from the fixed voltage data is as follows—

Let plate and screen current curves be available for screen voltages of 50, 75, 100 and 125 volts (Fig. 2.26) and take the case with a series screen resistor (R_s) of 250 000 ohms from a supply voltage of 300.

E_{c1}	E_{drop}^*	I_{c2}^{**}	Point	E_{c1}^\dagger	Point	I_{b1}^\ddagger
50 V	250 V	1.0 mA	A	-0.1	E	3.7 mA
75	225	0.9	B	-1.7	F	3.15
100	200	0.8	C	-3.3	G	2.6
125	175	0.7	D	-5.2	H	2.1

*The voltage drop in the screen resistance = $300 - E_{c2}$.

** $I_{c1} = E_{drop}/R_s$.

†Derived from the screen characteristics and transferred to the plate characteristics.

‡Derived from the plate characteristics.

(v) Cathode loadlines

The static operating point with cathode self bias may be determined graphically by the use of the mutual characteristic. The mutual characteristic of a triode shown

in Fig. 2.27 applies to the voltage between plate and cathode—the total supply voltage will be greater by the drop in the cathode resistor R_k .

Through O should be drawn a straight line OD, having a slope of $-1/R_k$ ohms. The point P where OD intersects the curve corresponding to the plate-to-cathode voltage (here 250 V) will be the static operating point, with a bias $-E_{c1}$ and plate current I_{b1} .

In the case of pentodes, with equal plate and screen voltages, the "triode" mutual characteristic should be used, if available. With the plate voltage higher than the screen voltage, the triode mutual characteristic may be used as a fairly close approximation, provided that the triode curve selected is for a voltage the same as the screen voltage.

Alternatively, pentodes may be treated as for triodes, except that the slope of OD should be

$$-\frac{1}{R_k} \cdot \frac{I_b}{I_b + I_{c2}}$$

where I_b and I_{c2} may be taken to a sufficient degree of accuracy as being the values under published conditions. The plate current (I_b) may then be read from the curve, and the screen current calculated from the ratio of screen to plate currents.

For the use of cathode loadlines with resistance coupled triodes and pentodes, refer to Chapter 12.

Fig. 2.26. Plate and screen current characteristics of pentode illustrating procedure for deriving "sliding screen" characteristics.

FIG. 2.27

Fig. 2.27. Triode mutual characteristics with cathode bias loadline OD.

(vi) With reactive loads

When the load on the secondary of the transformer is not purely resistive, the loadline is normally in the form of an ellipse instead of a straight line. Fig. 2.28 shows three different examples of elliptical loadlines for purely reactive loads. A purely capacitive load has exactly the same shape of loadline as a purely inductive one, but the direction of rotation of the point is opposite, as indicated by the arrows. Curve A is for a high reactance, curve B for an intermediate value of reactance, and curve C for a low reactance. In each case the maximum current is E_o/X_o , where E_o is the peak voltage across the reactance and $X_o = \omega L$ for the inductive case, and $X_o = 1/\omega C$ for the capacitive case. The voltage E_o is shown as negative to the right of O, so as to be suitable for applying directly to the plate characteristics of the valve.

For convenience in application, the horizontal and vertical scales should be the same as in the valve characteristics to which the loadline is to be applied. For example, if on the plate characteristics one square represents 1 mA in the vertical direction and 25 V in the horizontal direction, the same proportion should be maintained for the elliptical loadline. Having drawn the ellipse for any convenient value of E_o , it may be expanded or contracted in size, without changing its shape (that is the ratio of the major to the minor axis when both are measured in inches).

(a) Resistance and inductance in series

The load is more commonly a combination of resistance and reactance. When the load is a resistance R_L in series with an inductive reactance ωL , the maximum current through both will be I_o and the procedure is to draw both the straight resistive loadline for R_L (AB in Fig. 2.29) and the elliptical loadline for ωL , and then to combine them in series. It will be seen that in Fig. 2.29 the peak current of the ellipse and of the resistive loadline are identical (I_o).

To combine these in series, it is necessary to consider the phase relations. When the current is a maximum (OE), the voltage drop across R_L is a maximum (AE) and that across L is zero, because there is 90° phase difference between the voltage and current: the total voltage drop across R_L and L in series is therefore AE and point A is on the desired loadline. When the current is zero, the voltage drop across R_L is zero, and that across L is OC; the total voltage drop is therefore OC, and point C is on the desired loadline. At any intermediate point (OF) with current increasing the voltage drop across R_L is FG, and that across L is FH, so that the total drop is

FIG. 2.28

Fig. 2.28. Three examples of elliptical loadlines for purely reactive loads.

FIG. 2.29

Fig. 2.29. Resistive loadline (R_L); inductive loadline (ωL); and elliptical resultant for R_L in series with ωL (dashed curve).

$FJ = FG + FH$. With similar procedure in the other three quadrants, the combined loadline is shown to be an ellipse CJADB which is tilted, or rotated in the clockwise direction as compared with the original ellipse. The maximum voltage drop is greater than that across either R_L or L alone, as would be expected.

If an elliptical loadline is known, as for example the dashed ellipse of Fig. 2.29, its series components may readily be determined. Mark points A and B where the ellipse reaches its maximum and minimum current values, then draw the line AB; the slope of AB gives R_L . Mark O as the centre of the line AB; draw COD horizontally to cut the ellipse at points C and D.

Then $\omega L = E_o/I_o$ ohms,

where E_o = voltage corresponding to length OD

and I_o = current (in amperes) corresponding to max. vertical height of ellipse above line COD.

Alternatively

$$\omega L = \frac{\text{Length of horizontal chord of ellipse through O, in volts}}{\text{Maximum vertical extent of ellipse, in amperes}}.$$

(b) Resistance and inductance in parallel

When the load is a resistance R_L in parallel with an inductive reactance ωL , the maximum voltage across both will be E_o , and the resistive loadline and reactive ellipse may be drawn as for the series connection. In this case, however, the currents have to be added. In Fig. 2.30 the maximum current through R_L is CK (corresponding to $+E_o$), while the maximum current through L is OE. When the voltage is zero and increasing, the current through R_L is zero, and that through L is the minimum value OP; point P is therefore on the desired loadline. When the voltage is its positive maximum (OC), the current through R_L is CK and that through L is zero; point K is therefore on the desired loadline. Similarly with points E and M. At an intermediate value, when the voltage is negative and approaching zero (OR), the current through R_L is RS, and that through L is RT; the total current is therefore $RT + RS = RW$, and W is on the desired loadline. The loadline is therefore the ellipse PKEMW.

Fig. 2.30. Resistive loadline (R_L); inductive loadline (solid ellipse); and elliptical resultant for R_L in parallel with ωL (dashed curve).

FIG. 2.30

If an elliptical loadline is known, as for example the dashed ellipse of Fig. 2.30, its parallel components may readily be determined. Mark points K and M where the ellipse reaches its maximum and minimum voltage values, then draw the line KM; the slope of KM gives R_L . Mark O as the centre of the line KM; draw EOP vertically to cut the ellipse at points E and P.

Then $\omega L = E_o/I_o$ ohms,

where E_o = voltage difference between points O and K,

and I_o = current corresponding to length OE, in amperes.

Alternatively

$$\omega L = \frac{\text{Maximum horizontal length of ellipse, in volts}}{\text{Length of vertical chord of ellipse through O, in amperes}}.$$

(c) Resistance and capacitance

A similar shape of loadline is obtained when the inductance is replaced by a capacitance of equal reactance, except that the direction of rotation is opposite.

(d) Applying elliptical loadlines to characteristics

The elliptical loadlines derived by the methods described above may be applied to the plate characteristics of a valve, but it is first necessary to enlarge or reduce their size until they just fit between grid voltage curves corresponding to extreme swing

Fig. 2.31. Triode plate characteristics with elliptical loadlines corresponding to resistance 25 000 ohms in series with reactance of 18 000 ohms.

in each direction. The examples taken have all been based on an arbitrary current (I_o) or voltage (E_o), which may be made larger or smaller as desired. In Fig. 2.31 there is shown the elliptical loadline corresponding to a resistance of 25 000 ohms in series with a reactance of 18 000 ohms, on triode plate characteristics with $E_b = 250$ volts, $E_c = -10$ volts and peak grid amplitude $E_{gm} = 8$ volts.

Fig. 2.32. Beam power amplifier plate characteristics with elliptical loadline corresponding to a resistance of 4750 ohms in parallel with a reactance of 23 000 ohms.

Fig. 2.32 shows a typical beam power amplifier with an elliptical loadline with a resistive load of 4750 ohms shunted by a reactance of 23 000 ohms. The plate voltage is 250 volts, grid bias -12.5 volts, and grid swing from 0 to -25 volts.

In all applications of elliptical loadlines to characteristics, the shape of the ellipse (i.e. the ratio of its major to its minor axis) and the slope of the major axis are determined solely by the nature of the load. The ellipse can be imagined as being slowly blown up, like a balloon, until it just touches without cutting the two curves of extreme voltage swing. If there is no distortion, the centre of the ellipse will coincide with the quiescent working point, but in the general case the centre of the ellipse will be slightly displaced.

SECTION 5 : TRIODE OPERATION OF PENTODES

(i) *Triode operation of pentodes* (ii) *Examples of transconductance calculation* (iii) *Triode amplification factor* (iv) *Plate resistance* (v) *Connection of suppressor grid.*

(i) Triode operation of pentodes

Any pentode may be operated as a triode, provided that none of the maximum ratings is exceeded, and the characteristics may readily be calculated if not otherwise available.

When the cathode current of a valve is shared by two collecting electrodes (e.g. plate and screen) the mutual conductance of the whole cathode stream (i.e. the "triode g_m ") is shared in the same proportion as is the current.

Let I_k = cathode current

I_{c2} = screen current

I_b = plate current

g_m = pentode transconductance (to the plate)

g_t = triode transconductance (with screen and plate tied together)

and g_s = screen transconductance (with pentode operation).

Then $I_k = I_{c2} + I_b$ (1)

$g_t = g_m + g_s$ (by definition) (2)

and $g_m/g_t = I_b/I_k$ (3)

If it is desired to find the screen transconductance, this can be derived from the expression

$g_s/g_m = I_{c2}/I_b$ (4)

or $g_s/g_t = I_{c2}/I_k$ (5)

(ii) Examples of transconductance calculation

Example 1: Type 6J7-G as a pentode with 100 volts on both screen and plate, and with a grid bias of -3 volts, has the following characteristics:—

Transconductance	1185 micromhos
Plate Current	2.0 mA
Screen Current	0.5 mA

It is readily seen that the cathode current (see equation 1 above) is given by

$$I_k = 0.5 + 2.0 = 2.5 \text{ mA.}$$

The triode transconductance is calculated by inverting equation (3) above,

$$g_t/g_m = I_k/I_b.$$

Therefore $g_t/1185 = 2.5/2.0$

and $g_t = 1482 \text{ micromhos.}$

The example selected was purposely chosen so as to have equal plate and screen voltages. Under these conditions the method is exact, and the calculated triode mutual conductance applies to the same conditions of plate and grid voltages as for the pentode operation (in this example 100 volts and -3 volts respectively).

Example 2: Type 6J7-G as a pentode with 250 volts on the plate, 100 volts on the screen, and -3 volts grid bias.

In this case a similar method may be used, but it is necessary to make an assumption which is only approximately correct. Its accuracy is generally good enough for most purposes, the error being within about 5% for most conditions.

The assumption (or approximation) which must be made is—*That the plate current of a pentode valve does not change as the plate voltage is increased from the same voltage as that of the screen up to the voltage for pentode operation.*

This assumption means, in essence, that the plate resistance is considered to be infinite—a reasonable approximation for most r-f pentodes, and not seriously in error for power pentodes and beam power valves.

In this typical example we can take the published characteristics, and assume that the plate current and transconductance are the same for 100 as for 250 volts on the plate. From then on the procedure is exactly as in the previous example. It is important to note that the calculated triode characteristics only apply for a triode plate voltage of 100 volts and a grid bias of -3 volts.

Example 3: To find the screen transconductance under the conditions of Example 1.

From eqn. (2) we may derive the expression—

$$\begin{aligned} g_s &= g_t - g_m = 1482 - 1185 \\ &= 297 \text{ micromhos.} \end{aligned}$$

This could equally well have been derived from eqn. (4) or (5).

(iii) Triode amplification factor

The triode amplification factor (if not available from any other source) may be calculated by the following approximate method.

Let μ_t = triode amplification factor
 E_{co} = negative grid voltage at which the plate current just cuts off
 and E_{c2} = screen voltage.
 Then $\mu_t = E_{c2}/E_{co}$ approx. (6)

For example, with type 6J7-G having a screen voltage of 100 volts, the grid bias for cut-off is indicated on the data sheet as being -7 volts approx. This is the normal grid bias for complete plate current cut-off, but it is not very suitable for our purpose since equation (6) is based on the assumption that the characteristic is straight, whereas it is severely curved as it approaches cut-off. The preferable procedure is to refer to the plate current-grid voltage characteristic, and to draw a straight line making a tangent to the curve at the working point—in this case with a screen voltage of 100 volts and grid bias -3 volts. When this is done, it will be seen that the tangent cuts the zero plate current line at about -5 volts grid bias. If this figure is used, as being much more accurate than the previous value of -7 volts, the triode amplification factor will be

$$\mu_t = 100/5 = 20.$$

Alternatively, if only the plate characteristics are available, much the same result may be obtained by observing the grid bias for the lowest curve, which is generally very close to plate current cut-off.

In the case of remote cut-off characteristics it is essential to adopt the tangent method, and the result will only apply to the particular point of operation, since the triode amplification factor varies along the curve.

The amplification factor of the screen grid in a pentode valve with respect to the control grid is almost exactly the same as the triode amplification factor.

The amplification factor of the plate of a pentode valve with respect to its screen grid may be calculated from the expression—

where $\mu_{s1 \cdot p} = \mu_{s1 \cdot s2} \mu_{s2 \cdot p}$ (7)
 $\mu_{s1 \cdot p}$ = pentode amplification factor
 and $\mu_{s2 \cdot p}$ = screen grid-plate mu factor.

This expression can only be used when the pentode amplification factor is known. If this is not published, it may be determined from a knowledge of the plate resistance and mutual conductance. If the former is not published, it may be derived graphically; this derivation is only very approximate in the case of sharp cut-off r-f pentodes, since the characteristics are nearly horizontal straight lines.

For example type 6AU6 has the following published values—

$$\left. \begin{array}{l} r_p = 1.5 \text{ megohms} \\ g_m = 4450 \text{ } \mu\text{mhos} \end{array} \right\} \text{ at } E_b = 250, E_{c2} = 125, E_{c1} = -1 \text{ V}$$

and from which $\mu = 6675$.
 But $\mu_{o1 \cdot c2} = 36$ approx.
 Therefore $\mu_{o2 \cdot p} = 6675/36 = 185$ approx.

(iv) Plate resistance

The “plate resistance” of each electrode (plate or screen) in the case of pentode operation, and the “triode plate resistance” when plate and screen are tied together, may be calculated from the corresponding values of μ and g_m .

(v) Connection of suppressor grid

The suppressor may be connected either to cathode or to the screen and plate, with negligible effect on the usual static characteristics. Some valves have the suppressor internally connected to the cathode, so that there is no alternative. In other cases, connection to cathode slightly increases the output capacitance. In low level amplifiers, connection of the suppressor to cathode may give lower noise in certain cases if there is a high resistance leakage path from suppressor to cathode; similarly its connection to screen and plate will give lower noise if there is leakage to the latter electrodes.

SECTION 6 : CONVERSION FACTORS, AND THE CALCULATION OF CHARACTERISTICS OTHER THAN THOSE PUBLISHED

(i) *The basis of valve conversion factors* (ii) *The use of valve conversion factors* (iii) *The calculation of valve characteristics other than those published* (iv) *The effect of changes in operating conditions.*

Conversion Factors provide a simple approximate means of calculating the principal valve characteristics when all the voltages are changed by the same factor. It is possible to make certain additional calculations so as to allow for the voltage of one electrode differing from this strict proportionality.

(i) The basis of valve conversion factors

Valve Conversion Factors are based on the well-known mathematical expression of valve characteristics

$$I_b = A(E_b - \mu E_c)^x \quad (1)$$

where I_b = plate current

E_b = plate voltage

E_c = grid voltage

A = a constant depending upon the type of valve

μ = amplification factor

and x = an exponent, with a value of approximately 1.5 over the nearly straight portion of the characteristics.

If we are concerned merely with changes in the voltages and currents, then we can reduce the expression to the form

$$I_b \propto (E_b - \mu E_c)^x. \quad (2)$$

Now if we agree to change the grid voltage in the same proportion as the plate voltage, we obtain the very simple form

$$I_b \propto E_b^x. \quad (3)$$

Finally, if we take x as 1.5 or $3/2$, we have the approximation

$$I_b \propto E_b^{3/2}. \quad (4)$$

Put into words, this means that the plate current of a valve varies approximately as the three-halves power of the plate voltage, provided that the grid voltage is varied in the same proportion as the plate voltage.

The same result may be obtained with pentodes, provided that both the grid and screen voltages are varied in the same proportion as the plate voltage. This result is the basis of Valve Conversion Factors, so that we must always remember that their use is restricted to cases in which all the electrode voltages are changed in the same proportion.

Let F_e be the factor by which all the voltages are changed (i.e. grid, screen, and plate), and let I_b' be the new plate current.

$$\text{Then } I_b' \propto (F_e E_b)^{3/2}. \quad (5)$$

$$\text{But } I_b' = F_t I_b$$

where F_t is the factor by which the plate current is changed.

$$\text{Therefore } F_t I_b \propto (F_e E_b)^{3/2}. \quad (6)$$

From the combination of (4) and (6) it will be seen that

$$F_t = F_e^{3/2} \quad (7)$$

Now the power output is proportional to the product of plate voltage and plate current so that

$$P_o \propto E_b I_b \quad (8)$$

$$\text{and } P_o' \propto (F_e E_b) (F_t I_b) \quad (9)$$

$$\text{so that } P_o' \propto F_e F_t (E_b I_b) \quad (10)$$

$$\propto F_e F_t (P_o). \quad (11)$$

We may therefore say that the power conversion factor F_p is given by the expression

$$F_p = F_e F_t. \quad (12)$$

$$\text{Therefore } F_p = F_e^{5/2}. \quad (13)$$

The mutual conductance is given by

$$g_m = \frac{\text{change of plate current}}{\text{change of grid voltage}}$$

$$\text{Therefore } F_{gm} = F_t / F_e = F_e^{3/2} / F_e = F_e^{1/2}. \quad (14)$$

The Plate Resistance is given by

$$r_p = \frac{\text{change of plate voltage}}{\text{change of plate current}}$$

$$\text{Therefore } F_r = F_e / F_t = F_e / F_e^{3/2} = F_e^{-1/2}. \quad (15)$$

This also applies similarly to the load resistance and cathode bias resistance.

We may therefore summarize our results so far:—

$$F_t = F_e^{3/2} \quad (7)$$

$$F_p = F_e^{5/2} \quad (13)$$

$$F_{gm} = F_e^{1/2} \quad (14)$$

$$F_r = F_e^{-1/2} \quad (15)$$

These are shown in graphical form on the Conversion Factor Chart (Fig. 2.32A).

(ii) The use of valve conversion factors

It is important to remember that the conversion factors may only be used when all the voltages (grid, screen and plate) are changed simultaneously by the same factor. If it is required to make any other adjustments, these may be carried out before or after using conversion factors, by following the method given under (iii) below.

Conversion factors may be used on any type of valve whether triode, pentode or beam tetrode, and in any class of operation whether class A, class AB1, class AB2 or class C.

The use of conversion factors is necessarily an approximation, so that errors will occur which become progressively greater as the voltage factor becomes greater. In general it may be taken that voltage conversion factors down to about 0.7 and up to about 1.5 times will be approximately correct. When the voltage factors are extended beyond these limits down to 0.5 and up to 2.0, the accuracy becomes considerably less, and any further extension becomes only a rough indication.

Fig. 2.32A. Conversion factor chart (by courtesy of R.C.A.).

The example given below is a straightforward case of a pentode valve whose characteristics are given for certain voltages and which it is desired to operate at a lower plate voltage.

Plate and screen voltage	50 volts
Control grid voltage	-15 volts
Plate current	30 mA

Screen current	6 mA
Mutual conductance	2,000 μ mhos
Power Output	2.5 watts.

It is required to determine the optimum operating conditions for a plate voltage of 200 volts.

The Voltage Conversion Factor (F_v) = $200/250 = 0.8$.

The new screen voltage will be $0.8 \times 250 = 200$ volts.

The new control grid voltage will be $-(0.8 \times 15) = -12$ volts.

Reference to the chart then gives the following:

Current Conversion Factor (F_i) 0.72

Mutual Conductance Conversion Factor (F_{gm}) 0.89

Power Output Conversion Factor (F_p) 0.57

The new plate current will be $0.72 \times 30 = 21.6$ mA.

The new screen current will be $0.72 \times 6 = 4.3$ mA.

The new mutual conductance will be $0.89 \times 2000 = 1780$ μ mhos.

The new power output will be $0.57 \times 2.5 = 1.42$ watts.

There are two effects not taken into account by conversion factors. The first is contact potential, but its effects only become serious for small grid bias voltages. The second is secondary emission, which occurs with the old type of tetrode at low plate voltages; in such a case the use of conversion factors should be limited to regions of the plate characteristic in which the plate voltage is greater than the screen voltage. With beam power amplifiers the region of both low plate currents and low plate voltages should also be avoided for similar reasons.

The application of conversion factors to resistance-capacitance-coupled triodes and pentodes is covered in Chapter 12 Sect. 2(x) and Sect. 3(x) respectively.

FIG. 2.33

Fig. 2.33. Zero bias plate characteristics for type 807 beam power amplifier with six values of screen voltage (Ref. E2).

Greater accuracy in the use of conversion factors over a wide range of screen voltages may be obtained, if curves are available for zero bias at a number of different screen voltages as in Fig. 2.33 (Ref. E2).

When the plate, screen, and grid voltages of a pentode or beam power amplifier are multiplied by the same voltage conversion factor, the ratio of the plate current at a given grid bias to that at zero bias does not change. In order to convert a given family of plate characteristics to a new screen voltage condition, it is therefore only necessary to have a zero-bias plate characteristic for the screen voltage of interest.

Example

Suppose that the family of plate characteristics shown in Fig. 2.34, which obtains for a screen voltage of 250 volts, is to be converted for a screen voltage of 300 volts. The zero-bias plate characteristic for $E_{c2} = 300$ volts, which is shown in Fig. 2.33, is replotted as the upper curve in Fig. 2.35.

Since all bias values shown in Fig. 2.34 must be multiplied by $300/250 = 1.2$, corresponding plate characteristics for the new family obtain for bias values that are 20 per cent. higher than those shown in Fig. 2.34. Consider the conversion of -10 -volt characteristic of Fig. 2.34. At a plate voltage (E_b) of 250 volts in Fig. 2.34, $AB/AC = 100/187 = 0.535$. On the new characteristic in Fig. 2.35 which corresponds to a bias of -12 volts, $A'B'/A'C'$ must also equal 0.535 at $E_b = 300$ volts. Therefore, $A'B' = 0.535 \times A'C'$. From the given zero-bias characteristic of Fig. 2.35, $A'C' = 244$ at $E_b = 300$ volts; hence $A'B' = 131$ milliamperes. At $E_b = 200$ volts in Fig. 2.34 $DE/DF = 98/183 = 0.535$. Therefore, at $E_b = 200 \times 1.2 = 240$ volts in Fig. 2.35, $D'E' = 0.535 \times 238 = 127$ milliamperes. This process is repeated for a number of plate voltages and a smooth curve is drawn through the points on the new characteristic.

FIG. 2.34

Fig. 2.34. Plate characteristics for type 807 with fixed screen voltage and eight values of grid voltage (Ref. E2).

The factor 0.535 can be used for the -10 -volt characteristic at plate voltages greater than that at which the knee on the zero-bias characteristic of Fig. 2.34 occurs; for plate voltages in the immediate region of the knee, a new factor should be determined for each point. The plate characteristics of Fig. 2.34 should not be converted to the left of the dashed line of Fig. 2.34 because of space-charge effects. This limitation is not a serious one, however, because the region over which the valve usually operates can be converted with sufficient accuracy for most applications. The converted plate characteristic of Fig. 2.35 for $E_{c1} = -30$ volts was obtained in a similar manner to that for $E_{c1} = -12$ volts.

The curves of Fig. 2.35 were checked under dynamic conditions by means of a cathode-ray tube and the dotted portions show regions where measured results departed from calculated results.

(iii) The calculation of valve characteristics other than those published

It is frequently desired to make minor modifications in the operating conditions of a valve, such as by a slight increase or decrease of the plate voltage, change in grid

bias or load resistance. It is proposed to describe the effects which these changes will have on the other characteristics of the valve.

The procedure to be adopted is summarized below :—

FIG. 2.35

Fig. 2.35. Derived plate characteristics for type 807 with different screen voltage, making use of Figs. 2.33 and 2.34 with conversion factors (Ref. E2).

(a) In the absence of valve curves

Triode—Use conversion factors to adjust the plate voltage to its new value, and apply the correct conversion factors to all other characteristics; then adjust the grid bias to its desired new value by the method given below, and finally adjust the load resistance.

Pentode or beam power amplifier—Use conversion factors to adjust the screen voltage to its new value, and apply the correct conversion factors to all other characteristics; then adjust the plate voltage to the desired new value by the method given below; then adjust the grid bias to its desired new value, and finally adjust the load resistance.

(b) When valve curves are available

Triode with no d.c. load resistance in the plate circuit: Refer to the published characteristics to find the maximum plate dissipation; calculate the maximum plate current which can be permitted at the desired new plate voltage; select a suitable plate current for the particular application (which must not exceed the maximum); and refer to the curves to find the grid bias to give the desired plate current.

If the valve is a power amplifier, the load resistance may be determined by one of the methods described in Chapter 13 [e.g. triodes Sect. 2(iii); pentodes Sect. 3(iii)A].

Triode with resistor in plate circuit: Use conversion factors, with adjustments as required in accordance with the method given in (iv) below.

Pentode or beam power amplifier: If curves are available for the published value of screen voltage, use the method in (iv) below to obtain the characteristics for a plate voltage such that, when conversion factors are applied, the plate voltage is the desired value. For example, if curves and characteristics are available for plate and screen voltages of 250 volts, and it is desired to determine the characteristics for a plate voltage of 360 volts and screen voltage of 300 volts: firstly determine the characteristics for a plate voltage of 300 and screen voltage of 250; then apply voltage

conversion factors of 1.2 to the plate, screen and grid voltages so as to provide the desired conditions.

If curves are available for the new value of screen voltage, use conversion factors to bring the screen voltage to the desired value, then apply the method below to adjust the plate voltage, load resistance and grid bias.

(iv) The effect of changes in operating conditions

(A) Effect of Change of Plate Voltages of Pentodes and Beam Power Amplifiers

(a) On plate current

The plate current of a pentode or beam power valve is approximately constant over a wide range of plate voltages, provided that the plate voltage is maintained above the "knee" of the curve. The increase of plate current caused by an increase in plate voltage from E_{b1} to E_{b2} is given by the expression

$$\Delta I_b = \frac{\Delta E_b}{r_p} = \frac{E_{b2} - E_{b1}}{r_p} \quad (16)$$

In many cases the plate characteristic curves are available, and the change in plate current may be read from the curves.

(b) On screen current

In the case of both pentodes and beam power valves the total cathode current (i.e., plate plus screen currents) is approximately constant over a wide range of plate voltages (see Fig. 2.4). The increase in plate current from E_{b1} to E_{b2} is approximately equal to the decrease in screen current over the same range.

Fig. 2.36. Plate characteristics of power pentode illustrating effect of change of plate voltage.

(c) On load resistance and power output

The plate characteristics of a typical power pentode are shown in Fig. 2.36 in which I_{b1} is the "published" plate current at plate voltage E_{b1} and grid bias $-E_{c1}$. The loadline MPJ swings up to I_{max} at $E_c = 0$ and down to I_{min} at $2E_{c1}$, the assumption being made that the $2E_{c1}$ curve is straight and horizontal over the range of plate voltages in which we are interested.

If the plate voltage is increased to E_{b2} , the new loadline will be MP'H, the point M being common to both, since it is at the knee of the characteristic. The quiescent operating point P' is at a higher plate current than P, the difference being ΔI_b .

Since the power output is proportional to the area of the triangle under the loadline, it is also proportional to the value of the load resistance, all triangles having ML as a common side. It may readily be shown that

$$R_L = \frac{E_{b1} - E_{min}}{I_{max} - I_{b1}}$$

and

$$R_L' = \frac{E_{b2} - E_{min}}{I_{max} - I_{b2}}.$$

Therefore

$$\frac{R_L'}{R_L} = \frac{E_{b2} - E_{min}}{E_{b1} - E_{min}} \cdot \frac{I_{max} - I_{b1}}{I_{max} - I_{b2}} \quad (17)$$

which is also the ratio of the output powers. If $I_{b2} = I_{b1}$ or the rise of plate current is neglected as an approximation, then

$$\frac{R_L'}{R_L} = \frac{E_{b2} - E_{min}}{E_{b1} - E_{min}}. \quad (18)$$

As an example, apply this to type 6V6-GT under the following conditions—

	Published Condition	Desired Condition
Plate voltage	250	300 V
Screen voltage	250	250 V
Grid voltage	-12.5	-12.5 V
Load resistance	5000	(see below) ohms
Plate current (I_{b1})	47	48* mA
Peak plate current (I_{max})	90*	90* mA
Min. plate current (I_{min})	8*	8* mA
Min. plate voltage (E_{min})	35	35 V
Power output	4.5	(see below) W

*From curve.

Using equation (17)—

$$\frac{R_L'}{R_L} = \frac{300 - 35}{250 - 35} \cdot \frac{90 - 47}{90 - 48} = \frac{265}{215} \cdot \frac{43}{42} = 1.26$$

whence $R_L' = 1.26 \times 5000 = 6300$ ohms.

The increase of power output is in proportion to the increase in load resistance. i.e. $P_o = 4.5 \times 1.26 = 5.66$ watts.

This method is remarkably accurate when there is very small rectification in the plate circuit, as is usually the case with power pentodes. With beam power amplifiers of the 6L6 and 807 class, in which the rectification is considerable (strong second harmonic component), the "corrected" loadline should be used as a basis, and the values of I_{max} , I_{b1} and E_{min} should be those corresponding to the corrected loadline.

If the rise in plate current (ΔI_b) is considerable, the point P' will be above the centre point of the loadline MH , and there will be an appreciable amount of second harmonic distortion; this may be reduced to zero (if desired) by increasing the load resistance slightly.

(B) Effect of change of load resistance

In a r.c.c. triode the effect of a change in R_L on stage gain is very slight, provided that $R_L \geq 5r_p$. In any case where the change cannot be neglected, eqn. (7) of Chapter 12 Sect. 2 may be used to calculate stage gain.

In a r.c.c. pentode the effect of a change in R_L on stage gain is given by eqn. (7) of Chapter 12 Sect. 3, bearing in mind that the mutual conductance at the operating plate current is increased when R_L is decreased. As a rough approximation, the voltage gain is proportional to the load resistance. If optimum operating conditions are to be obtained, conversion factors should be applied to the whole amplifier—see Chapter 12 Sect. 3(x)C.

(C) Effect of change of grid bias

In any valve which is being operated with fixed voltages on all electrodes and without any resistance in any of the electrode circuits, a change of grid bias will result in a change of plate current as given by the expression

$$\Delta I_b = \Delta E_g \times g_m \quad (19)$$

where ΔI_b = increase of plate current,

ΔE_g = change of grid bias in the positive direction,

and g_m = mutual conductance of valve at the operating plate current.

In most practical cases, however, the valve is being operated with an impedance in the plate circuit and in some cases also in the screen circuit. The effect of a change in grid bias is therefore treated separately for each practical case.

(a) On resistance-coupled triodes

In this case a plate load resistor is used, resulting in a considerable voltage drop and a decrease in the effective slope of the valve.

The change in plate current brought about by a change in grid bias is given by the expression

$$\Delta I_b = \Delta E_g \times \mu / (r_p + R_L) \quad (20)$$

where μ = amplification factor of valve at the operating point,

r_p = plate resistance of valve at the operating point,

and R_L = resistance of plate load resistor.

(b) On resistance-coupled pentodes

The change of plate current with grid bias is given by the expression.

$$\Delta I_b = \Delta E_g \times g_d \quad (21)$$

where g_d = dynamic transconductance at the operating point,

= slope of dynamic characteristic at the operating point.

The change of screen current (with fairly low screen voltages) is approximately proportional to the plate current up to plate currents of $0.6 E_{bb}/R_L$ and the change in screen current is given by the expression

$$\Delta I_{c2} = \Delta I_b (I_{c2}/I_b) \text{ approx.} \quad (22)$$

where I_{c2} = screen current

and E_{bb} = plate supply voltage.

For further information on resistance coupled valves, see Chapter 12, Sects. 2 and 3.

(c) On i-f or r-f amplifier

In this case there is no d.c. load resistor and the full supply voltage reaches the plate of the valve. The change of plate current is given by eqn. (19) while the change in screen current may be calculated from the ratio of screen and plate currents, which remains approximately constant. The voltage gain is proportional to the mutual conductance* of the valve, and is therefore a maximum for the highest plate current at the minimum bias. A decrease in bias will therefore normally result in increased gain, while increased bias will result in decreased gain. The limit to increased gain is set by the plate or screen dissipation of the valve, by positive grid current, and, in some circuits, by instability. In most cases the mutual conductance curves are published so as to enable the change of gain to be calculated.

(d) On power valves

This subject is covered in detail in Chapter 13.

*The voltage gain is also affected by the plate resistance, but this is quite a secondary effect unless the plate resistance is less than 0.5 megohm. In most remote cut-off pentodes the plate resistance falls rapidly as the bias is decreased towards the minimum bias, but this is more than counterbalanced by the rise in mutual conductance.

SECTION 7 : VALVE EQUIVALENT CIRCUITS AND VECTORS

(i) *Constant voltage equivalent circuit* (ii) *Constant current equivalent circuit* (iii) *Valve vectors.*

Much useful information can be derived from an equivalent circuit of a valve, even though this may only be valid under limited conditions. The equivalent circuit is only a convenient fiction, and it must be remembered that it is the plate supply which, in reality, supplies the power—the valve merely controls the current by its varying d.c. plate resistance. The equivalent circuit is merely a device to produce in the load the same a.c. currents and voltages which are produced by the valve when alternating voltages are applied to its grid.

FIG. 2.37

Fig. 2.37. (A) Equivalent circuit of valve using constant voltage generator (B) Equivalent circuit of valve and load.

(i) Constant voltage equivalent circuit

The simplest equivalent circuit treats the valve as an a.c. generator of constant r.m.s. voltage μE_g , which is applied through an internal generator resistance r_p (Fig. 2.37A). This is valid for small alternating voltages (under which conditions the characteristics are practically uniform) but is of no assistance in determining direct currents or voltages, phase angles or operating conditions. It is also limited to frequencies at which the effects of capacitances are negligible.

This may be elaborated, as in Fig. 2.37B, with the inclusion of the input circuit GK and the load Z_L . The input voltage E_g is shown by the \pm signs to be such that the grid is instantaneously positive, and the plate negative (with respect to the cathode) at the same instant. It is assumed that the grid is biased sufficiently to prevent grid current flow.

The current I_p flowing through the load Z_L produces across the load a voltage E_L which is of opposite sign to E_g . It will be noted that the "fictitious" voltage μE_g is opposite in sign to E_g , although μ is positive; this apparent inversion is a consequence of treating the valve as an a.c. generator.

In the simplest case, Z_L is a resistance R_L . We can then derive the following relationships—

$$\mu E_g = (r_p + R_L) I_p \quad (1)$$

$$E_L = -I_p R_L = -\mu E_g \frac{R_L}{r_p + R_L} \quad (2)$$

$$\text{and} \quad \frac{E_L}{E_g} = \text{voltage gain} = -\frac{\mu R_L}{r_p + R_L} \quad (3)$$

If the load is made up of a resistor R_L and an inductor X_L in series—

$$\begin{array}{ll} \text{Complex Values} & \text{Scalar Values} \end{array} \quad (4)$$

$$Z_L = R_L + jX_L \quad \sqrt{R_L^2 + X_L^2} \quad (4)$$

$$\mu E_g = (r_p + R_L + jX_L) I_p \quad \sqrt{(r_p + R_L)^2 + X_L^2} I_p \quad (5)$$

$$\frac{E_L}{E_g} = -\frac{\mu(R_L + jX_L)}{r_p + R_L + jX_L} = -\frac{\mu \sqrt{R_L^2 + X_L^2}}{\sqrt{(r_p + R_L)^2 + X_L^2}} \quad (6)$$

and similarly for any other type of load.

The **interelectrode capacitances** are shown in the equivalent circuit of Fig. 2.38, and may be taken as including the stray circuit capacitances. This circuit may be applied at frequencies up to nearly 10 Mc/s, beyond which the inductances of the leads and electrodes become appreciable. It may also be applied to a screen grid (tetrode) or pentode, provided that the screen is completely by-passed to the cathode; in this case C_{gk} becomes the input capacitance ($C_{g1k} + C_{g1g2}$) and C_{pk} becomes the output capacitance (C_p to all other electrodes).

(ii) Constant current equivalent circuit

An alternative form of representation is the constant current generator equivalent circuit (Fig. 2.39), this being more generally convenient for pentodes, in which the plate resistance is very high. Either circuit is equally valid for both triodes and pentodes.

FIG. 2.38

Fig. 2.38. Equivalent circuit of valve on load, with interelectrode capacitances.

FIG. 2.39.

Fig. 2.39. Equivalent circuit of valve on load, using constant current generator.

FIG. 2.40

Fig. 2.40. Equivalent circuit of valve on load, using constant current generator, with interelectrode capacitances.

In the constant voltage generator equivalent circuit, the current varies with load impedance and plate resistance; in the constant current equivalent circuit, the voltage across the load and plate resistance varies with load impedance and plate resistance.

A constant current generator equivalent circuit, in which account is taken of capacitances, is shown in Fig. 2.40. This circuit may be applied at frequencies up to nearly 10 Mc/s, beyond which the inductances of the leads become appreciable. It will be seen that C_{pk} (which may be taken to include all capacitances from plate to cathode, and the output capacitance of a pentode) is shunted across both r_p and Z_L . In the case of a resistance-capacitance coupled stage, Z_L would be the resultant of R_f and R_p (following grid resistor) in parallel.

Maximum power output is obtained when the valve works into a load resistance equal to its plate resistance provided that the valve is linear and completely distortionless over the whole range of its working, and also that it is unlimited by maximum electrode dissipations or grid current. In practice, of course, these conditions do not hold and the load resistance is made greater than the plate resistance.

At frequencies of 10 Mc/s and above, the effects of the inductance of connecting leads (both internal and external to the valve) become appreciable. Although it is possible to draw an equivalent circuit for frequencies up to 100 Mc/s, in which

each capacitance is split into an electrode part and a circuit part (Ref. B21 Fig. 38) the circuit is too complicated for analysis, and the new circuit elements that have been introduced cannot be measured directly from the external terminals alone.

At frequencies above about 50 Mc/s, transit time effects also become appreciable. The circuit which is commonly used for frequencies above 50 Mc/s is Fig. 2.47 in which the valve is treated as a four terminal network with two input and two output terminals. This is described in Sect. 8(iii)e.

Fig. 2.41. Voltage and current relationships in a resistance-loaded valve.

(iii) Valve vectors

Vectors [see Chapter 6 Sect. 5(iv)] may be used to illustrate the voltage and current relationships in a valve, but great care must be taken on account of the special conditions. Vectors are normally restricted to the representation of the a.c. voltages and currents when the grid is excited with a sine-wave voltage limited to such a value that the operation is linear. The grid and output voltages (with respect to the cathode) are normally of opposite polarity when the load is resistive; under the conditions noted above this is almost the same as being 180° out of phase except there is no half-cycle time lag between them.

The voltage and current relationships for a resistance loaded valve are shown in Fig. 2.41; peak total plate current occurs with peak positive grid voltage and results in maximum voltage across the load (e_L) and minimum voltage from plate to cathode (e_b). It will be seen that $e_b + e_L = E_{bb}$ (the supply voltage) under all conditions, and that e_L is naturally measured in the downward direction from E_{bb} . If only alternating components are considered, a negative peak e_p corresponds to a positive peak e_g and a negative peak e_L . If the supply voltage E_{bb} is omitted from the equivalent circuit, we are left with $e_p = -e_L$.

Each case must be considered individually and the vectors drawn to accord with the conditions. The only general rule is that E_g and μE_g are always either in phase or of opposite phase.

Fig. 2.42 shows the vector diagram (drawn with respect to the cathode) of an amplifying valve with a resistance load and a.c. grid excitation. Commencing with the grid-to-cathode voltage E_g , the vector μE_g is drawn in the same direction but is μ times as large. The output voltage E_L is also in the same direction as μE_g , but smaller by the value $I_p r_p$. All of these voltages are with respect to the cathode and the centre-point of the vector diagram has accordingly been marked K. The a.c. component of the plate current (I_p) is in phase with E_L , since E_L is the voltage drop which it produces in R_L . The grid-to-plate voltage E_c is the sum of E_L and E_g owing to the phase reversal between grid and plate.

FIG. 2.42

FIG. 2.43

FIG. 2.44

Fig. 2.42. Equivalent circuit and vector diagram of resistance-loaded valve.

Fig. 2.43. Vector diagram of valve with resistance load and capacitance from grid to plate.

Fig. 2.44. Vector diagram of valve with partially inductive load and capacitance from grid to plate.

When the equivalent circuit includes more than one mesh, it is usual to proceed around each mesh in turn, using some impedance, common to both, as the link between each pair of meshes. For example Fig. 2.43 shows a valve with a capacitor C_{gp} from grid to plate, and a resistive load. Firstly, set down E_L in any convenient direction (here taken horizontally to the right) and I_L in the same direction; then draw I_c leading by approximately 90° (actually I_c leads E_c by 90°) and complete the parallelogram to find the resultant current I_p ; then draw $I_p r_p$ in the same direction as I_p and complete the parallelogram to find the resultant μE_g —this completes the first mesh. Finally take E_g along μE_g , and complete the parallelogram to find the resultant of E_g and E_L , which will be E_c .

If the load is partially inductive (Fig. 2.44) the plate current and $I_p r_p$ lag behind E_L and the resultant μE_g is determined by the parallelogram; E_g and E_L combine to give the resultant E_c ; I_c leads E_c by 90° , and I_L is determined by completing the parallelogram of which I_c is one side and I_p the resultant.

FIG. 2.45

Fig. 2.45. Vector diagram of valve with partially capacitive load and capacitance from grid to plate.

With a partially capacitive load (Fig. 2.45) the plate current and $I_p r_p$ lead E_L , and the resultant μE_g is determined by the parallelogram; E_g and E_L combine to give the resultant E_c ; I_c leads E_c by 90° , and I_L is determined by completing the parallelogram of which I_c is one side and I_p the resultant.

SECTION 8 : VALVE ADMITTANCES

(i) Grid input impedance and admittance (ii) Admittance coefficients (iii) The components of grid admittance—Input resistance—Input capacitance—Grid input admittance (a) with plate-grid capacitance coupling; (b) with both plate-grid and grid-cathode capacitance coupling; (c) with grid-screen capacitance coupling; (d) with electron transit time; (e) equivalent circuit based on admittances (iv) Typical values of short-circuit input conductance (v) Change of short-circuit-input capacitance with transconductance (vi) Grid-cathode capacitance (vii) Input capacitances of pentodes (published values) (viii) Grid-plate capacitance.

(i) Grid input impedance and admittance

When a valve is used at low audio frequencies, it is sometimes assumed that the grid input impedance is infinite. In most cases, however, this assumption leads to serious error, and careful attention is desirable to both its static and dynamic impedances.

As with any other impedance (see Chapter 4 Sect. 6) it may be divided into its various components:—

Component	Normal	Reciprocal
Resistive	Grid input resistance (r_g)	conductance (g_g)
Reactive	Grid input reactance (X_g)	susceptance (B_g)
Resultant	Grid input impedance (Z_g)	admittance (Y_g)

Normal values are measured in ohms, while reciprocal values are measured in reciprocal ohms (mhos). It is interesting to note that

a resistance of	} is equivalent to	a conductance of
a reactance of		a susceptance of
an impedance of		an admittance of
1 megohm		1 micromho
0.1 megohm		10 micromhos
10 000 ohms		100 micromhos
1000 ohms		1000 micromhos
		= 1 mA/volt

The following relationships hold :

$$g_o = \frac{r_g}{r_g^2 + X_g^2}, \quad r_o = \frac{g_g}{g_o^2 + B_o^2} \quad (1)$$

$$B_o = \frac{X_g}{r_g^2 + X_g^2}, \quad X_o = \frac{B_g}{g_o^2 + B_o^2} \quad (2)$$

$$|Y_o| = \sqrt{g_o^2 + B_o^2} = 1/|Z_o|, \quad Y_o = g_o + jB_o = 1/Z_o \quad (3)$$

Similar relationships hold for other electrodes.

It is usual to carry out calculations with admittances, even though the resultant may then have to be changed to the form of an impedance. With a number of conductances (or susceptances) in parallel, the total conductance (or susceptance) is found by adding all together, with due regard to positive and negative quantities :—

$$\text{e.g. } g_o = g_1 + g_2 + g_3 + \dots + g_k \quad (4)$$

$$B_o = B_1 + B_2 + B_3 + \dots + B_k \quad (5)$$

Inductive reactance is regarded as positive.

Capacitive reactance is regarded as negative.

Inductive susceptance is regarded as positive.

Capacitive susceptance is regarded as negative.

With Complex Notation (see Chapter 6 Sect. 6) we have

$$Z_o = R_o + jX_o, \quad Y_o = g_o - jB_o. \quad (6)$$

(The “j” merely indicates a vector at 90° which must be added vectorially.)

(ii) Admittance coefficients

The operation of a valve may be expressed by the two equations

$$i_p = A e_g + B e_o \quad (7)$$

$$i_o = C e_g + D e_p \quad (8)$$

where A, B, C and D are complex values determined by the valve characteristics, being in the form of admittances and known as the Admittance Coefficients. The effect of these Admittance Coefficients may be understood more easily by considering two special cases, one with a short-circuited output (i.e. short-circuited from plate to cathode) and the other with a short-circuited input (i.e. short-circuited from grid to cathode).

Case 1: Short-circuited output ($e_o = 0$).

$$\text{From equation (7), } i_p = A e_g$$

$$\text{From equation (8), } i_o = C e_g$$

where A is defined as the short-circuit forward admittance, and C is defined as the short-circuit input admittance.

Case 2: Short-circuited input ($e_g = 0$).

$$\text{From equation (7), } i_p = B e_o$$

$$\text{From equation (8), } i_o = D e_p$$

where B is defined as the short-circuit output admittance, and D is defined as the short-circuit feedback admittance.

At frequencies up to about 10 Mc/s, the Admittance Coefficients are given approximately by :

$$\text{Short-circuit forward admittance } (A) = g_m - j\omega C_{gp} \approx g_m \quad (9)$$

$$\text{Short-circuit output admittance } (B) = 1/r_p + j\omega(C_{pk} + C_{op}) \quad (10)$$

$$\text{Short-circuit input admittance } (C) = 1/r_g + j\omega(C_{gk} + C_{gp}) \quad (11)$$

$$\text{Short-circuit feedback admittance } (D) = j\omega C_{gp} \quad (12)$$

If the grid is negatively biased to prevent the flow of positive grid current, the grid resistance r_g becomes very high, and $1/r_g$ may be negligible in the expression for C.

At frequencies above 10 Mc/s the Admittance Coefficients are somewhat modified, the capacitances and admittances containing a term which is proportional to the square of the frequency.

The short-circuit forward admittance (A) is affected by the transit time of electrons and the inductance of the cathode lead, thus causing a phase shift between anode current and grid voltage. This is treated in detail in Chapter 23 Sect. 5.

The short-circuit output admittance (B) is affected by the reduction in r_p , which occurs with increasing frequency due to the capacitances and inductances of the electrodes. The capacitance term is practically constant.

The short-circuit input admittance (C) is affected by the transit time of electrons, the inductances of the electrodes (particularly the cathode) and the capacitance between grid and cathode. The capacitance term is practically constant.

The short-circuit feedback admittance (D) remains purely reactive even at very high frequencies, although it changes from capacitive at low frequencies, through zero, to inductive at high frequencies. This can cause instability in certain circumstances.

(iii) The components of grid admittance

Input resistance may be due to several causes :

1. Leakage between the grid and other electrodes.
2. Negative grid current (caused by gas or grid emission).
3. Positive grid current (may be avoided by negative grid bias).
4. Coupling between the grid and any other electrode presenting an impedance to the input frequency (e.g. C_{gp}).
5. Transit time of the electrons between cathode and grid (at very high frequencies only).

Input capacitance (C_{in}) is dependent on several factors :

1. The static (cold) capacitance (C_i) from the grid to all other electrodes, except the plate.

$$\text{For a pentode, } C_i = C_{g1 \cdot k} + C_{g1 \cdot g2} \quad (13)$$

$$\text{For a triode, } C_i = C_{pk} \quad (14)$$

2. The very slight increase in capacitance caused by thermal expansion of the cathode (0.1 to 0.6 $\mu\mu\text{F}$ for the majority of r-f pentodes).
3. The increase in capacitance caused by the space charge and by conduction (0.5 to 2.4 $\mu\mu\text{F}$ for r-f pentodes).
4. Coupling between the grid and any other electrode presenting an impedance to the input frequency ; this holds both with capacitive and inductive reactance (Miller Effect—see below).
5. Transit time of the electrons between cathode and grid (at very high frequencies only).

References to change of input capacitance : B13, B15, B16, B17, C1, C4, C5.

The measurement of interelectrode capacitances is covered in Chapter 3 Sect. 3(ii)g, together with some general comments and a list of references to their significance and measurement.

Grid Input Admittance

(a) With plate-grid capacitance coupling

In the circuit of Fig. 2.46A, in which $C_{g1 \cdot k}$ and $C_{g1 \cdot g2}$ are not considered, it may be shown* that

$$r_g = \frac{1}{g_g} = \frac{(g_p + G_L)^2 + (B_L + B_{gp})^2}{B_{gp}[g_m \cdot B_L + B_{gp}(g_p + G_L + g_m)]} \quad (15)$$

and

$$C_g = \frac{B_g}{\omega} = \frac{C_{gp}[(g_p + G_L + g_m)(g_p + G_L) + B_L(B_L + B_{gp})]}{(g_p + G_L)^2 + (B_L + B_{gp})^2} \quad (16)$$

where $g_p = 1/r_p$, $Y_L = G_L + jB_L = 1/Z_L$, $B_{gp} = 1/X_{Cgp} = 1/2\pi f C_{gp}$.

As an approximation, if $g_p \ll G_L$, and $B_{gp} \ll B_L$,

$$r_g = \frac{1}{g_g} = -\frac{1}{g_m \omega^2 L_o C_{gp}} \quad \text{when the load is inductive} \quad (17)$$

$$= \frac{C_L}{g_m C_{gp}} \quad \text{when the load is capacitive} \quad (18)$$

*Sturley, K. R. "Radio Receiver Design, Part 1" (Chapman & Hall, London, 1943) p. 37 et seq

$$C_g = C_{gp} \left[1 + \frac{g_m G_L}{G_L^2 + B_L^2} \right] \quad (19)$$

When B_L is infinite, i.e. when $Z_L = 0$, R_g is infinite and $C_g = C_{gp}$.

When the load is inductive, the input resistance is usually negative, thus tending to become regenerative, although for values of B_L between 0 and

$$-B_{gp} (g_p + G_L + g_m)/g_m,$$

the input resistance is positive.

When the load is capacitive, the input resistance is always positive, thus causing degeneration.

As an approximation, if $B_{gp} \ll g_m$ and $B_{gp} \ll (g_p + G_L)$, the positive and negative minimum values of r_g are given by

$$r_g (\min) \approx \pm \frac{2(g_p + G_L)}{g_m B_{gp}} \quad (20)$$

and these occur at $B_L = \pm (g_p + G_L)$.

FIG. 2.46 A.

FIG. 2.46 B.

Fig. 2.46. Conditions for deriving input admittance (A) with plate-grid capacitance coupling (B) general case including cathode circuit impedance.

Similarly, the maximum value of the input capacitance is given by

$$C_g (\max) = C_{gp} \left[1 + \frac{g_m r_p R_L}{r_p + R_L} \right] = C_{gp} \left[1 + \frac{\mu R_L}{r_p + R_L} \right] \quad (21)$$

which occurs at $B_L = -B_{gp}$. This is the well known "Miller Effect" [see Chapter 12 Sect. 2(xi) for a-f amplifiers]. The effect on the tuning of r-f amplifiers is treated in Chapter 23 Sect. 5, and on i-f amplifiers in Chapter 26 Sect. 7.

In the circuit of Fig. 2.46B, which includes an impedance Z_k in the cathode circuit, with the screen decoupled to the cathode, the input resistance is given approximately by

$$r_g = \frac{1}{g_g} \approx \frac{G_L^2 + B_L^2}{g_m B_{gp} B_L} \left[1 + \frac{g_m (g_m + 2G_k)}{G_k^2 + B_k^2} \right] \quad (22)$$

where B_{gp} and g_p are neglected in comparison with the other components, and $(B_L G_k - B_k G_L)$ is very small. Thus the reflected resistance is increased, and the damping decreased, as the result of the insertion of Z_k .

The input capacitance under these conditions is given by

$$C_g = C_{gp} \left[\frac{(G_L + g_m) G_L + B_L^2}{G_L^2 + B_L^2} - \frac{g_m [g_m^2 G_L + g_m (G_k G_L - B_k B_L)]}{(G_L^2 + B_L^2) [(G_k + g_m)^2 + B_k^2]} \right] \quad (23)$$

which is less than with $Z_k = 0$.

If the screen is by-passed to the cathode,

$$r_g = \frac{1}{g_g} = \frac{G_L^2 + B_L^2}{g_m B_{gp} B_L} \left[1 + \frac{g_t (g_t + 2G_k)}{G_k^2 + B_k^2} \right] \quad (24)$$

$$C_g = C_{gp} \left[\frac{(G_L + g_m) G_L + B_L^2}{G_L^2 + B_L^2} - \frac{g_m [g_t^2 G_L + g_t (G_k G_L - B_k B_L)]}{(G_L^2 + B_L^2) [(G_k + g_t)^2 + B_k^2]} \right] \quad (25)$$

where g_t = triode g_m (whole cathode current)
 $= g_m (I_p + I_{g2})/I_p$.

(b) **With both plate-grid and grid-cathode capacitance coupling**

The circuit is as Fig. 2.46B with the addition of a capacitance C_{gk} between grid and cathode. The input resistance is given by

$$r_g = \frac{[(G_k + g_m)^2 + B_k^2][G_L^2 + B_L^2]}{g_m[B_{gp}B_L(G_k^2 + B_k^2) - B_{gk}B_k(G_L^2 + B_L^2)]} \quad (26)$$

This becomes infinite when $B_{gp}B_L(G_k^2 + B_k^2) = B_{gk}B_k(G_L^2 + B_L^2)$, which is the condition for input resistance neutralization (see Chapter 26 Sect. 8 for i-f amplifiers). This condition may be put into the form

$$\frac{B_{gp}}{B_{gk}} = \frac{C_{gp}}{C_{gk}} = \frac{L_k}{L_p} \quad (27)$$

Thus, by including an inductance $L_p = L_k C_{gk}/C_{gp}$ between the load and the plate, the input resistance may be increased to a very high value. The same effect may also be achieved by means of an inductance in the screen circuit.

The input capacitance under the conditions of Fig. 2.46B is given approximately by

$$C_g \approx C_{gp} + C_{gk} + g_m \left[\frac{C_{gp} G_L}{G_L^2 + B_L^2} - \frac{C_{gk}(G_k + g_m)}{(G_k + g_m)^2 + B_k^2} \right] \quad (28)$$

If $g_m \ll G_k$ it is possible to prevent change of input capacitance when g_m is varied (for example with a.v.c.), by making

$$\frac{C_{gp}}{C_{gk}} = \frac{R_k}{R_L}$$

(c) **With grid-screen capacitance coupling**

Conditions as in Fig. 2.46B, but with screen by-pass capacitor.

$$r_g = \frac{(g_{g2} + G_s)^2 + (B_s + B_{s1 \cdot g2})^2}{B_{g1 \cdot g2}[g_{g1 \cdot g2}B_sB_{g1 \cdot g2}(g_{g2} + G_s + g_{g1 \cdot g2})]} \quad (29)$$

$$C_g = C_{g1 \cdot g2} \left[\frac{(g_{g2} + G_s + g_{g1 \cdot g2})(g_{g2} + G_s) + B_s(B_s + B_{g1 \cdot g2})}{(g_{g2} + G_s)^2 + (B_s + B_{g1 \cdot g2})^2} \right] \quad (30)$$

where g_{g2} = screen conductance,

$g_{g1 \cdot g2}$ = grid-screen transconductance,

and $B_{g1 \cdot g2}$ = susceptance due to capacitance from g_1 to g_2 .

In an r-f amplifier, $B_{g1 \cdot g2}$ and $(g_{g2} + G_s)$ may usually be neglected in comparison with B_s , and thus

$$r_g \approx - \frac{1}{g_{g1 \cdot g2} \omega^2 L_s C_{g1 \cdot g2}} \quad \text{when } B_s \text{ is inductive} \quad (31)$$

$$r_g \approx \frac{C_1}{g_{g1 \cdot g2} C_{g1 \cdot g2}} \quad \text{when } B_s \text{ is capacitive} \quad (32)$$

The input resistance may be made infinite by making

$$C_{g1 \cdot g2}/C_{gk} = L_k/L_s \quad (33)$$

(d) **With electron transit time**

This subject is treated fully in Chapter 23 Sect. 5.

(e) **Equivalent circuit based on admittances**

In determining valve admittances at frequencies higher than approximately 10 Mc/s, it is not practicable to introduce voltages or measure them directly at the electrodes of a valve. The lead inductances and interelectrode capacitances form a network too complex for exact analysis. The most practical method of avoiding such difficulties is to consider the valve, the socket, and the associated by-pass or filter circuits as a unit, and to select a pair of accessible input terminals and a pair of accessible output terminals as points of reference for measurements. When such a unit is considered as a linear amplifier, it is possible to calculate performance in terms of four admittance coefficients. These are:

Phase angle of added component = phase angle of voltage gain + phase angle of feedback admittance. (36)

$$\begin{aligned} \text{Grid input admittance } (Y_g) &= Y_{in} + AY_{fb} \\ &= Y_{in} + \frac{Y_{fo} Y_{fb}}{Y_{out} + Y_L} \end{aligned} \quad (37)$$

See also Ref. B21.

The measurement of the four short-circuit admittances is covered in Chapter 3 Sect. 3(vi) A, B, C and D and also Refs. B17, B21.

(iv) Typical values of short-circuit input conductance

Pentodes tested under typical operating conditions (Ref. B17).

*degeneration due to unbypassed cathode resistor (see below).

$$\text{Gain factor} = \frac{\text{gain with cathode unbypassed}}{\text{gain with cathode by-passed}} \quad (38)$$

$$= \frac{1}{1 + R_k g_m (I_b + I_{c2}) / I_b} \quad (39)$$

where R_k = cathode resistor for complete compensation of input capacitance change with bias

$$\approx \frac{\Delta C}{C_{gk} g_m (I_b + I_{c2}) / I_b}$$

ΔC = change in input capacitance in farads from normal operating condition to cut-off,

C_{gk} = grid-to-cathode capacitance in farads measured with valve cold,

g_m = mutual conductance in mhos at normal operating condition,

I_b = direct plate current in amperes

and I_{c2} = direct screen current in amperes.

(vi) Grid-cathode capacitance

The mathematical treatment of the effects of grid-cathode capacitance has been given above. Methods of neutralization are described in Chapter 26 Sect. 8.

The published grid-plate capacitances are usually in the form of a maximum value, without any indication of the minimum or average value. In some cases the average is fairly close to the maximum, while in others it may be considerably less. The average value is likely to vary from one batch to another, and from one manufacturer to another. Equipment should be designed to avoid instability with the maximum value, although fixed neutralization should be adjusted on an average value, determined by a test on a representative quantity of valves.

Effect of electrode voltages on grid-cathode capacitance—see Ref. B23.

(vii) Input capacitances of pentodes (published values)

1. Indirectly heated	$\mu\mu F$
High slope r-f (metal)	8 to 11
Ordinary metal r-f	
All glass and miniature r-f }	4.3 to 7
Small power amplifiers	5 to 6
Ordinary power amplifiers	6.5 to 10
Large power amplifiers	10 to 15
Pentode section of diode-pentodes :	
Metal	5.5 to 6.5
Glass	3 to 5.5
2. Directly heated	
2 volt r-f pentodes	5 to 6
1.4 volt r-f pentodes	2.2 to 3.6
2 volt power pentodes	8
1.4 volt power pentodes	4.5 to 5.5

(viii) Grid-plate capacitance

The grid-plate capacitance decreases with increasing plate current. Eventually the rate of change becomes very small and even tends to become positive. The total change in triodes does not usually exceed $0.06 \mu\mu\text{F}$ for high- μ types, or $0.13 \mu\mu\text{F}$ for low- μ voltage amplifiers, although it may exceed $2 \mu\mu\text{F}$ in the case of triode power amplifiers (Ref. B13).

SECTION 9 : MATHEMATICAL RELATIONSHIPS

(i) *General* (ii) *Resistance load* (iii) *Power and efficiency* (iv) *Series expansion ; resistance load* (v) *Series expansion ; general case* (vi) *The equivalent plate circuit theorem* (vii) *Dynamic load line—general case* (viii) *Valve networks—general case* (ix) *Valve coefficients as partial differentials* (x) *Valve characteristics at low plate currents.*

(i) General

Valve characteristics may be represented mathematically as well as graphically (see Chapter 6 for mathematical theory).

The plate (or space) current is a function (F) of the plate and grid voltages and may be expressed exactly as

$$i_b = F(e_b + \mu e_c + e_1) \quad (1)$$

where e_1 is the equivalent voltage which would produce the same effect on the plate current as the combined effects of the initial electron velocity of emission together with the contact potentials. The amplification factor μ is not necessarily constant. There will be a small current flow due to e_1 when e_b and e_c are both zero.

As an approximation, when e_b and μe_c are large, e_1 may be neglected. The function in eqn. (1) may also be expressed approximately in the form

$$i_b \approx K(e_b + \mu e_c)^n \quad (2)$$

in which K is a constant. The value of n varies from about 1.5 to 2.5 over the usual operating range of electrode voltages, but is often assumed to be 1.5 (e.g. Conversion Factors) over the region of nearly-straight characteristics, and 2.0 in the region of the bottom bend (e.g. detection). We may take the total differential* of eqn. (2),

$$di_b = \frac{\partial i_b}{\partial e_b} de_b + \frac{\partial i_b}{\partial e_c} de_c \quad (3)$$

which expresses the change in i_b which occurs when e_b and e_c change simultaneously. Now—see (ix) below—provided that the valve is being operated entirely in the region in which μ , g_m and r_p are constant,

$$\frac{\partial i_b}{\partial e_b} = \frac{1}{r_p} \quad \text{and} \quad \frac{\partial i_b}{\partial e_c} = g_m,$$

so that

$$di_b = \frac{1}{r_p} de_b + g_m de_c. \quad (4)$$

If i_b is held constant,

$$\frac{1}{r_p} de_b + g_m de_c = 0,$$

and thus

$$g_m r_p = - \frac{de_b}{de_c} \quad (i_b \text{ constant}) \quad (5)$$

whence $g_m r_p = \mu$ [see (ix) below]. (6)

The treatment so far has been on the basis of the total instantaneous voltages and currents, e_b , e_c , i_b ; it is now necessary to distinguish more precisely between the steady (d.c.) and varying (signal) voltages and currents.

*For total differentiation see Chapter 6 Sect. 7(ii).

Instantaneous total values
 Steady (d.c.) values
 Instantaneous varying values
 Varying (a.c.) values (r.m.s.)
 Supply voltages

e_b e_c i_b
 E_{bo} E_{co} I_{bo}
 e_p e_g i_p
 E_p E_g I_p
 E_{bb} E_{cc}

For definitions of symbols refer to the list in Chapter 38 Sect. 6.

In normal operation each of the voltages and currents is made up of a steady and a varying component :

$$\left. \begin{aligned} i_b &= I_{bo} + i_p \\ e_b &= E_{bo} + e_p \\ e_c &= E_{co} + e_g \end{aligned} \right\} \quad (7)$$

Eqn. (4) may therefore be extended in the form

$$d(I_{bo} + i_p) = \frac{1}{r_p} d(E_{bo} + e_p) + g_m d(E_{co} + e_g).$$

But the differentials of constants are zero, and the relation between the varying components may be expressed in the form

$$i_p = \frac{e_p}{r_p} + g_m e_g \quad (8)$$

or

$$i_p = \frac{e_p + \mu e_g}{r_p} \quad (9)$$

This only holds under the condition that μ , g_m and r_p are constant over the operating region.

(ii) Resistance load

If there is a resistance load (R_L) in the plate circuit,

$$e_b + e_L' = E_{bb} \quad (10)$$

where e_L' is the instantaneous total voltage across R_L .

Breaking down into steady and varying components,

$$(E_b + e_p) + (E_L + e_L) = E_{bb} \quad (11)$$

where e_L is the instantaneous varying voltage across R_L ,

and E_L is the steady (d.c.) voltage across R_L .

Under steady conditions $e_p = e_L = 0$, and therefore

$$E_b + E_L = E_{bb}.$$

Now, by Ohm's Law, $E_L = I_b R_L$

Therefore

$$I_b = \frac{E_{bb} - E_b}{R_L} \quad (12)$$

Eqn. (12) represents a straight line on the plate characteristics, passing through the points

$$E_b = E_{bb}, I_b = 0 \text{ and } E_b = 0, I_b = E_{bb}/R_L,$$

in other words, the loadline.

The quiescent operating point must satisfy both the equation for the valve characteristics (1) and that for the loadline (12), therefore

$$F(e_b + \mu e_c + e_1) = \frac{E_{bb} - E_b}{R_L} \quad (13)$$

Under varying conditions, neglecting steady components, we may derive from equation (11) the relation

$$e_p + e_L = 0$$

i.e.

$$e_p = -e_L \quad (14)$$

Also $e_L = i_p R_L$ by Ohm's Law,

Therefore

$$e_p = -i_p R_L \quad (15)$$

Substituting this value of e_p in equation (9) we obtain

$$i_p = \frac{-i_p R_L + \mu e_g}{r_p}$$

$$\text{i.e.} \quad i_p = \frac{\mu e_g}{r_p + R_L} \quad (16)$$

which is a fundamentally important relation but which holds only in the region where μ , g_m and r_p are constant.

Substituting $-e_L$ (eqn. 14) in place of e_p in equation (9) we obtain, **for the valve alone**,

$$i_p = \frac{-e_L + \mu e_g}{r_p}$$

$$\text{i.e.} \quad e_L = \mu e_g - i_p r_p \quad (17)$$

which is **the basis of the constant voltage generator equivalent circuit** as in Sect. 7(i).

Eqn. (17) may be put into the form

$$e_L = r_p (g_m e_g - i_p). \quad (18)$$

This voltage e_L across the valve and the load can be developed by means of a current $g_m e_g$, passed through r_p in the opposite direction to i_p , so that the total current through r_p is $(g_m e_g - i_p)$. Eqn. (18) is **the basis of the constant current equivalent circuit** as in Sect. 7(ii).

The **voltage gain** (A) of an amplifying stage with a load resistance R_L is

$$A = \left| \frac{e_L}{e_g} \right| = \left| \frac{i_p R_L}{e_g} \right| = \left| \frac{\mu R_L}{r_p + R_L} \right|. \quad (19)$$

When the load is an impedance Z_L , the voltage gain may be shown to be

$$A = \left| \frac{\mu Z_L}{r_p + Z_L} \right| = \left| \frac{\mu}{1 + r_p/Z_L} \right| \quad (20)$$

where r_p and Z are complex values (see Chapter 6).

If $Z_L = R_L + jX_L$, the scalar value of A is given by

$$A = \mu \frac{\sqrt{R_L^2 + X_L^2}}{\sqrt{(r_p + R_L)^2 + X_L^2}}. \quad (21)$$

The voltage gain may also be put into the alternative form

$$A = \left| g_m \frac{r_p Z_L}{r_p + Z_L} \right| \quad (22)$$

$$\approx |g_m Z_L| \text{ if } r_p \gg Z_L. \quad (23)$$

(iii) Power and efficiency

When the operation of a valve as a Class A_1 amplifier is perfectly linear we may derive* the following:—

Zero-Signal :

Plate current	$= I_{b0}.$
Power input from plate supply	$P_{bb} = E_{bb} I_{b0}.$
D.C. power absorbed in load	$P_{dc} = I_{b0}^2 R_L = E_{Lc} I_{b0}.$
Quiescent plate dissipation	$P_{p0} = E_{b0} I_{b0}.$
But	$E_{bb} = E_{b0} + E_{L0}.$
Therefore	$P_{bb} = E_{b0} I_{b0} + E_{L0} I_{b0}.$
	$= P_{p0} + P_{dc}.$

(24)

Signal Condition :

$$\text{Average value of total input} = P_{bb} = E_{bb} I_{b0} \quad (25)$$

which is constant irrespective of the signal voltage.

*After book by M.I.T. Staff "Applied Electronics" (John Wiley & Sons Inc. New York, 1943) pp. 419-425.

Power absorbed by load = P_L

$$P_L = \frac{1}{2\pi} \int_0^{2\pi} i_b^2 R_L d(\omega t) \quad (26)$$

$$= \frac{1}{2\pi} \int_0^{2\pi} (I_{bo} + i_p)^2 R_L d(\omega t) \\ = \frac{1}{2\pi} \int_0^{2\pi} I_{bo}^2 R_L d(\omega t) + \frac{1}{2\pi} \int_0^{2\pi} 2I_{bo}i_p R_L d(\omega t) + \frac{1}{2\pi} \int_0^{2\pi} i_p^2 R_L d(\omega t) \quad (27)$$

$$= I_{bo}^2 R_L + 0 + P_{ac} \\ \text{i.e. } P_L = P_{dc} + P_{ac} \quad (28)$$

$$\text{where } P_{ac} = \frac{1}{2\pi} \int_0^{2\pi} i_p^2 R_L d(\omega t) \quad (29)$$

$$\text{Plate dissipation } P_p = \frac{1}{2\pi} \int_0^{2\pi} e_p i_b d(\omega t) \quad (30)$$

From eqns. (28) and (29) it will be seen that the power absorbed by the load increases when the signal voltage increases, but the power input remains steady; the plate dissipation therefore decreases as the power output increases,

$$\text{i.e. } P_p = P_{bd} - P_L \quad (31)$$

$$\text{from (26), (28)} \quad = E_{bb}I_{bo} - E_{Lo}I_{bo} - P_{ac} \quad (32)$$

$$= E_{bo}I_{bo} - P_{ac} \\ = P_{po} - P_{ac} \quad (33)$$

$$\text{where } P_{po} = E_{bo}I_{bo}.$$

That is to say, the plate dissipation (P_p) is equal to the apparent d.c. power input to the valve (P_{po}) minus the a.c. power output.

$$\text{The plate efficiency } \eta_p = \frac{\text{power output}}{\text{d.c. power input}} \\ = \frac{P_{ac}}{E_{bo}I_{bo}}. \quad (34)$$

$$\left[\text{For non-linear operation } \eta_p = \frac{P_{ac}}{E_b I_b} \right] \quad (35)$$

With sinusoidal grid excitation, linear Class A₁ valve operation and resistive load,

$$P_{ac} = E_p I_p = I_p^2 R_L.$$

Applying equation (16),

$$P_{ac} = \frac{\mu^2 E_g^2 R_L}{(r_p + R_L)^2}. \quad (36)$$

Differentiating with respect to R_L and equating to zero in order to find the condition for maximum power output,

$$\frac{dP_{ac}}{dR_L} = \mu^2 E_g^2 \left[\frac{(r_p + R_L)^2 - 2R_L(r_p + R_L)}{(r_p + R_L)^4} \right] = 0$$

$$\text{i.e. when } (r_p + R_L)^2 - 2R_L(r_p + R_L) = 0 \\ \text{or when } R_L = r_p \quad (37) \\ \text{and the maximum power output is}$$

$$P_{acm} = \frac{\mu^2 E_g^2}{4r_p} = \frac{E_g^2}{4} \mu g_m. \quad (38)$$

The factor μg_m is a figure of merit for power triodes.

If the load is an impedance ($Z_L = R_L + jX_L$) the condition for maximum power output is when

$$R_L = \sqrt{r_p^2 + X_L^2}. \quad (39)$$

In the general case, with a resistive load, the power output is given by eqn. (36) which may be put into the form

$$P_{ac} = \frac{\mu^2 E_g^2}{r_p} \cdot \frac{1}{\frac{r_p}{R_L} + 2 + \frac{R_L}{r_p}} \quad (40)$$

If $R_L/r_p = 2$, the loss of power below the maximum is only 11%, while if $R_L/r_p = 4$ the loss of power is 36%, so that "matching" of the load is not at all critical.

The treatment above is correct for both triodes and pentodes provided that both are operated completely within the linear region, that is with limited grid swing. A pentode is normally operated with a load resistance much less than the plate resistance on account of the flattening of the output voltage characteristic which would otherwise occur at low plate voltages.

This subject is considered further in Chapter 13, under practical instead of under ideal conditions.

(iv) Series expansion ; resistance load

Except in eqn. (1), which is perfectly general, certain assumptions have been made regarding linearity and the constancy of μ , g_m and r_p which restrict the use of the equations. If it is desired to consider the effects of non-linearity in causing distortion in amplifiers and in producing detection or demodulation, it is necessary to adopt a different approach.

The varying component of the plate current of a valve may be expressed in the form of a series expansion :

$$i_p = a_1 e + a_2 e^2 + a_3 e^3 + a_4 e^4 + \dots \quad (41)$$

This form may be derived* from eqn. (1), and it may be shown that

$$a_1 = \frac{\mu}{r_p + R_L} \quad (42)$$

$$a_2 = -\frac{\mu^2 r_p}{2(r_p + R_L)^2} \cdot \frac{\partial r_p}{\partial e_b} \quad (43)$$

$$a_3 = \frac{\mu^3 r_p}{6(r_p + R_L)^3} \left[(2r_p - R_L) \left(\frac{\partial r_p}{\partial e_b} \right)^2 - r_p (r_p + R_L) \frac{\partial^2 r_p}{\partial e_b^2} \right] \quad (44)$$

If μ is assumed to be constant (this is only approximately true for triodes and not for pentodes)

$$e = e_g + \frac{v_p}{\mu}$$

where v_p = instantaneous value of plate excitation voltage. (Normally for an amplifier $v_p = 0$ and $e = e_g$).

The value of $\partial r_p / \partial e_b$ may be determined by plotting a curve of r_p versus e_b for the given operating bias, and drawing a tangent at the point of operating plate voltage. The value of $\partial^2 r_p / \partial e_b^2$ may be determined by plotting a curve of ∂r_p versus ∂e_b and treating in a similar manner.

The higher terms in the series expansion (41) diminish in value fairly rapidly, so that a reasonably high accuracy is obtained with three terms if the valve is being used as an amplifier under normal conditions with low distortion.

*Reich, H. J. "Theory and Applications of Electron Tubes" (2nd edit.). McGraw-Hill, New York and London, 1944, pp. 74-77.

The first term $a_1 e = \mu e / (r_p + R_L)$ is similar to eqn. (16) above, which was regarded as approximately correct for small voltage inputs; that is to say for negligible distortion.

The first and second terms

$$i_p = a_1 e + a_2 e^2$$

express the plate current of a "square law detector" which is closely approached by a triode operating as a grid or plate ("anode-bend") detector with limited excitation voltage.

The second and higher terms are associated with the production of components of alternating plate current having frequencies differing from that of the applied signal—i.e. harmonics and (if more than one signal frequency is applied) intermodulation frequencies.

For example, with a single frequency input,

$$e = E_m \sin \omega t \quad (45)$$

Therefore

$$e^2 = E_m^2 \sin^2 \omega t = \frac{1}{2} E_m^2 - \frac{1}{2} E_m^2 \cos 2\omega t \quad (46)$$

and

$$e^3 = \frac{3}{4} E_m^3 \sin \omega t - \frac{1}{4} E_m^3 \sin 3\omega t. \quad (47)$$

The second term (e^2) includes a d.c. component ($\frac{1}{2} E_m^2$) and a second harmonic component. The third term includes a fundamental frequency component ($\frac{3}{4} E_m^3 \sin \omega t$) and a third harmonic component.

If the input voltage contains two frequencies (f_1 and f_2) it may be shown that the second term of eqn. (41) produces

- a d.c. component
- a fundamental f_1 component
- a second harmonic of f_1
- a fundamental f_2 component
- a second harmonic of f_2
- a difference frequency component ($f_1 - f_2$)
- a sum frequency component ($f_1 + f_2$)

The third term of equation (41) produces

- a fundamental f_1 component
- a third harmonic of f_1
- a fundamental f_2 component
- a third harmonic of f_2
- a difference frequency component ($2f_1 - f_2$)
- a difference frequency component ($2f_2 - f_1$)
- a sum frequency component ($2f_1 + f_2$)
- a sum frequency component ($2f_2 + f_1$)

In the case of an A-M mixer valve, f_2 may be the signal frequency and f_1 the oscillator frequency. The normal i-f output frequency is ($f_1 - f_2$) while there are spurious output frequencies of ($f_1 + f_2$), ($2f_1 + f_2$), ($2f_2 + f_1$), ($2f_1 - f_2$) and ($2f_2 - f_1$). Even though no oscillator harmonics are injected into the mixer, components with frequencies ($2f_1 + f_2$) and ($2f_1 - f_2$) are present in the output, thus demonstrating mixing at a harmonic of the oscillator frequency.

If the input voltage contains more than two frequencies, or if the terms higher than the third are appreciable, there will be greater numbers of frequencies in the output. The effect of this on distortion is treated in Chapter 14.

It may be shown that the effect of the load resistance, particularly when it is greater than the plate resistance, is to decrease the ratio of the harmonics and of the intermodulation components to the fundamental. This confirms the graphical treatment in Chapter 12.

(v) Series expansion : general case

The more general case of a series expansion for an impedance load and variable μ has been developed by Llewellyn* and the most important results are given in most text books.†

(vi) The equivalent plate circuit theorem

It was shown above (eqn. 41) that the plate current may be expressed in the form of a series expansion. If the distortion is very low, as may be achieved with low input voltage and high load impedance, sufficient accuracy may be obtained by making use of only the first term in the equation, i.e.

$$i_p = \frac{\mu e}{r_p + Z_L} \quad (48)$$

where $e = e_g$ (for amplifier use)

and Z_L = impedance of the plate load at the frequency of the applied voltage. For amplifier use this may be put into the form

$$I_p = \frac{\mu E_g}{r_p + Z_L} \quad (49)$$

This is the same as eqn. (16), except that R_L has been replaced by Z_L .

This is the basis of the Equivalent Plate Circuit Theorem which states‡ that **the a.c. components of the currents and voltages in the plate (load) circuit of a valve may be determined from an equivalent plate circuit in one of two forms—**

- (1) a fictitious constant-voltage generator (μE_g) in series with the plate resistance of the valve, or
- (2) a fictitious constant-current generator ($I = g_m E_g$) in parallel with the plate resistance of the valve.

These are applied in Sect. 7 of this chapter.

If a distortionless Class A₁ amplifier or its equivalent circuit is excited with an alternating grid voltage, the a.c. power in the load resistor R_L (i.e. the output power) is $I_p^2 R_L$.

The d.c. input from the plate supply to the valve and load (in the actual case) is $P_{bb} = I_{b0} E_{bb}$. Under ideal Class A₁ conditions the d.c. current I_{b0} remains constant, since the a.c. current is symmetrical and has no d.c. component.

Now the a.c. power input from the generator is

$$P_g = \mu E_g I_p \quad (50)$$

But

$$I_p = \frac{\mu E_g}{(r_p + R_L)}$$

Therefore

$$\mu E_g = r_p I_p + R_L I_p$$

and

$$P_g = \mu E_g I_p = r_p I_p^2 + R_L I_p^2. \quad (51)$$

In this equation

P_g = a.c. power input from generator

$r_p I_p^2$ = a.c. power heating plate

$R_L I_p^2$ = a.c. power output = P_{ac} .

The a.c. power P_g can only come from the d.c. power P_{p0} dissipated in the valve, which decreases to the lower value P_p when the grid is excited.

The total plate dissipation (P_p) is therefore

$$P_p = P_{p0} - P_g + r_p I_p^2 \quad (52)$$

where P_{p0} = d.c. plate dissipation.

This may be put into the form

$$\begin{aligned} P_p &= P_{p0} - (P_g - r_p I_p^2) \\ &= P_{p0} - P_{ac} \end{aligned} \quad (53)$$

where

$$P_{ac} = R_L I_p^2 = (P_g - r_p I_p^2) = \text{a.c. power output.}$$

*Llewellyn, F. B. Bell System Technical Journal, 5 (1926) 433.

†such as Reich, H. J. "Theory and Application of Electron Tubes," p. 75.

‡for a completely general definition see Reich, H. J. (letter) "The equivalent plate circuit theorem," Proc. I.R.E. 33.2 (Feb., 1945) 136.

The statement may therefore be made, that the plate dissipation is equal to the d.c. plate dissipation minus the a.c. power output.

A more general statement covering all types of valve amplifiers and oscillators is that the plate input power is equal to the plate dissipation plus the power output.

This analysis, based on the equivalent plate circuit, reaches a conclusion in eqn. (46) which is identical with eqn. (33) derived from a direct mathematical approach. It is, however, helpful in clarifying the conditions of operation of a distortionless Class A₁ amplifier.

The preceding treatment only applies to amplifiers ($e = e_p$ in eqn. 41), but it may be extended to cover cases where the load impedance contains other e.m.f.'s, by using the principle of superposition—see Chapter 4 Sect. 7(viii).

It is possible to adopt a somewhat similar procedure to develop the **Equivalent Grid Circuit**, or that for any other electrode in a multi-electrode valve.

(vii) Dynamic load line—general case

If the a.c. plate current is sinusoidal,

$$\begin{aligned} i_p &= I_{pm} \sin \omega t \\ \text{and} \quad e_p &= -I_{pm} |Z_L| \sin(\omega t + \theta) \\ \text{where} \quad \theta &= \tan^{-1} X_L / R_L. \end{aligned}$$

From this it is possible to derive*

$$e_p^2 + 2e_p i_p R_L + i_p^2 |Z_L|^2 = I_{pm}^2 X_L^2 \quad (54)$$

which is the equation of an ellipse with its centre at the operating point, this being the dynamic path of operation.

(viii) Valve networks ; general case

The ordinary treatment of a valve and its circuit—the Equivalent Plate Circuit Theorem in particular—is a fairly satisfactory approximation for triodes or even pentodes up to frequencies at which transit-time effects become appreciable. If it is desired to calculate, to a higher degree of precision, the operation of a valve in a circuit, particularly at high frequencies, a very satisfactory approach is the preparation of an equivalent network which takes into account all the known characteristics. This method has been described† in considerable detail, and those who are interested are referred to the original article.

(ix) Valve coefficients as partial differentials

Valve coefficients, as well as other allied characteristics, may be expressed as partial differential coefficients—see Chapter 6 Sect. 7(ii).

Partial differential coefficients, designated in the form $\frac{\partial y}{\partial x}$ are used in considering the relationship between two of the variables in systems of three variables, when the third is held constant.

" $\frac{\partial y}{\partial x}$ " is equivalent to " $\frac{dy}{dx}$ (z constant)" when there are three variables, x , y and z . Partial differentials are therefore particularly valuable in representing valve coefficients.

Let e_p = a.c. component of plate voltage,

e_g = a.c. component of grid voltage,

and i_p = a.c. component of plate current.

(These may also be used with screen-grid or pentode valves provided that the screen voltage is maintained constant, and is completely by-passed for a.c.).

*Reich, H. J. "Theory and application of electron tubes" (2nd edit.), p. 99.

†Llewellyn, F. B. and L. C. Peterson "Vacuum tube networks," Proc. I.R.E. 32.3 (March, 1944), 144.

$$\text{Then } \mu = - \frac{\partial e_p}{\partial e_g} (i_p = \text{constant}), \quad (55)$$

$$\text{or more completely } + \frac{\partial i_p / \partial e_g}{\partial i_p / \partial e_p},$$

$$g_m = + \frac{\partial i_p}{\partial e_g} (e_p = \text{constant}). \quad (56)$$

$$r_p = + \frac{\partial e_p}{\partial i_p} (e_g = \text{constant}), \quad (57)$$

$$\text{or more correctly* } + \frac{1}{\partial i_p / \partial e_p}$$

In a corresponding manner the gain (A) and load resistance (R_L) of a resistance-loaded amplifier may be given in the form of total differentials—

$$|A| = \left| \frac{de_p}{de_g} \right|^\dagger \quad (58)$$

$$\text{and} \quad R_L = - \frac{de_p}{di_p} \quad (59)$$

Particular care should be taken with the signs in all cases, since otherwise serious errors may be introduced in certain calculations.

(x) Valve characteristics at low plate currents

In the case of diodes and diode-connected triodes at very low plate currents (from 1 to about 100 microamperes) an increment of plate voltage of about 0.21 volt produces a 10-fold increase of plate current. If the \log_{10} of current is plotted against plate voltage, the result should approximate to a straight line with a slope of $1/0.21$.

In the case of triodes operating as triodes the relationship of plate current to grid-cathode voltage is still approximately logarithmic, up to a value of plate current which varies from type to type, but the slope of the curve is decreased by the plate-grid voltage. The decrease in slope is approximately proportional to the grid bias and therefore to $1/\mu$ times the plate voltage. The curve at a given plate voltage is, in general, steeper for a high- μ than for a low- μ triode. Over the region in which the logarithmic relationship holds, the mutual conductance is proportional to the plate current. For a given plate voltage and plate current, the g_m in the low-current region is greater for high- μ than for low- μ triodes, regardless of ratings. Also, for a given triode at a given plate current, g_m is greater than at lower plate voltages. Maximum voltage gain in a d-c amplifier is obtained if the valve is operated at as low a plate voltage as possible, and at a plate current corresponding to the top of the straight portion of the characteristic when \log_{10} of current is plotted against the grid voltage.

With pentodes at low plate currents, the maximum gain is obtained when the screen voltage is as low as is permissible without resulting in the flow of positive grid current.

Reference A12 pp. 414-418.

*The simple inversion of partial differentials cannot always be justified.

† A is a complex quantity which represents not only the numerical value of the stage gain but also the phase angle between the input and output voltages. The vertical bars situated one on each side of A and its equivalent indicate that the numerical value only is being considered.

(i) Fundamental physical properties

The characteristics and operation of a high vacuum oxide-coated cathode- or filament-type valve under normal conditions of operation, initially and throughout life, are determined primarily by the following fundamental general physical properties –

- (a) the **vacuum** within the envelope surrounding the cathode and electrode structure.
- (b) the total available **cathode emission** and **uniformity of activation of the cathode surface**.
- (c) the **geometrical configuration of the electrode system**.
- (d) the **electrode contact potentials** with respect to the cathode.
- (e) **primary and secondary emission** from electrodes, other than the cathode.
- (f) the **interelectrode admittances**.
- (g) the **stability of the electrical characteristics**.
- (h) the **stability, robustness and durability of the mechanical construction**.
- (j) the **external size and shape**, and the **system of electrode connections**.

The maintenance of a satisfactory **vacuum** under maximum rating conditions and continued operation, together with the availability of an adequate cathode emission under all prescribed electrode conditions and normal variations of heater/filament power, are essential to the fundamental operation of a valve, since an activated cathode surface requires a certain degree of vacuum to be maintained for its emissive properties to remain unimpaired, while the emission available from the cathode must always be sufficient to supply the total peak and average space currents required.

At the same time, it is necessary that the cathode surface be **uniformly activated** over the regions from which emission current is supplied, since the parameter transconductance is directly proportional to the activated cathode area.

The **electrode geometry** determines the electrical static and dynamic characteristics, within the limitations imposed by the available cathode emission, to the extent to which the emission is incompletely space charge limited and the capacity of the gettering to maintain a satisfactory vacuum.

Electrode contact potentials and **electrode primary and secondary emission** depend upon the electro-chemical condition of the electrode surfaces. This is determined usually by the extent to which contamination of these surfaces has occurred during manufacture or operation, due to the deposition of active material from the cathode or getter. **Contact potential** is of importance in the case of a low- or zero-voltage electrode since it may contribute a sufficiently large fraction of the total electrode voltage to modify significantly the characteristics determined by the electrode geometry and applied electrode voltages alone.

Primary and secondary electrode emission may occur if electrode temperatures become sufficiently high and the deposited films of active material in combination with the electrode material have a low work function. The effect on operation of primary or secondary electrode emission depends on the value of resistance in series with the emitting electrode.

The **interelectrode short-circuit admittances** are determined both by the geometry of the electrode construction, the d.c. and r-f properties of the insulation supporting the electrode system and electrode connections, and the frequency and conditions of operation. The susceptive components are dependent mainly on the interelectrode and lead capacitances and inductances. The conductive components are due to transit-time effects and the interelectrode resistances which are determined mainly by the d.c. resistance of the interelectrode insulation, but may also include a frequency-dependent component. The d.c. insulation resistance is determined by the surface condition of the electrode supports (mica, glass, ceramic), the extent to which contamination of these surfaces has occurred, and also by leakage between electrode leads within the base or between base pins due to leakage over or through the base material. A high value of interelectrode resistance is required throughout the life of a valve in order to avoid—

(1) **uncontrolled changes in electrode voltages** supplied through series resistive circuits from the electrode voltage source, due to the flow of leakage conduction currents through or across the interelectrode insulation from higher to lower voltage electrodes and thence through the externally connected circuits to the negative terminal of the electrode voltage supply. This characteristic is particularly important, e.g., in the case of negatively biased control grids which obtain their bias through a high value of grid resistor, and power dissipating electrodes which obtain their voltages through high resistance series dropping resistors.

(2) **noisy operation** due to intermittent conduction under the conditions described in (1).

(3) **lowering the resistive component** of the interelectrode admittances and thus increasing the damping by the valve on resonant circuits connected between electrodes, either directly or as a result of increased "Miller Effect".

The interelectrode r-f resistance must also be high throughout the life of the valve up to all normal frequencies of operation, in order to avoid damping high impedance resonant circuits connected between electrodes. In general, it is determined by the r-f properties of—

- (a) the interelectrode insulation,
- (b) films of active material deposited on the interelectrode insulation,
- (c) the base material.

The stability of the electrical characteristics depends on the goodness of the vacuum and its maintenance, stable emission from a properly and uniformly activated cathode surface, stable electro-chemical surface conditions, high interelectrode resistance, and the mechanical stability of the electrode structure. Variations of any of these characteristics throughout life produce changes in the valve parameters and, through them, changes in circuit performance.

Two types of instability of electrical characteristics occur; initial instability which is sometimes experienced early in life due to incomplete or unsatisfactory processing, and the normal gradual deterioration of characteristics dependent on emission, which continues until the valve is no longer serviceable. Generally, the ultimate electrical life of a valve which has been properly exhausted, which has a properly activated cathode and which has been operated within its maximum ratings, depends mainly on the cathode current at which it has been operated and the ability of the getter to prevent deterioration of the vacuum and consequent "poisoning" of the cathode emission, by absorbing the gases produced in the cathode coating during operation, and also the gases released from the electrodes, the walls of the envelope and other parts of the internal construction during storage, and throughout life.

The stability, robustness and durability of the mechanical construction in general determine the ultimate reliability and effective life of a valve, also the extent to which electrical performance is affected by conditions of vibration or mechanical shock under which it may be transported or operated and the ability of the construction to withstand such conditions without mechanical failure.

(ii) Basic functional characteristics

Space current—When the cathode surface is raised to its normal emitting temperature, by supplying the required power to the filament or heater, and suitable voltages are applied to the other electrodes, an electron space current flows from the cathode emitting surface to the electrode system, its value depending on the electrode geometry and the combined effect of the electrode voltages acting in the plane(s) of the control electrode(s).

For electrode systems consisting of an inner control electrode adjacent to the cathode and one or more outer electrodes, providing that a virtual cathode is not formed between the control electrode and the outermost electrode, the **total space current from the cathode** may be expressed, generally, to a good approximation by the following equation—

$$i_s \approx G \left[(e_{c1} + e_1) + \frac{e_{c2}}{\mu_{1-2}} + \frac{e_{c3}}{\mu_{1-3}} + \dots + \frac{e_b}{\mu_{1-b}} \right]^{3/2} \quad (1)$$

where i_s = total cathode space current,

e_{c1} = voltage of the first electrode,

e_1 = contact potential of the first electrode,

e_{c2}, e_{c3}

etc. = voltages of the successive outer electrodes,

e_0 = voltage of the outer plate current collecting electrode,

μ_{1-2} = amplification factor of the first electrode with respect to the second electrode,

μ_{1-3} = amplification factor of the first electrode with respect to the third electrode,

μ_{1-n} = amplification factor of the first electrode with respect to the outermost electrode,

and G = pervance of the cathode-control-electrode region

$$\approx 2.33 \times 10^{-6} \times \frac{\text{cathode area}}{(\text{cathode-to-first-electrode spacing})^3}$$

In eqn. (1), the terms within the brackets represent the effect of the various electrode voltages considered as acting in the plane of the first electrode, so that the sum of the terms combined represents an "equivalent electrode voltage". For purposes of space current calculation, the factors depending on the geometry of the electrode system and on the effect of the electrode voltages may thus be reduced to the pervance of the cathode-to-first-electrode space and the equivalent electrode voltage acting in the plane of the first electrode, so that the space current equation becomes—

$$i_s \approx G [\text{equivalent electrode voltage}]^{3/2} \quad (2)$$

The equations for the total cathode current in diodes, triodes, tetrodes and pentodes follow directly from eqn. (1).

In the case of electrode systems having two control electrodes and which operate with a virtual cathode before the second control electrode, as in converter and mixer valves, the space current cannot be expressed in a simple form. Such systems may be regarded as consisting of two separate but related systems, and reduced to equivalent diodes, with the space current of the outer equivalent diode supplied from, and controlled by, the space current of the equivalent diode adjacent to the cathode.

Generally, it can be stated that whatever the electrode system, the **total space current** from the cathode depends primarily upon the total activated cathode surface area, the total available emission, the cathode temperature, the extent of temperature and space charge limiting of emission, the geometry of the electrode system and the electrode voltages.

The **distribution of the space current** to the various electrodes depends only upon electrode geometry, space charge effects and the electrode voltages and, in general, cannot be expressed in a simple form.

In addition to the electron space current from the cathode, there are always some positive ions present due initially to the presence of the infinitesimal traces of residual gases remaining after the exhausting and gettering processes and, during life, to the release of absorbed gases from the surfaces of the electrode structure and envelope walls, and the gases produced as a result of physical-chemical changes occurring in the cathode coating during the emission processes. The positive ions, so produced, flow to the negative voltage electrodes and are prevented from bombarding the cathode surface during operation, when space current is flowing, by collision effects and the presence of the space charge surrounding the cathode.

A primary or secondary electron emission current may also flow from the surface of an electrode and represents a negative electrode current. Small positive or negative leakage conduction currents, due to conducting or semi-conducting leakage paths over or through the interelectrode insulation, may also contribute to the electrode currents; their values depend on the voltages of the electrodes concerned, and the conducting properties of the contaminated surfaces or insulating material, and often on their temperature. When the effects above are present, the total current of an electrode is the algebraic sum of the positive and negative components.

Static Characteristics—The various electrical characteristics, which result from the electrode geometry and the application of steady **direct voltages** only to the

electrodes, with the cathode emitting, are termed "static characteristics". These characteristics consist of—

- (a) the voltage-current relationship for each electrode, when constant voltages are applied to all remaining electrodes.

e.g., Diode, — $I_b - E_b$,

Triode, — $I_b - E_b$, E_{c1} constant
 $I_{c1} - E_{c1}$, E_b constant

and similarly in the case of other types.

- (b) the mutual voltage-current relationships between electrodes, when constant voltages are applied to all electrodes except the voltage-varying electrode.

e.g., Triode, — $I_b - E_{c1}$ E_b constant

Pentode, — $I_b - E_{c1}$ E_b, E_{c3}, E_{c2} constant

$I_{c3} - E_{c1}$ E_b, E_{c3}, E_{c2} constant

$I_{c2} - E_{c1}$ E_b, E_{c3}, E_{c2} constant

and similarly in the case of other types.

Derived Characteristic Parameters—By considering infinitesimal changes of voltage and current of the static characteristics, described under (a) and (b) above, the characteristic parameters—amplification factor, transconductance and variational plate resistance are obtained, which are related as follows,

$$\text{Transconductance} = \frac{\text{Amplification Factor}}{\text{Plate Resistance}}$$

These characteristic parameters are derived by the following relations—

$$\text{transconductance} = \frac{\delta I_b}{\delta E_{c1}}; E_b, E_{c3}, E_{c2} \text{ constant} \quad (3)$$

$$\text{amplification factor} = \frac{\delta E_b}{\delta E_{c1}}; E_{c3}, E_{c2} \text{ constant} \quad (4)$$

$$\text{plate resistance} = \frac{\delta E_b}{\delta I_b}; E_{c3}, E_{c2}, E_{c1} \text{ constant} \quad (5)$$

The amplification factor is a function of the electrode geometry only, but becomes also dependent on the control grid voltage as the cut-off condition is approached. The transconductance, as defined by eqn. (3) may be derived from the general space current eqn. (1), and is a function of the electrode geometry, the total cathode space current and uniformity of activation of the cathode surface.

The characteristic parameters normally used to describe the electrode geometry, and in terms of which performance is interpreted, are—the amplification factor, transconductance of the control grid with respect to the plate and the (a.c.) plate to cathode resistance.

Dynamic Characteristics—By superimposing alternating voltages on the direct voltage(s) of the control electrode(s), with suitable impedances in series with the output electrode(s), dynamic characteristics are obtained which depend directly on the static characteristics and characteristic parameters. These dynamic characteristics include rectification, frequency conversion, voltage and power gain, oscillation, and impedance transformation characteristics.

The static characteristics, characteristic parameters and the fundamental properties previously described comprise the basic mechanical and electrical characteristics, which determine the serviceability and application of a valve and its performance under given conditions.

In order to appreciate the significance and limitations of the various tests, which normally are applied to determine the condition of a valve and the probability that it will continue to operate satisfactorily, the performances and individual tests must be properly interpreted in terms of all the relevant characteristics and corresponding fundamental physical properties. The manner and extent of the dependence and interdependence of the various characteristics and fundamental physical properties must also be recognized and understood.

The important basic functional characteristics, together with the fundamental physical properties on which they depend, are shown in the following tabulation :

GENERAL PHYSICAL PROPERTIES	RELATED FUNCTIONAL CHARACTERISTICS
1. Mechanical	
Size, shape and material of external construction	Physical dimensions Type of envelope Type of base Type of top cap Base pin and top cap connections
System of electrode connections	Ruggedness of envelope, basing and internal electrode structure
Stability, robustness and durability of mechanical construction	Microphony Noise
2. Electrical	
Interelectrode resistance	D.C. interelectrode insulation resistance R-F interelectrode insulation resistance Noise
Vacuum	Gas pressure within the envelope*
Cathode emission	Total available peak cathode current* Total available average cathode current*
Uniformity of cathode activation	Transconductance or dynamic performance characteristic at reduced heater/filament voltage*
Electrode geometry	Electrode currents* Interelectrode transconductances* Interelectrode μ factors* Interelectrode variational resistances* Interelectrode capacitances
Electrode contact potentials	} Modify characteristics dependent upon electrode geometry (see above)
Primary and secondary emission	
Stability of electrical characteristics	
	Affect all electrical characteristics.

(iii) Fundamental characteristic tests

The characteristic tests which are of fundamental importance in specifying the performance and determining the condition, acceptability and usability of an oxide-coated cathode- or filament-type valve, are as follows :

(a) Tests common to all valve types

- Visual inspection of internal and external construction, and finish.
- Maximum overall length.
- Maximum diameter.
- Interelectrode short-circuits.
- Electrode continuity (open-circuits).
- Interelectrode insulation resistance (d.c.).*
- Heater/filament power.*
- Heater/cathode leakage.*
- Emission or emission-dependent dynamic test.*
- Interelectrode capacitances.*

(b) Tests common to all types except diodes*

- Reverse grid current (gas, leakage, grid emission).
- { Control grid current commencement potential, or
- { Positive control grid current.
- Electrode currents (d.c.).
- Electrode current (d.c.) cut-off.

*Under specified operating conditions.

Transconductance (see Ref. 47).

Amplification factor.

Plate resistance.

Noise (a-f and/or r-f).

Microphony.

(c) Tests common to diodes only*

Signal diodes

Plate current commencement or zero signal plate current.

Back emission.

Power diodes

(d) Dynamic performance tests*

Signal diodes

Rectification (operation)

Power diodes

Rectification (operation)

A-F amplifiers

A.C. amplification

R-F and I-F amplifiers

Stage gain.

Converters

Conversion stage gain or conversion transconductance

and

Oscillator transconductance or oscillator grid current.

Power output types

Power output.

(e) Dynamic performance tests at reduced heater/filament voltage*

Dynamic performance tests are also performed at reduced filament/heater voltages during manufacture, in order to control initial characteristics and performance, and also to provide a manufacturing process control of the uniformity of activation of the emitting surface. In some cases, with the reduction of filament/cathode temperature, changes occur in contact potential and/or reverse grid current, which make the normal-voltage tests ineffective or unsatisfactory as a control of activation, depending on the conditions of operation. In such cases a transconductance test is normally used instead.

Notwithstanding the control exercised by such tests over initial characteristics and performance, it is a very difficult manufacturing problem to avoid the wide variations and deterioration of characteristics which often occur under conditions of reduced filament/heater operation throughout life although the characteristics at normal filament/heater voltage may be satisfactory. For this reason, and also as performance may be critically dependent on circuit design and electrode supply voltages, particularly the operation of the oscillator circuits of a converter valve and the power output and distortion of a power output valve, it is not in general normal practice for valve specifications to specify any minimum requirements for characteristics or performance at reduced filament/heater voltage during life. Reasonable performance at reduced filament/heater and electrode voltage conditions is achieved by most manufacturers, however, as a result of the pressure of competition combined with the user's demand for acceptable performance under slump voltage conditions.

Under American practice the reduced heater/filament voltages at which specified dynamic performance tests are normally performed during manufacture are as follows :

0.625 volt types	0.55 volt
1.25 volt types	1.1 volts
1.4 volt types	1.1 volts
2 volt types	1.6 or 1.7 volts
2.5 volt types	2.2 volts
6.3 volt types	5.5 volts
7.5 volt types	6.0 volts
12.6 volt types	11.0 volts
19 volt types	16.5 volts
25 volt types	22 volts
26.5 volt types	23.5 volts

*Under specified operating conditions.

32	volt types	28.5	volts
35	volt types	31.0	volts
45	volt types	40	volts
50	volt types	44	volts
117	volt types	100	volts

(iv) Valve ratings and their limiting effect on operation

(A) Limiting ratings

In order to assist the designer to obtain the maximum service from a given valve type, within the limits of safe operation, in the various applications in which it may be used, the limiting conditions under which the type can be operated without impairing its performance and normal life are usually specified by the valve manufacturer in the form of maximum (or minimum) ratings for relevant basic characteristics which may only be exceeded at the user's risk. These ratings, unless otherwise stated, apply to valves having bogie values of characteristics. It is therefore the responsibility of the equipment designer to see that a bogie valve will not exceed any of its ratings.

Maximum ratings are established on the basis of life tests and operating performance. It is a matter of experience that when one or more ratings are exceeded for any appreciable time, depending on the period and the extent of the overload, the particular rating exceeded and the capability of the type to withstand such overload, the serviceability of the particular valve may be impaired, its life may be shortened or its performance may be unsatisfactory.

Maximum ratings usually are specified only for those characteristics which normally determine the limits of safe operation in the intended applications for which a particular type has been designed. Generally, the limits of safe operation for any application may be prescribed completely by specifying the maximum ratings for the electrode voltages, peak inverse voltage in the case of rectifiers, electrode dissipations and the maximum peak and average total cathode current.

In the case of high transconductance and power output types it is necessary, in addition, to limit the maximum value of resistance which may be used between the negative control grid and cathode, in order to avoid either excessive variation of circuit performance, excessive space current or excessive electrode dissipations due to reverse grid current. Maximum ratings, in general, can only be determined satisfactorily by extensive life tests.

(B) Characteristics usually rated

The characteristics of individual types for which ratings are required to specify performance are as follows :

(a) General mechanical ratings (common to all types)

- Maximum overall length.
- Maximum seated height.
- Maximum diameter.
- Dimensions and locations of top caps, bases and base pins.
- Materials and design of external construction.

(b) General electrical ratings common to all types

	Nature of rating
Heater/filament voltage (a.c. or d.c.)	nominal
Heater/filament current (a.c. or d.c.)	nominal
Heater to cathode voltage (d.c.)	maximum
Control grid circuit resistance	maximum
Interelectrode capacitances—	
control grid to plate capacitance	maximum
all other capacitances (single unit)	nominal
capacitances between electrodes of multiple units	nominal or maximum

(c) Specific additional electrical ratings applied to particular types

Type	Application	Fundamental rating	Nature of rating
Diodes	Detector	Average (d.c.) plate current per plate	Maximum
		Peak plate current per plate	Maximum
	Power Rectifier	Peak inverse plate voltage	Maximum
		Average (d.c.) plate current per plate	Maximum
Triodes	Voltage amplifier	Peak plate current per plate	Maximum
		Plate Voltage	Maximum
		Plate dissipation	Maximum
		Grid voltage—negative	Maximum
	Power amplifier	positive	Maximum
		Cathode current (d.c.)	Maximum
		Plate voltage	Maximum
		Plate dissipation	Maximum
		Grid voltage—negative	Maximum
		positive	Maximum
Pentodes	Voltage amplifier	Grid dissipation**	Maximum
		Cathode current (d.c.)	Maximum
		Cathode current (peak)*	Maximum
		Plate voltage	Maximum
		Screen voltage	Maximum
		Screen supply voltage	Maximum
	Power amplifier	Grid voltage—negative	Maximum
		positive	Maximum
		Plate dissipation	Maximum
		Screen dissipation	Maximum
		Cathode current (d.c.)	Maximum
		Plate voltage	Maximum
		Screen voltage	Maximum
		Grid voltage—negative	Maximum
		positive	Maximum
		Plate dissipation	Maximum
		Screen dissipation	Maximum
		Grid dissipation**	Maximum
Converters	Frequency converter	Cathode current (d.c.)	Maximum
		Cathode current (peak)*	Maximum
		Mixer plate voltage	Maximum
		Mixer screen voltage	Maximum
		Mixer screen supply voltage	Maximum
		Oscillator plate voltage	Maximum
		Oscillator plate supply voltage	Maximum
		Mixer signal grid voltage—	
		positive	Maximum
		negative	Maximum
		Mixer plate dissipation	Maximum
		Mixer screen dissipation	Maximum
		Oscillator plate dissipation	Maximum
		Cathode current (d.c.)†—	
		mixer	Maximum
		oscillator	Maximum

*Power amplifier types only, for other than Class A operation.

**For operation in the positive grid current region.

†In converters of the 6SA7, 6BE6 class having no separate oscillator positive electrode, the total cathode current is the fundamental rating.

Notwithstanding the ratings shown against each type, the actual ratings of an individual type depend entirely on its intended applications and may not include all those listed. The absence of a rating for a particular characteristic may be taken to indicate either that it has not previously been necessary to specify a rating for this characteristic, or that the type in question was not intended originally for this application and has not been processed accordingly. In the latter case, operation may not be satisfactory, and reference should be made to the valve manufacturer for specific information.

(C) Rating systems

Valves are rated by either of two systems—the “ absolute maximum ” system, or the “ design-centre maximum ” system. The absolute maximum system originated in the early days of valve development and was based on the voltage characteristics of battery supplies. Battery voltages could fall below their nominal values but seldom appreciably exceeded them, so that valve maximum ratings set on the basis of specified battery voltages were absolute maximum ratings. This system is still widely used by British and European valve manufacturers and is the system of ratings used in the British Services’ Electronic Valve Specification K1001 and the U.S.A. Services’ Specification for Electron Tubes, JAN-1A (Ref. S2). With the introduction of power line and car-radio operated receivers and the tendency of many designers to interpret absolute maximum ratings as nominal values, it became necessary to re-rate valves according to a system in which allowance was made in the ratings for the variations which occur under both conditions of operation. Accordingly, the design-centre system was adopted in U.S.A. by the Radio Manufacturers Association in 1939 for the rating of receiving valves and since then has become the standard system for rating most receiver types of American design, manufactured both in U.S.A. and elsewhere.

With either system, each maximum rating for a given valve type must be considered in relation to all other maximum ratings for that type, so that no one maximum rating will be exceeded in utilizing any other maximum rating.

Thus it will often happen that one rating alone will determine the limiting operating conditions while other characteristics are below their maximum ratings.

(D) Interpretation of maximum ratings

In the absolute maximum or “ absolute ” system (except for filament or heater voltage) the maximum ratings are limiting values above which the serviceability of the valve may be impaired from the viewpoint of life and satisfactory performance. Therefore, in order not to exceed these absolute ratings, the equipment designer has the responsibility of determining an average design value for each rating below the absolute value of that rating by an amount such that the absolute values will never be exceeded under any usual condition of supply-voltage variation, load variation, or manufacturing variation in the equipment itself.

The equipment should be designed to operate the filament or heater of each valve type at rated normal value for full-load operating conditions under average voltage-supply conditions. Variations from this normal value due to voltage-supply fluctuation or other causes, should not exceed ± 5 per cent. unless otherwise specified by the valve manufacturer.

Under the “ British Standard Code of Practice ” B.S.1106, 1943 (Ref. 49) and the British Radio Valve Manufacturers’ Association’s publication “ Radio Valve Practice,” August, 1948 (Ref. 48), recommended British practice is that in general it is not permissible that the heater voltage should vary more than 7 per cent. from the rated value.

It is a matter of experience, however, that the heaters and filaments of most modern receiving valve oxide-coated cathode and filament types may be operated at voltages whose maximum fluctuations do not exceed ± 10 per cent. from their rated values, without serious effect on life or marked reduction in performance, provided that the maximum ratings of the other electrodes are not exceeded. In cases where the heater or filament voltage variations exceed, or are likely to exceed, ± 10 per cent., the maximum ratings should be reduced and recommendations obtained from the valve manufacturer as to the maximum ratings permissible under the particular conditions.

In the design-centre maximum or “ design-centre ” system, the maximum ratings are working design-centre maxima. The basic purpose underlying this system

is to provide satisfactory average performance in the greatest number of equipments on the assumption that they will not be adjusted to local power-supply conditions at the time of installation. Under the design-centre system, ratings are based on the normal voltage variations which are representative of those experienced with the three important types of power supply commonly in use, namely a.c. and d.c. power lines, storage battery with connected charger, and dry batteries, so that satisfactory performance from valves so rated will ordinarily be obtained in equipment which is so designed that the design-centre maximum ratings are not exceeded at the supply design-centre voltage.

The following interpretation of receiving valve design-centre ratings is based partly on R.M.A. (U.S.A.) Standard M8-210 entitled "Tube Ratings" (Ref. S11), and partly on established design practice recommended by valve manufacturers.

1. Cathode

The heater or filament voltage is rated as a normal value, unless otherwise stated, so that transformers or resistances in the heater or filament circuit should be designed to operate the heater or filament at the rated value at the supply design-centre voltages, indicated hereunder. Where the permissible heater or filament voltage variations are exceeded, or are liable to be exceeded, maximum ratings should be reduced in accordance with recommendations obtained from the valve manufacturer.

2. Indirectly-heated and a.c. filament types

(2.1) **A.C. or d.c. power line operation**—Maximum ratings have been chosen so that valves will give satisfactory performance at these maximum ratings in equipment operated from power line supplies, the normal voltage of which, including normal variations, fall within ± 10 per cent. of a specified value. Heaters or filaments as well as positive and negative voltage electrodes, unless otherwise specified, may therefore be operated at voltages up to ± 10 per cent. from their rated values, provided that at the specified line design-centre voltage the heater or filament is operated at its rated voltage and the maximum ratings of plate voltages, screen-supply voltages, electrode dissipations, total cathode current and rectifier output currents are not exceeded.

The prescribed power line voltage variation of ± 10 per cent. is based on surveys made in the U.S.A., which have shown that the line voltages delivered fall within 10 per cent. of 117 volts, which is taken as the line design-centre voltage in that country. In using design-centre ratings with other power line systems elsewhere, it is usually satisfactory to regard ± 10 per cent. as being representative of the line voltage variation likely to be experienced under normal conditions, so that it is then only necessary to determine the line design-centre voltage. In extreme cases, where power line variations exceed ± 10 per cent., as for example when operation is in remote areas supplied by long lines subject to variable and heavy peak loading, adjustment to the equipment should be made locally.

(2.2) **Storage battery operation**—When storage battery equipment is operated without a charger, it should be designed so that the heaters or filaments are operated at their normal rated values and published maximum values of plate voltages, screen-supply voltages, electrode dissipations, total cathode currents and rectifier output currents are never exceeded for a terminal voltage at the battery source of 2.0 volts per cell. When storage battery equipment is operated with a charger or similar supplies, the normal battery fluctuation may be as much as 35 per cent. or more, which imposes severe operating conditions on valves. Under these conditions, the equipment should be designed so that the effect of high heater or filament voltages on valve life and performance (due mainly to excessive reverse grid current) is reduced to a minimum, and so that 90 per cent. of the above maximum ratings is never exceeded for a terminal voltage at the battery source of 2.2 volts. In both classes of operation, progressively reduced and unreliable performance is to be expected as the heater or filament voltage falls below 90 per cent. of its rated value and approaches the "slump" value specified for the reduced performance tests of the valve test specification.

(2.3) **"B" battery operation**—The design-centre voltage for "B" batteries supplying positive voltage electrodes is the normal voltage rating of the battery block,

such as 45 volts, 90 volts, etc. Equipment should be designed so that under no condition of battery voltage will the plate voltages, screen-supply voltages, electrode dissipations, or total cathode currents ever exceed the recommended respective maximum values specified for each valve type by more than 10 per cent.

(3) 2.0 Volt battery filament types

(3.1) **Filament**—The 2.0 volt battery filament types are designed to be operated with 2.0 volts across the filament. In all cases the operating voltage range should be maintained within ± 10 per cent. of the rated filament voltage, i.e., within the limits of 1.8 to 2.2 volts.

(3.2) **Positive and negative electrodes**—The electrode voltage supplies may be obtained from dry-cell batteries, storage batteries or from a power line and should be chosen so that the maximum ratings of plate voltages, screen-supply voltages, electrode dissipations and total cathode current are not exceeded at the supply design-centre voltages specified under 2.3, 2.2 and 2.1.

(4) 1.4 volt battery valve types

(4.1) **Filament**—The filament power supply may be obtained from dry-cell batteries, from storage batteries, or from a power line.

(4.11) **Dry-cell battery supply**—The filament may be connected either directly across a battery rated at a terminal potential of 1.5 volts, or in series with the filaments of similar valves across a power supply consisting of dry cells in series. In either case, the voltage across each 1.4 volt section of filament should not exceed 1.6 volts. In order to meet the recommended conditions for operating filaments in series it may be necessary to use shunting resistors across the individual 1.4 volt sections of filament.

(4.12) **Storage battery supply**—The filament may be operated either singly or in series with the filaments of similar valves. For such operation in either case, design adjustments should be made so that, with valves of rated characteristics, operating with all electrode voltages applied on a normal storage-battery voltage of 2.0 volts per cell (without a charger) or 2.2 volts per cell (with a charger), the voltage drop across each 1.4 volt section of filament will be maintained within a range of 1.25 to 1.4 volts with a nominal centre of 1.3 volts. In order to meet the recommended conditions for operating filaments in series it may be necessary to use shunting resistors across the individual 1.4 volt sections of filament.

(4.13) **Power line supply**—The filament may be operated either singly or in series with the filaments of similar valves. For such operation, in either case, design adjustments should be made so that, with valves having rated characteristics operating with all electrode voltages applied and on a line voltage equal to the design-centre voltage, the voltage drop across each 1.4 volt section of filament will be maintained within a range of 1.25 to 1.4 volts with a nominal centre of 1.3 volts. In order to meet the recommended conditions for operating filaments in series, it may be necessary to use shunting resistors across the individual 1.4 volt sections of filament.

(4.2) **Positive and negative voltage electrodes**—The electrode voltage supplies may be obtained from dry-cell batteries, storage batteries, or from a power line. For such operation the electrode voltages should be chosen so that the maximum ratings of plate voltages, screen-supply voltages, electrode dissipations and total cathode currents are not exceeded at the supply design-voltages specified under 2.3, 2.2 and 2.1 respectively.

(5) General (all types)

(5.1) **Screen voltage supply**—When the screen voltage is supplied through a screen-dropping resistor, the maximum screen voltage rating may be exceeded provided :

- (a) The screen supply voltage does not exceed the maximum plate voltage rating.
- (b) At any signal condition, the average screen dissipation does not exceed the maximum rating.
- (c) At the signal condition which results in maximum screen current, the screen voltage does not exceed the maximum rating.

(5.2) **Grid voltage limits**—Where a grid voltage is specified as “positive bias value 0 maximum” or “never positive”, this indicates that grid dissipation is not

permitted. In such cases it may be inferred that the grid has not been suitably treated to permit dissipation.

(E) Operating conditions

Typical operation—In addition to maximum ratings, information is published on typical operating conditions for most of the various types, when used in particular applications. These typical operating conditions are intended to provide guiding information for the use of each type. They must not be considered as ratings, because each type can, in general, be used under any suitable conditions within its rating limitations.

Datum point for electrode potentials—In published data, it is standard practice for the values of grid bias and positive-potential-electrode voltages to be given with reference to a specified datum point, as follows :—For types having filaments heated with direct current, the negative filament terminal is taken as the datum point to which other electrode voltages are referred. For types having filaments heated with alternating current, the mid-point (i.e., the centre tap on the filament transformer secondary, or the mid-point on a resistor shunting the filament) is taken as the datum point. For types having equi-potential cathodes (indirectly heated) the cathode is taken as the datum point.

Grid bias for a.c. or d.c. filament excitation—If the filament of any type whose data are given for a d.c. filament voltage is to be operated from an a.c. supply, the grid bias given for d.c. filament operation should be increased by an amount approximately equal to one half the rated filament voltage and be referred to the filament mid-point. Conversely, if it is required to use d.c. filament excitation on any filament type whose data are given for an a.c. filament voltage, the value of grid bias given should be decreased by an amount approximately equal to one-half the rated filament voltage, and be referred to the negative filament terminal, instead of the mid-point as in a.c. operation. This rule is only approximate and does not, in general, provide identical currents for both types of filament excitation.

(v) Recommended practice and operation

The following additional limitations on valve practice and operation are based partly on the recommendations of the British Standard Code of Practice (Ref. 49) also on the B.V.A. Radio Valve Practice (Ref. 48), and on established design practice.

(a) **Mounting**—(1) Unless otherwise stated it is desirable that valves should be mounted base down and in a vertical position. Where it is necessary to depart from vertical mounting, the plane of the filament of directly heated valves should be vertical. Similarly, the plane of the grid side rods (or major axis of the control grid) of indirectly heated valves having a high transconductance and/or a long unsupported cathode, should be vertical. This reduces the possibility of filament- and cathode-to-grid short circuits and microphony in filament valves.

It is particularly undesirable that valves having high plate dissipation ratings should be mounted base upwards without agreement from the valve manufacturer, as this method of mounting seriously affects the flow of air around the bulb and may result in the limiting temperature being exceeded.

Depending on the distribution of the bulb temperature, gas may be released from the getter deposit under these conditions and the vacuum and emission affected.

(2) It is particularly important that the connections to floating contacts of sockets for glass based valves should be as flexible as possible and that the contacts themselves should float properly and not become rigidly locked in position. The use of a wiring jig, having the nominal specified dimensions for the base type, inserted in the valve socket during wiring, is desirable in order to locate the socket contacts correctly, so that strain on the base pin seals is minimized when the valve is inserted. Prior to insertion, the base pins of miniature valves should be straightened by means of a pin-straightener, if misaligned. The pin-straightener may consist simply of a steel block drilled with countersunk holes of the correct diameter and location, to slightly larger tolerances than those specified for the pins of the base type. For specific information and design, reference should be made to the valve manufacturer.

(3) It is undesirable to use socket contacts as connecting tags in circuit wiring because of circumstances which may arise if the valve is subsequently replaced by another

having different or additional pin connections. In particular, contact No. 1 of octal sockets should not be used in this connection, as frequently internal base shielding is brought out to pin No. 1 of octal-based valves, which should be connected to chassis. Furthermore, in glass-based valves the above-mentioned practice may adversely affect the valve characteristics by the application of a voltage to pins which are not connected to any valve element, but which project into the envelope.

(4) Valves with rigid pins in glass bases and valves without bases which have short rigid lead-out wires are normally intended to be mounted in sockets, and it is recommended that such valves should not be soldered directly into the wiring, as such connections can impose sufficient strain to endanger the seals.

(5) If valves are to be subjected to continuous vibration, means should be employed to damp out such vibration by the use of cushioned valve socket mountings.

(b) Ventilation

(1) The layout and design of equipment should afford sufficient ventilation to ensure a safe bulb temperature under all conditions. As a general guide, the maximum temperature of the hottest part of the bulb under operating conditions in the equipment should not exceed by more than 20°C. that temperature which would be attained if the valve were operated at its maximum ratings under conditions of free air circulation in an ambient temperature of 20°C. Where exceptional increases of temperature may occur (e.g., when valves are used in screening cans or in equipment working in tropical conditions) the valve manufacturer should be consulted on each type concerned.

The present trend in valve design is to reduce dimensions with the object of saving space and of improving efficiency at high frequencies, and the extent to which the reduction can be made is usually limited by the amount of heat which can be dissipated from the exterior surface of the bulb.

For valves of present day sizes operating at normal temperatures, about half the heat is dissipated by convection and half by radiation. It is therefore necessary to allow free convection of reasonably cool air past the bulb and free radiation from the surface of the bulb to cooler surroundings.

The increase in the temperature of air in convective cooling is very small and it is therefore more important that the flow of air should be copious and unimpeded than that it should be particularly cold. No great risk is incurred if the air is slightly warmed by passing near other components if this allows it to flow through a less obstructed path.

In order to improve radiation from a valve, surrounding surfaces should not be polished but should be kept as cool as possible. The temperature of a valve surrounded by a plated shield can, or by components at about its own temperature, may rise seriously.

(2) When valves are mounted in other than upright vertical positions, greater care should be taken to ensure that adequate ventilation is provided.

(3) Adequate ventilation is particularly important in the case of output valves and rectifiers.

(c) Heater-cathode insulation

(1) It is generally desirable to avoid a large potential difference between heater and cathode. This potential should not normally exceed 100 volts except in the case of certain indirectly-heated rectifier valves and valves specially designed for a.c./d.c. operation. Where a design necessitates higher heater-cathode potentials, a recommendation of the maximum permissible value should be obtained from the valve manufacturer. For convenience, the maximum heater-cathode voltage rating is usually given as a d.c. value.

(2) The insulation resistance between the heater and the cathode should not be included in r-f circuits where frequency stability is required or in a-f circuits followed by a high gain amplifier.

The leakage currents make themselves apparent as noise or hum, which may assume serious proportions if the valve in which they originate is followed by a large degree of amplification. Moreover, if the heater-cathode insulation is included in a tuned circuit, any alteration to the physical or electrical properties of the insulation will alter the frequency to which the circuit is tuned, and if both r-f and mains frequency voltages

exist across the insulation, there is a risk of modulation hum, particularly in cathode-coupled oscillators and the like.

(d) Control grid circuit resistance

In all cases where published recommendations are available from the valve manufacturer, they should be followed. The maximum value of grid circuit resistance in the case of a particular type of valve cannot be specified without knowledge of the valve characteristics and conditions of operation. In no circumstances should valves be operated without a d.c. connection between each electrode and cathode.

The maximum value of control grid circuit resistance which may be used under any condition of operation depends initially upon the stability of performance required but ultimately upon the transconductance under that condition, the increase in cathode current and electrode dissipations which may occur due to the cumulative effects of reverse grid current (gas, grid emission and leakage) permitted by the specification, the maximum ratings for these characteristics, and the limiting effect of resistances in series with the cathode and in the electrode circuits in series with the various electrode supply voltages. The following formulae, expressing the relationships between the various resistances, direct currents and electrode parameters in typical grid controlled triodes, tetrodes and pentode circuits hold providing the control grid current is negligible in comparison with the total cathode current.

For pentodes and tetrodes (Ref. 41)

$$R_{g1} = \frac{\Delta I_k}{\Delta I_{c1}} \left[\frac{1}{g_k} + R_k \left(1 + \frac{1}{\mu_{g1, g2}} \right) + P \frac{R_{g2}}{\mu_{g1, g2}} \right] \quad (6)$$

For triodes (Ref. 41)

$$R_{g1} = \frac{\Delta I_b}{\Delta I_{c1}} \left[\frac{1}{g_m} + R_k \left(1 + \frac{1}{\mu} \right) + \frac{R_L}{\mu} \right] \quad (7)$$

where ΔI_k = change in cathode current permitted by maximum ratings of plate dissipation and/or cathode current ; or change in performance which can be tolerated.

ΔI_b = change in plate current permitted by maximum ratings of plate dissipation and/or cathode current ; or change in performance which can be tolerated.

ΔI_{c1} = change in control grid (No. 1) current which is likely to occur or is permitted by the valve specification.

R_{g1} = grid resistor (ohms).

R_{g2} = series screen resistor (ohms).

R_k = cathode resistor (ohms).

R_L = series plate load resistor (ohms).

$\mu_{g1, g2}$ = triode amplification factor of pentode or tetrode.

μ = amplification factor of triode.

P = ratio of screen current (I_{c2}) to cathode current

$$= \frac{I_{c2}}{I_{c2} + I_b}$$

g_m = grid-plate transconductance (mhos).

g_k = grid-cathode transconductance (mhos)

$$= g_m \frac{I_k}{I_b}$$

To determine the limiting value of grid resistor which may be used, ΔI_{c1} should be taken as the maximum value of reverse grid current permitted by the specification, under maximum electrode dissipation and cathode current conditions ; ΔI_b and ΔI_k are the changes in plate and cathode currents which result in maximum rated plate and/or screen dissipations and/or maximum cathode current.

The maximum rating which is reached first determines the limiting value of the grid resistor.

If the specified value of ΔI_{c1} is not available, the highest typical value of reverse grid current given in Sect. 3(iv)A for each major group of valve types may be used with

discretion. In cases where the valve is being operated below maximum rated conditions and at a total cathode current less than that for the grid current test conditions, the value of ΔI_{c1} may be taken as varying approximately as the cathode current.*

It should be clearly understood that equations (6) and (7) are fundamental, and, in cases where no maximum grid circuit resistance values are published, may be used to calculate maximum safe values. These equations are based on the margin (ΔI_b) between the operating plate current and that value of plate current which gives maximum plate dissipation or maximum cathode current or which gives the maximum tolerable change in performance, the limiting condition of operation being determined by the rating which is reached first. It may happen that the published typical operating conditions give maximum rated plate dissipation—in this case ΔI_b or ΔI_k is zero, and the equations cannot therefore be applied to calculate R_{g1} directly. In such a case the procedure is to assume reasonable values of R_{g1} and ΔI_{c1} , and then to use the equations to derive ΔI_b or ΔI_k . The operating plate or cathode current would then be made less than the permissible maximum by the margin ΔI_b or ΔI_k . Alternatively a lower value of R_{g1} may be chosen and the conditions of operation recalculated.

If a maximum value of R_{g1} is published for fixed bias operation, then the value for cathode bias may be determined from equations (8) to (13):

For pentodes and tetrodes—general case

$$\frac{R_{g1} \text{ for cathode bias}}{R_{g1} \text{ for fixed bias}} = 1 + g_k \left[R_k \left(1 + \frac{1}{\mu_{g1 \cdot g2}} \right) + \frac{PR_{g2}}{\mu_{g1 \cdot g2}} \right] \quad (8)$$

$$\text{or approximately } \approx 1 + g_k \left[R_k + \frac{PR_{g2}}{\mu_{g1 \cdot g2}} \right] \quad (9)$$

$$(\text{or when } R_{g2}=0) \approx 1 + g_k R_k \quad (10)$$

For triodes—general case

$$\frac{R_{g1} \text{ for cathode bias}}{R_{g1} \text{ for fixed bias}} = 1 + g_m \left[R_k \left(1 + \frac{1}{\mu} \right) + \frac{R_L}{\mu} \right] \quad (11)$$

$$\text{or approximately } \approx 1 + g_m \left[R_k + \frac{R_L}{\mu} \right] \quad (12)$$

$$(\text{or when } R_L=0) \approx 1 + g_m R_k \quad (13)$$

In the case of resistance-loaded triodes and pentodes with series screen resistors, the values of R_{g1} as derived from eqn. (6) or (7) respectively will be very high. In such cases the limiting factor is the effect of the reverse grid current on the operating bias. This effect is considered in detail in Chapter 12, Sect. 2(iv) for triodes with fixed bias and Sect. 2(iii) with cathode bias also Sect. 3(v) for pentodes with fixed bias, and Sect. 3(iv)C with cathode bias.

A high value of resistance between the control grid and the cathode should be avoided wherever possible. In B.S.1106, 1943 (Ref. 49) it is recommended that, in general, 1 megohm with self-bias and 0.5 megohm with fixed bias are suitable maxima and that with receiving valves having an anode dissipation exceeding 10 watts the grid-circuit resistance should not exceed 0.5 megohm when self-bias is used and 0.1 megohm with fixed bias. These values must be reduced when one resistor is common to more than one control grid circuit.

The maximum values of grid circuit resistance with r-f pentodes controlled by a.v.c. is covered in Chapter 27 Sect. 3(iv)b.

Some valve types have an inherent negative resistance region in the positive portion of the grid characteristic, due to secondary emission from the grid as a result of the deposition or evaporation of active material from the cathode or deposition from the getter during manufacture. In such cases the resultant grid current may change sign from positive to negative as the grid voltage increases from zero in a positive direction, ultimately becoming positive again. The maximum value of grid circuit resistance

*This assumes that the grid leakage current is small compared with the ionization current, and that the latter does not increase appreciably during operation.

which may be used under these conditions without **grid blocking** occurring, is that value of resistance represented by the line drawn from the operating bias point on the abscissa, tangential to the cross-over loop of the grid current characteristic below the abscissa as shown in Fig. 2.11.

If the grid circuit resistance is such that the line cuts the loop of the characteristic below the abscissa, blocking will occur if the instantaneous values of grid voltage exceed the voltage of the point at which the line crosses the grid characteristic nearer to the origin. See also Chapter 2 Sect. 2(iii).

Because of the difficulty of controlling the grid current commencement point of oxide-coated cathode and filament valves during manufacture, due mainly to **contact potential variations** caused by variable control grid surface conditions, it is desirable that operating conditions should be chosen, such that the control grid bias is always sufficiently large in relation to the contact potential, so that variations of the latter produce only minor effects on performance. In general, the grid current commencement voltage of indirectly heated cathode types is negative and may have a value up to -1.0 volt but as a rule varies during life. The grid current commencement voltage of filament types is usually positive and seldom exceeds about $+0.5$ volt, but usually becomes less positive during life and may even become negative. The plate current commencement voltage of diodes due to contact potential behaves in a similar manner.

(c) Operation at low screen voltages

As the grid current commencement voltage may in certain cases be dependent on the value of screen voltage and may become more negative as the screen voltage is reduced, it is in general undesirable to operate valves having low or zero control grid-bias at low screen voltages. In the case of zero-bias operated filament types, operation at low screen voltages may result in the grid current commencement voltage becoming negative and in the flow of positive current, causing either a change in operating conditions due to additional negative bias developed across the grid resistor or damping of tuned grid circuits due to lowered input resistance. In either case undesirable and often wide variations in performance may result.

(f) Microphony

Small variations of electrode spacing cause corresponding variations in the output of the valve, and it is desirable to ensure that little or no vibration reaches the valve. Such vibration may reach the valve by way of the valve socket or acoustically, and it should be noted that microphonic trouble may originate in the converter or i-f stages through modulation of the signal or i-f carrier at audio frequencies. It is recommended that, if possible, the position of the valve in relation to the source of vibration be so chosen that microphony effects will be at a minimum. Methods which may be used to minimize microphony effects are described in Chapter 35 Sect. 3(iv).

(g) Hum

Hum due to conditions within the valves is analysed in Chapter 31 Sect. 4(i). See also Ref. 91 on heater-cathode leakage as a source of hum.

(h) Stand-by operation

Where it is necessary to maintain cathodes and filaments at normal operating temperatures during stand-by periods, better life in general will be obtained when the equipment is so designed that **some**, rather than no, cathode current flows during such periods. It is also essential that the heater or filament voltage be maintained as close to the rated value as possible. Continuous operation of heaters or filaments at voltages exceeding their rated values by more than 10 per cent., without cathode current flowing, will result, generally, in progressively short life being obtained.

In equipments which are designed so that no cathode current flows during stand-by periods for periods of less than 15 minutes, the filament voltage of quick-heating filament types should be reduced to 80 per cent. of normal, while the heater voltage of indirectly heated cathode types should be maintained at normal rated value. For longer periods, both filament and heater power should be turned off.

SECTION 2: CONTROL OF CHARACTERISTICS DURING MANUFACTURE

(i) *Importance of control over characteristics* (ii) *Basic manufacturing test specification* (iii) *Systematic testing* (iv) *Tolerances on characteristics*.

(i) Importance of control over characteristics

The successful design and continued satisfactory operation of electronic equipment require that the valves used have certain prescribed characteristics, the initial values of which do not vary from valve to valve sufficiently to affect operation seriously and which, throughout life, remain within a prescribed range with only gradual change until the end of useful life is reached. Owing however to the highly complex nature of the physical-chemical processes involved in manufacture and the difficulty of controlling the variations of many of these processes under mass production conditions, the ultimate degree of uniformity obtainable in the final product, both in initial characteristics and their variation throughout life, must always be a compromise between the performance required by the equipment designer and user and the manufacturing cost in obtaining that performance. In any individual case, however, the degree to which variation of one or more characteristics affects operation, either initially or during life, depends entirely on the particular application and the critical features of the circuit design. For good circuit performance, it therefore is essential to take into consideration the range of variation of the various characteristics on which operation depends and to ensure that operation, so far as is practicable, is independent of the variation of characteristics, particularly of critical characteristics and characteristics over which limited or no control is exercised in manufacture by the valve test specification.

(ii) Basic manufacturing test specification

Owing to the relatively limited range of variation of mechanical and electrical characteristics for which usability and performance of the various types of valves in their intended applications may be satisfactory, it is necessary to apply tolerances, or "limits" to control the range of characteristics obtained under mass production conditions. For commercial applications these tolerances are chosen to be both satisfactory to the equipment designer and sufficiently wide to be economical and thus enable valves to be manufactured in large quantities at a reasonable cost. **These requirements are embodied in the complete manufacturing test specification, which normally comprises—**

- (1) Maximum permissible conditions of operation or **ratings**, as determined by emission capability, goodness of vacuum maintenance and interelectrode insulation.
- (2) Nominal values for the principal physical dimensions and electrical **characteristics**, relevant to intended applications under specified operating conditions.
- (3) A schedule of mechanical and electrical **tests** (including tolerances and sequence) sufficiently comprehensive to ensure that the prescribed dimensions, and electrical characteristics are maintained in production, and sufficiently severe to indicate likely failure, during life, when operated under maximum ratings.
- (4) A **life test** schedule sufficiently severe in conditions of operation and permissible deterioration of the main functional characteristics, to indicate reliability and performance of the product on life, under both normal recommended and maximum rating conditions.

As most valve types are designed to give a certain performance and life in a specific application or limited range of applications, it is important to note that each type is processed accordingly and that, in general, the test specification for a particular type normally includes only those tests which are necessary for adequate and economic control of the characteristics, and are required for satisfactory performance and life in the intended applications. Unintended applications not covered by the maximum ratings or test specification should be referred to the valve manufacturer, as performance and life in many cases can often be decided only by laboratory investigation and special life tests.

Reference to quality control: Ref. 45. Reference to life testing: Ref. 97.

(iii) Systematic testing

For the purpose of systematic testing, valve characteristics may be divided into the following three categories.

(a) **Primary characteristics**, which are fundamental to the basic operation and life of the valve as a thermionic device and its functional operation and usability. These include the mechanical stability of the envelope and electrode structure, external physical dimensions and construction, continuity of electrode connections, characteristics indicating the goodness of the vacuum and emission and the principal functional characteristics dependent on the electrode geometry.

(b) **Secondary characteristics**, which are not fundamental to the operation of the valve, but are, in general, dependent on the primary functional characteristics and essentially determine the degree of performance obtainable in intended applications of the particular type.

(c) **Tertiary characteristics**, which are not fundamental to the operation of the valve, but are dependent on, and are in general controlled by the primary and/or secondary characteristics and either affect performance in a minor degree only, seldom vary sufficiently to affect performance or are important only in certain applications or for purposes of valve design.

In order to control the above-mentioned characteristics after manufacture in accordance with their specification, the acceptance testing procedure is usually organized into the following group of tests, the functions of which are described in detail in the following subsections.

- (A) Production Tests.
- (B) Design Tests.
- (C) Recorded Readings.
- (D) Life Tests.
- (E) Warehouse Tests.

(A) Production Tests

(1) First Testing

All primary characteristics, except those which are subject only to minor variation from valve to valve, are usually tested 100 per cent. in the factory after manufacture. Tests performed on this basis are designated Production or Factory Tests and failure of any valve to meet the prescribed test limits for any production test constitutes cause for total rejection of that particular valve. When characteristics are uniform and quality satisfactory, production tests are usually limited to primary characteristics only and particular characteristics which cannot be otherwise controlled satisfactorily. The normal production tests are performed in the sequence prescribed by the specification and for all types the tests normally include interelectrode shorts and continuity, reverse grid current (gas, grid emission, leakage), cathode current, series-resistance-supplied electrode currents, transconductance, emission or equivalent dynamic characteristic test, noise and microphony.

(2) Holding period

After the schedule of production tests has been completed, it is usual for all valves to be held in storage for periods varying from 24 hours upwards to allow any deterioration of mechanical or electrical characteristics, due to unsatisfactory manufacture, to develop.

(3) Second testing

Following the holding period, all, or the most important production tests are usually repeated either on all valves 100 per cent. or on a representative sample using statistical sampling procedures which have been established as reliable, economical methods of determining either that the maximum percentage of defectives in a given quantity shall not exceed a certain value, or that the average percentage of defectives in the outgoing product shall not exceed a certain level.

When statistical sampling is used, if the product fails to meet the sampling acceptance criteria in one or more tests, or totally, the batch in question is then re-tested 100 per cent. for those tests in which failure occurred, and all defectives screened out. In addition to repeating first-production tests, tests are often included at the second

production-sampling test to control characteristics, 100 per cent. testing of which may not be warranted or necessary.

Subject to the product having passed the design and life test criteria to be described, it is now usually transferred to the warehouse for shipping and distribution to manufacturers and wholesalers.

(B) Design tests

All important secondary characteristics are controlled by regularly testing and recording the characteristics of a relatively small sample selected at random, either from each production batch, or each day's production in the case of continuous production, after all the first-production tests have been performed and the defectives for these tests screened out. The sample size is determined by the production batch size on the daily production level, provided characteristics are reasonably uniform. Typical sample sizes used are 1 per cent. (minimum 5 valves) of each batch, or a fixed sample size of 5 to 10 valves per type per day for types in continuous production.

The tests performed on the characteristics included in this group, on the above basis, are called Design Tests and the usual procedure is that failure of more than a stipulated percentage of the valves in the sample to meet the prescribed test limits for a particular characteristic, or failure of more than a stipulated percentage of all the characteristics to meet their prescribed limits, constitute cause, initially for retesting a larger sample—usually 100 valves—for the characteristic(s) failed, and in the event of the failure being confirmed, for 100 per cent. testing of the complete batch for those characteristics in which failure occurred. Failure of any valve of the batch to meet the specification for the characteristic(s) in question is then cause for rejection.

In the case of continuous production, the usual practice is for the failed design tests to be made production tests temporarily until satisfactory control of the characteristics in question has been re-established and the design test criteria for these characteristics can again be met consistently.

Typical design test acceptance criteria require that not more than 10 per cent. of the valves of the sample fail for any one design test or that all the design tests failed do not exceed 20 per cent.

In addition to essential secondary characteristics, other characteristics which are often controlled on a design test basis include those characteristics which are not independent parameters but have their values determined by characteristics which are tested 100 per cent., also characteristics which require to be controlled for particular applications.

Design tests are performed only on valves which meet the prescribed production tests. To this end, the latter normally are repeated and recorded when design tests are performed.

(C) Recorded readings

Tertiary characteristics are controlled, in general, on the basis of criticism and correction from recorded readings of all important characteristics obtained from the design test samples, taken either daily, weekly or monthly, depending on the importance of the characteristic and its liability to variation.

Failure of characteristics tested on this basis to meet the requirements of the specification (or, where not specified, to meet the average range of variation usually maintained) in respect of the design test criteria is cause for criticism only, and not rejection; individual valves having the characteristics indicated are not screened from the product, unless the effect of their variation on performance is likely to be serious.

Where a recorded reading test indicates continuing unsatisfactory control of any particular characteristic, it is usual for that recorded reading to be made a design test temporarily, if considered warranted, until satisfactory control has been re-established.

(D) Life tests

Due to the varying extent to which the mechanical and electrical characteristics may be affected by undetected and consequently uncontrolled variations of manufacturing processes, it is not possible to predict reliably by any schedule of instantaneous tests,

however comprehensive, the performance obtainable from any particular valve under operating conditions, and it is necessary to rely on recorded observations of characteristic variation during continuous or intermittent operation under controlled test conditions, to determine ultimate performance. Such tests are known as Life Tests.

Provided maximum ratings have not been exceeded, the life of most oxide-coated cathode high vacuum valves, assuming that the initial emission and electrode insulation are satisfactory, is determined almost entirely by the extent to which the initial vacuum is maintained during storage and during periods of operation and non-operation, as in general the supply of emission-producing material available on the average filament or cathode greatly exceeds that required for the lives normally obtained in practice.

The average rate and uniformity of deterioration of the vacuum- and emission-dependent characteristics which normally occur slowly and uniformly in all valves during operation, and which vary from valve to valve, and any excessive deterioration of mechanical and electrical characteristics due to defective manufacture are controlled by regular life tests of small samples of each type. These life tests are operated normally under maximum rating conditions, for a specified period during which the performance determining characteristic(s) may not deteriorate beyond prescribed values, or for the period (which may not be less than a prescribed minimum) required for such deterioration to occur.

Owing to limitations of equipment and cost, regular control life tests are run usually for periods of 500 to 1000 hours on small samples of the order of 5 valves per type per week for types in continuous production. As variations in characteristics are most liable to occur early in life, readings are usually spaced at increasing intervals to give an indication of the complete life characteristic over the control periods.

A typical life test acceptance criterion of satisfactory life is that the average life obtained per valve, considering all valves of the sample, must be not less than 80 per cent. of the specified duration of the life test. The valves used must also be selected at random and comply with the production and design test acceptance criteria.

In the event of the completed product failing to comply with the life test criteria, delivery of the product is then withheld from the warehouse, until satisfactory life has been re-established.

(E) Warehouse tests

When quality is uniform, the controls normally imposed prior to packing are retests of electrode mechanical stability and continuity, and maintenance of the vacuum, by means of a suitable interelectrode hot "shorts and continuity" test during which each valve is tapped lightly with a specified mallet. Each valve is also re-inspected for any deterioration of the envelope in the case of glass valves, cementing of phenolic bases and top caps, dry or badly soldered pin and top cap connections, type designation and general mechanical finish. Pins of miniature valves are also straightened, if necessary.

(iv) Tolerances on characteristics

(a) Initial characteristics

The tolerances on types of American origin to-day are substantially those published for these types in the American JAN-1A Specification which is based on common valve manufacturing practice in that country and was compiled by a committee which included the major valve manufacturers (Ref. S2 ; for tabulated characteristics see Ref. 65).

(b) Life test end points

Apart from the information published in the relevant American and British Service Specifications, no information is generally available concerning accepted life test end points. In R.M.A. Standard Specification ET-107 (Ref. S7) there is published a list of life test end points which may be regarded as typical of the practice followed by American valve manufacturers. A valve is considered to have reached its life test end point when, at rated filament or heater voltage and specified electrode voltages, the following values have been reached :

1. 65% of rated transconductance for r-f and i-f amplifiers.
2. 50% of rated conversion transconductance and 65% of rated oscillator grid current for converter and mixer types.
3. 50% of rated transconductance for general purpose triode types.
4. 50% of rated power output for power output types.
5. 40% of minimum rated direct current for diode types.
6. 80% of rated current or voltage for rectifier types.
7. 70% of normal alternating output voltage for resistance-coupled amplifier types.

Note.—Rated values are those referred to on R.M.A. Electron Tube Characteristic Sheets under maximum typical operating conditions.

(i) General conventions

The methods described in this section are typical of good practice and should only be taken as a guide of good practice. They represent, in general, the main operational tests which are used to control the performance of various types of receiving valves.

The valve under test should have its heater (or filament) operated at the specified voltage for constant voltage types or at the specified current for constant current types. Direct current is generally specified for all characteristic testing, although a.c. may be used for indirectly heated types and directly-heated a.c. power types, but it is essential that the filaments of all directly-heated battery types be operated from direct current.

The positive electrodes (e.g., plate, screen) should be supplied from suitable direct-voltage sources the voltages of which can be adjusted to the values specified. Good regulation (i.e., good voltage stability) is highly desirable for characteristic testing but is expensive to attain with valves drawing high cathode currents. The recommended source is an electronic voltage regulator such as that of Fig. 33.10, the output terminals being shunted by a r-f by-pass capacitor (e.g., 0.01 μ F mica). A large capacitance should not be used since this results in a tendency for the voltage regulator to "hunt". In other cases all supply voltages should be adequately by-passed for a.c. components.

In the case of emission testing, a special low voltage high current source of low internal resistance is essential. Where operation is required from a.c. mains, a selenium rectifier supply is usually the most suitable and inexpensive for high current emission testing.

The negative electrodes (e.g., control grid, suppressor) do not normally draw much current, and the voltage regulation of the current source is therefore not very important, but the voltage applied to the terminals of voltage divider supplies, as normally used, must be well stabilized. Either an electronic voltage regulator or a gas type voltage regulator tube, or both, may be used. If the characteristics are to be tested with the grid positive, the "screen" source may be used for triode grids; otherwise an additional electronic voltage regulator (of the same type as for the plate and screen) should be used. All direct electrode voltages are to be measured with respect to the cathode. In dynamic tests the voltages are to be measured under operating conditions.

In all methods of testing, depending upon the particular characteristic, well filtered supplies both positive and negative should be used.

The basic circuit for testing electrode currents with variable applied voltages is indicated in Fig. 3.1 for use with diode, triode or pentode valves and negative grid

voltages. If instability is experienced with valves having high transconductance, a screen stopper of 50 to 100 ohms with or without a control grid stopper of say 500 ohms should be connected directly to the electrodes concerned. It is very important that these resistors be non-inductive and, in the case of the screen stopper, of sufficient rated dissipation. The screen stopper should be by-passed directly from the supply side to the cathode using a mica capacitor of, say, $0.01 \mu\text{F}$ capacitance.

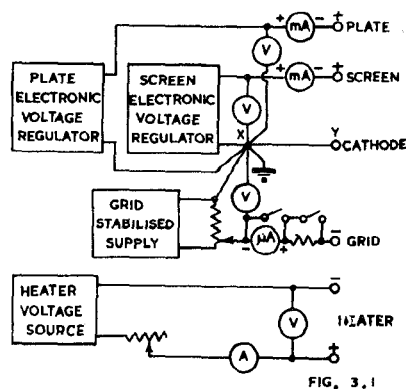

Fig. 3.1. Basic circuit for testing electrode currents.

Pre-heating

Pre-heating with heater voltage applied to the heater only is generally adequate for all ordinary purposes where it is necessary to conserve time, except where full electrode dissipation pre-heating is required by particular valve specifications under acceptance testing conditions, or when testing for reverse grid current (gas, grid emission and hot leakage). When full electrode dissipation is applied, the time of pre-heating is normally 2 minutes (JAN-1A) to 5 minutes (R.M.A.). Maximum valve ratings should not be exceeded during pre-heating.

See References S2, S7.

(ii) General characteristics

(a) **Physical dimensions**—Valves may be checked for overall length and maximum diameter either by the use of “go/not go” gauges or by an adjustable length gauge and outside calipers respectively.

Standard ring gauges for checking maximum and minimum base and sleeve diameters, also pin alignment gauges, are specified by R.M.A. Standard ET-106 (Ref. S6).

(b) **Shorts and continuity**—It is important to ensure that electrodes such as control and signal grids and suppressors, which do not normally dissipate any power, should not be subjected to any appreciable power dissipation during the shorts and continuity test, otherwise the valve may be damaged as the degassing treatment of these grids during manufacture is normally much lighter than that of electrodes which are required to dissipate power. In addition, the cathode current drawn, particularly in filament types, should not be excessive. It is also important that shorts be checked between the various electrode pin connections and pins designated as no connection, also that the continuity of internal jumper connections between base pins be checked.

The circuit arrangement accepted as the most generally satisfactory for both shorts and continuity with regard to sensitivity and speed of testing is that known as the hexaphase shorts and continuity test. This circuit is now widely used, particularly by valve manufacturers (e.g., Ref. 1, Fig. 54). A modification is shown in Fig. 3.2 which uses 6 110 volt $\frac{1}{2}$ watt neon lamps and is entirely satisfactory for valves not requiring more than 6 independent electrodes. The values shown for this circuit have been

chosen to suit the majority of receiving type valves in that the dissipations of the normally negative electrodes are kept low for reasons previously stated—see (b) above—and may not be satisfactory for all valve types. In the case of a semi-universal tester it is essential that the requirements above be observed, and also that all electrode dissipations and peak and average currents be kept within their maximum ratings, otherwise valves may be damaged. **It is also essential as in any shorts tester that the cathode-to-grid voltage, and battery-type filament-to-grid voltage particularly, be kept to a value not exceeding approximately 100 volts,** owing to the small spacing between these electrodes resulting in unreliable “flick” indications of the neon lamps in normally good valves. The test is carried out with the cathode hot, and the resistor R_1 is for the purpose of limiting the peak cathode current to a safe value (3 mA per 50 milliamp. filament strand for 1.4 volt battery valves). The tester uses split anode neon lamps and continuity of each valve electrode is indicated by the glowing of one half of the split-anode neon lamp connected to that electrode. In the case of a short-circuit to cathode, one lamp will light on both electrodes, while in the case of a short-circuit between two or more other electrodes, two or more lamps will so light. There is an optimum arrangement of connections from the terminals A, B, C, D and E to give fairly low voltages between cathode and control grid or other low-dissipation electrodes and to give uniform illumination on all lamps. In some cases, experimenting may be necessary in changing over connections to obtain fairly uniform illumination on all lamps. It is necessary that the insulation of the sockets and wiring be sufficiently good to avoid residual glows on the neon lamps when a valve is not in the socket. This is particularly important in humid climates.

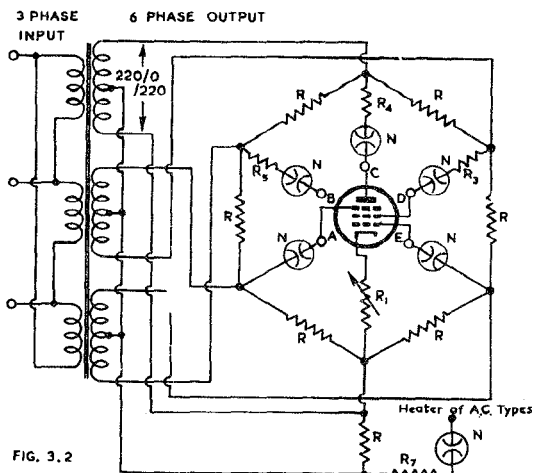

FIG. 3.2

Fig. 3.2. Hexaphase shorts and continuity tester. Suitable values are $R=5000$ ohms, $R_3=R_5=7500$ ohms, $R_1=1500$ ohms, $R_7=5000$ ohms, $R_1=50\,000$ ohms for battery valves other than power output, $33\,000$ ohms for normal a.c. types, or $15\,000$ ohms for power output valves. Lamps (N) are 110 volt $\frac{1}{2}$ watt split-anode neon.

If more than six lamps are required, additional lamps may be incorporated at suitable points in the “ring” network, but all such arrangements have the limitation that one or more conditions exist where no shorts indication is possible on one or more pairs of lamps.

In addition to the neon shorts and continuity test, filament type lamps may be used to indicate continuity from shield to cathode or along a “jumper” linking two pins.

Continuity of heaters and filaments is indicated by means of a current meter of suitable scale in series with the heater or filament, an open-circuit being indicated by

zero current. In the absence of a current meter and where a rheostat is used to drop the filament/heater source voltage, the voltmeter reading may be used to indicate open-circuited filaments or heaters since the voltmeter reading will then be much higher than normal.

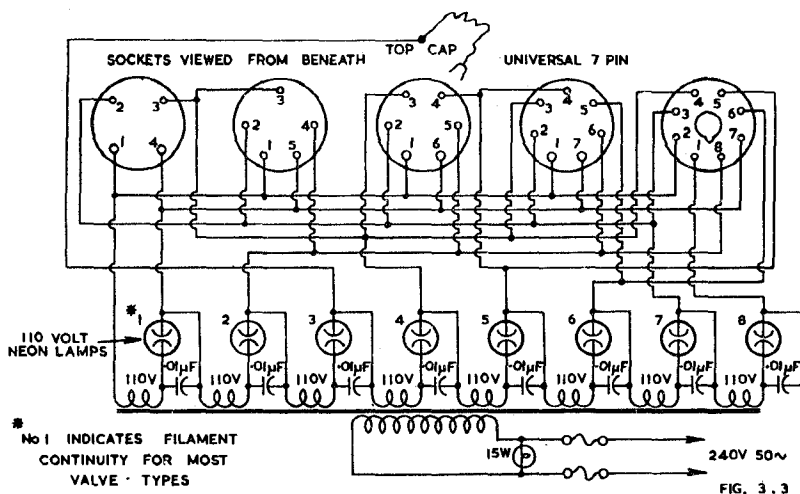

Fig. 3.3. Older type of shorts and continuity tester.

The older type of shorts tester is shown in Fig. 3.3 and operates on single phase and requires a total voltage of 880 volts for 8 lamps. This may be used as a hot or cold cathode shorts tester, but has the disadvantages that it only indicates electrode continuity of those electrodes which draw sufficient current to operate lamps to which they are connected. It also has the severe disadvantage that the voltages cannot be arranged conveniently with regard to the electrode configuration for semi-universal testing, as all voltages are in phase, and quite high voltages may be developed between adjacent electrodes in the absence of complicated switching.

When using this type of tester with either hot or cold filament (or cathode), it is essential to connect grid No. 1 to the lowest voltage in the chain with respect to earth, otherwise damage may be done to the valve, or else good valves may indicate as having a short circuit. The other points in the chain should be connected in the same sequence as the grids and plate.

A fairly satisfactory form of single lamp shorts and continuity tester commonly used in service testers is shown in Fig. 3.4. The electrode switch S is rotated with the cathode heated. If the neon lamp glows on one side only the particular electrode is connected; if on both sides a short-circuit is indicated. If only one electrode indicates short-circuit, the short is to heater (filament); if two or more electrodes indicate a short-circuit, they are shorted together. The continuity test only works well for the electrodes close to the cathode, the sensitivity decreasing towards the anode.

The same circuit Fig. 3.4 may also be used for a cold cathode shorts test.

(c) **Heater (or filament) current**—This is measured with a d.c. heater source, using the heater circuit as in Fig. 3.1. The heater voltmeter current passes through the ammeter A , so that it is necessary for greatest accuracy to subtract the voltmeter

Fig. 3.4. Simpler type of shorts and continuity tester, employing a single lamp.

current from the current reading. However, with a 1000 ohms-per-volt meter, the current is less than 1 mA and the error is quite small with heater currents of the order of 0.3 A. When measuring filament currents of small battery valves (e.g., 50 mA), the ammeter zero may be set to read zero when the voltmeter is at its nominal reading (e.g., 1.4 volts). The current is normally measured with no connections to any other electrodes. See also Ref. S12, Sect. 2.1.

(d) **Heater-to-cathode leakage**—This may be tested by applying the maximum rated direct voltage between one heater terminal and cathode and measuring the current with a microammeter (say 0-500 μ A) with a safety resistance in series (not greater than 100 000 ohms). The leakage current should be not greater than 20 μ A for ordinary 6.3 volt 0.3 ampere valves, or 50 to 100 μ A for power valves, with 100 volts applied.

The heater may be operated with either a.c. or d.c. supply if below 35 volts; at 35 volts and above it is usual to operate it on a.c. supply. The voltage between heater and cathode should be applied with both polarities, except in the case of rectifiers where the heater must be negative with respect to the cathode.

(e) **Inter-electrode insulation**—This is not normally a regular commercial test, except to meet service specifications. The test voltage specified is normally 300 volts for small valves or 500 volts for those which are able to stand the higher voltage. The insulation resistance may be measured by any ordinary type of insulation tester, but preferably by an electronic megohm-meter. In this test, the cathode should always be positive. The test is carried out on a valve which has reached a stable temperature under normal operating conditions. The minimum permissible insulation resistance usually specified is 10 megohms (Ref. S2).

This test is not used between heater and cathode.

(f) **Emission**—The purpose of the emission test is to ensure that the cathode emission is adequate to provide the peak and average space currents for the particular application of the type by a margin which has been found to be satisfactory for good life and performance.

Emission is normally tested by applying a suitable direct positive voltage to all grids connected together with the plate, and measuring the total cathode current.

Because of the very high value of the emission current normally drawn from the cathode, the resulting excessive dissipation of the inner grids and the gas produced as a result of this dissipation and also as a result of ion bombardment of the cathode, the emission test is a damaging test and should be performed as seldom as possible and then always very carefully.

In order to avoid damage to the cathode by this test, the applied voltage must be sufficiently large to approach current saturation without drawing sufficient current to damage the valve due to excessive dissipation of the inner grids. At the same time the test must be of sufficient duration to enable the stability of the emission to be indicated without being so long as to give risk of poisoning the emission. A safe value generally accepted for the duration of the emission test is 3 seconds. During this period the emission should not fall below a value recommended by the valve manufacturer. In general, emission is a minimum reading. As most of the cathode current goes to the No. 1 grid, which is usually wound with very fine wire, and treated lightly during manufacture, the applied voltage must be restricted to a value such that the emission current drawn does not result in damage to the valve. The voltages normally used in manufacture are listed below.

Emission testing with applied alternating voltage is also used, but in this case the test becomes one intermediate between a peak emission test and a high current trans-conductance test. In practice, there is no exact and simple correlation between a.c. and d.c. emission tests due to the fact that the a.c. emission current depends in part on the emission capability of the valve as well as on its geometry. Experience has shown that mains frequency a.c. emission tests tend to be unreliable owing to the fact that the emission "gets a rest" between cycles and, in a practical case, the rating of peak to average emission current drawn cannot be made sufficiently high to be effective.

Voltages given below are based on JAN-1A (Ref. S2); values of voltages and minimum emission currents are given by Ref. 65.

Signal diodes are normally tested for emission with an applied direct voltage of 10 volts, except that 20 volts are normally applied to type 6H6.

Power rectifiers are normally tested with applied voltages as listed below (suffixes of valve types have been omitted) :

20 volts—1V, 12A7, 32L7.

25 volts—84/6Z4, 70L7.

30 volts—5V4, 6ZY5, 7Y4, 12Z3, 25A7, 25Z5, 25Z6, 35Z3, 35Z4, 35Z5, 45Z3, 45Z5, 50Y6, 83V, 117N7, 117Z4, 117Z6.

50 volts—5Z4, 6W5, 6X5, 7Z4, 28Z5.

75 volts—5R4, 5T4, 5U4, 5W4, 5X3, 5X4, 5Y3, 5Y4, 5Z3.

Amplifier valves are normally tested for emission with an applied direct voltage of 30 volts. Some of the exceptions are listed below :

10 volts—1AB5, 6AC7, 6AG5, 7E5, 7F8, 7G8, 7V7, 7W7, 26A7.

15 volts—6BE6.

20 volts—1D8, 1J6, 2A3, 3A8, 6AB7, 6AG7, 6SD7, 6SQ7, 6SH7, 7G7, 7H7, 7J7, 7L7, 7Q7, 7R7, 7S7, 19, 28D7, 35L6, 70L7.

25 volts—117N7.

50 volts—6A6, 6B5, 6L6, 6N6, 6N7, 12A5, 2A4, 53, 59, 79.

All the voltages listed above are subject to variation by different valve manufacturers.

(g) **Direct interelectrode capacitances**—The following information is based on recognised engineering practice by the manufacturers of American-type valves, and is in line with the I.R.E. Standard (Ref. S1, S12), the R.M.A.-NEMA Standard (Ref. S8) and with JAN-1A (Ref. S2).

The capacitances which are measured are direct interelectrode capacitances, and not the total (self) capacitances which are the sum of two or more direct capacitances. The measured value of inter-electrode capacitance of a valve is dependent upon the valve shield or, in the absence of a shield, upon the geometry of the external environment. It is therefore necessary for the test to be made under strictly specified conditions of valve shielding and of electrode and internal valve screen connections.

Published values of interelectrode capacitances are stated either for the condition where the valve is shielded with a specified standard valve shield (see below) or is unshielded. Interelectrode capacitances are normally measured with the cathode cold and with no direct voltage applied to the electrodes. The base pins and leads are shielded from each other and from other elements of the valve so that they and their connections do not form part of the capacitance being measured. All external metal parts integral with the valve should be connected to the cathode ; such parts include lock-in valve bases, metal base shells, and pins with no connection. When capacitance measurements are made on indirectly-heated valves the heater should be connected to the cathode unless in special cases the measurement is between the cathode only and other elements, or the heater and other elements. For valves having elements other than a control grid, a plate, and a cathode, the additional elements of the active section including internal shields should be connected to the filament or cathode by the shortest possible connections. For a multiple-unit valve structure, all elements of the other section(s) should be earthed except when reading inter-section coupling capacitances.

The test sockets should be Standard Capacitance Sockets as specified by R.M.A.-NEMA (Fig. 3.4A). Valves with top caps should be tested with the R.M.A.-NEMA Standard Cap Connectors (Fig. 3.4B).

The connections to be made to the electrodes while testing for interelectrode capacitances are given below :

Input capacitance is tested by measuring the capacitance between grid and cathode, the latter being connected to heater, screen and shields ; the plate is earthed.

Output capacitance is tested by measuring the capacitance between plate and cathode, the latter being connected to heater, screen and shields ; the grid is earthed.

Capacitance from grid to plate for all types of valves is measured with all other electrodes earthed.

In multiple unit valves, the capacitance between the grid of one section and the plate of the other is measured with all other electrodes earthed ; similarly from one plate to the other.

The input capacitance of a diode is measured between its plate and cathode, the latter being connected to heater and shields ; other sections are earthed.

The capacitance between diode-plate and grid or plate of other sections is measured with all other electrodes earthed.

In a converter, the r-f input capacitance is measured between the signal grid and all other electrodes connected together.

The mixer output capacitance is measured between the mixer plate and all other electrodes connected together.

The capacitance from oscillator grid to oscillator plate is measured with all other electrodes earthed.

The oscillator input capacitance is measured between oscillator grid and cathode, the latter being connected to heater and shields ; the oscillator plate and all electrodes of the other section being earthed.

The oscillator output capacitance is measured between oscillator plate and cathode, the latter being connected to heater and shields ; the oscillator grid and all electrodes of the other section being earthed.

The capacitance between oscillator grid and signal grid, or oscillator plate and signal grid, is measured with all other electrodes earthed.

In converters in which there is usually a r-f voltage between cathode and earth (e.g., 6BE6), the oscillator output capacitance is measured between cathode and heater, the latter being connected to screen and shields ; the oscillator grid being earthed.

The oscillator input capacitance is measured between oscillator grid and all other electrodes connected together. The capacitance between oscillator grid and cathode is measured with all other electrodes earthed.

Standard sockets, cap connectors and shields for use in the measurement of valve capacitances (R.M.A.-NEMA, Ref. S8).

(1) Sockets

The construction and shielding of capacitance sockets and leads shall be such that when the holes for the insertion of the base pins are covered with a grounded, flat metal plate, the capacitance between any one socket terminal and all other socket terminals tied together does not exceed $0.000\ 10\ \mu\mu\text{F}$ for receiving valves.

Fig. 3.4A. RMA-NEMA Standard Capacitance Sockets (Ref. S8).

The hole for the accommodation of the locating lug of octal and lock-in bases shall be less than 0.500 inch diameter.

The diameter of holes for the insertion of the base pins (see Fig. 3.4A) shall be limited to the values shown in Table 1. The socket face plate shall be flat and shall have a minimum diameter as shown in Table 1. Any structure above the face plate shall have negligible effect on the capacitance being measured.

A thin insulating film may be permanently attached to the face plates of capacitance sockets to provide insulation for ungrounded shielding members.

The socket shall be so constructed that the base of the valve under test will seat on the face plate.

Table 1.

Base Designation	Max. diameter (A)*	Max. diameter (B)*
Standard 4, 5, 6 or 7-pin	0.250 in.	3 in.
Octal	0.175 in.	3 in.
Lock-in	0.093 in.	3 in.
7-pin miniature	0.075 in.	2½ in.
9-pin miniature	0.075 in.	2½ in.

*see Fig. 3.4A.

(2) Cap connectors.

Standard Cap Connectors shall be made as shown in Fig. 3.4B. A thin insulating film may be placed on surface X in Fig. 3.4B. Dimensions in inches shall be as tabulated below.

Designation	A	B	C
Medium	$\frac{31}{64} \pm \frac{1}{64}$	0.556	0.850
Small	$\frac{29}{64} \pm \frac{1}{64}$	0.352	0.750
Miniature	$\frac{31}{64} \pm \frac{1}{64}$	0.242	0.750

Fig. 3.4B. RMA-NEMA Standard Cap Connectors for use in measurement of valve capacitances (Ref. S8).

(3) Shields.

Standard shields are shown in Fig. 3.4C. It is recommended that these shields be used as indicated below, or as specified by the valve manufacturer.

Shield No.		Max. seated height with top cap	without top cap
308	GT glass types with T9 bulbs*	3	2⅞ in.
309	G glass types with T9 bulbs*	3½	3⅞ in.
311	G glass types with ST12 bulbs*	4⅞	3⅞ in.
312	{ G glass types with ST14 bulbs* G glass types with ST16 bulbs*	4⅞	4⅞ in.
315	Miniature types with T6½ bulbs*	5½	4⅞ in.
316	Miniature types with T5½ bulbs*	—	2⅞ in.

(4) Methods of measuring inter-electrode capacitances are described in the I.R.E. Standard (Ref. S12). The R.M.A.-NEMA Standard (Ref. S8) states that the r-f bridge method (Refs. 77, S8, S12) and the transmission method (Refs. S8, S12) shall be the standard methods of measuring interelectrode capacitances; both methods are described. These measurements are normally made only in valve laboratories.

*The maximum outside diameters of these bulbs are: T9 1-3/16 in.; ST12 1-9/16 in.; ST14 1-13/16 in.; ST16 2-1/16 in.; T5½ 3/4 in.; T6½ 7/8 in.

RMA-NEMA STANDARD SHIELDS FOR USE IN MEASUREMENT OF VALVE CAPACITANCES (Ref. S8)

The significance of interelectrode capacitances and their measurement are covered by many text books and some articles including Refs. 3, 4, 5, 8, 9, 10, 11, 12, 13, 16, 18, 21, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 74, 75, 76, 77.

The special low range capacitance bridge circuit used in the inter-electrode capacitance meter of Ref. 3 is capable of measuring directly the capacitances, with a range from

value, the test will not be so severe since it will reduce the peak plate current and also reduce the output voltage or current.

In view of this limitation, a rectification test which may be used and which should be satisfactory for all practical purposes is to make use of the maximum published conditions with a condenser input filter. These conditions include the maximum r.m.s. applied voltage, the maximum d.c. load current, the minimum plate supply impedance per plate and the maximum filter capacitance for these conditions, if published. In cases where the latter information is not available, it is usually safe to test with the maximum value of filter capacitance used in the published curves or typical operation data, provided that the plate supply impedance per plate is equal to the minimum rated value or to the value used for the curves or typical operation data, whichever is the greater. In all cases it is essential that the maximum peak plate current rating per plate be not exceeded.

The rectification test may be used for the purpose of checking the output voltage and so determining end of life. The circuit constants for the rectification test may be obtained by the following procedure. The value of R_L is given by E_0/I_0 where E_0 and I_0 are the direct voltage and current respectively across the load resistance under maximum ratings. The value of E_0 is obtainable from the usual operational curves published by valve manufacturers, and is the direct voltage for the maximum r.m.s. applied voltage at the maximum value of load current (I_0). If curves are published for more than one value of filter capacitance, the curve corresponding to the highest capacitance should be selected. The rectification test should be carried out with the value of C_L equal to that used for the derivation of E_0 , while the total effective plate supply impedance per plate should be as specified above. Under these conditions an average new valve should give a voltage E_0 and a current I_0 approximately equal to the published values, and individual valves will have values either higher or lower than the average as permitted by the manufacturing tolerances. The end-of-life point is commonly taken as 80 per cent. of the value obtained with a valve having bogie characteristics (R.M.A., Ref. S7).

The rectification test may be carried out either with full-wave rectification as in Fig. 3.5 or with half-wave rectification, each unit being tested separately with half the total average load current. The test is usually performed by inserting a cold valve and waiting until it has attained normal temperature.

In all cases, rectifier valves are required to operate satisfactorily in the rectification test without arcing or sputtering.

Where valve failure has been due to arcing or sputtering, the conditions under which this occurred may be reproduced for the purposes of testing either by

- (1) allowing the valve to heat up to normal temperature from cold, the heater and plate supply voltages being applied simultaneously, or
- (2) operating the valve at normal temperatures with heater and plate voltages applied, and then "keying" the plate voltage.

(b) Sputter and arcing

Sputter and arcing are closely akin. When an indirectly-heated close-spaced rectifier is warming up with plate voltage applied, there is no space charge and the electrostatic field gradient at any sharp peaks on the cathode surface may be high enough to vaporize the coating material and lead to the formation of an arc. Even when there are no sharp points on either cathode or plate, a discharge of gas leading to an arc may occur when there is no space charge, and the peak current required is greater than the available emission. Sputter does not usually occur with directly-heated rectifiers.

Signal diodes may be tested in a rectification test as an alternative or addition to the emission test. Diodes in diode-amplifier valves may be tested as half-wave rectifiers with $R_L=0.25$ megohm, $C_L=2\mu\text{F}$ and an applied voltage of 50 volts r.m.s.

(c) **Back emission**—Back emission is emission from the plate to the cathode during the half-cycle when the cathode is positive with respect to the plate. Any appreciable

amount of back emission results in severe bombardment of the cathode and ultimate plate-to-cathode arcing. Back emission may be tested by the circuit of Fig. 3.6. Switch S_1 is normally closed, and is only opened momentarily while taking a reading. The combined effect of contact potentials and initial electron velocities in the 6X5 and 6H6 rectifiers is to cause a residual current of perhaps 400 μ A to pass through the back emission meter while S_1 is closed. The back emission current is then taken as the increase in the meter reading when S_1 is opened.

(d) **Zero signal or standing diode current**—This is usually read by measuring the current through, say, 0.25 megohm connected between diode plate and cathode with no signal applied; the standing diode current is likely to vary during life. It should be noted that the diode direct plate voltage required to make the plate current just zero should never be positive if loss of detector sensitivity at very low signal levels is to be avoided.

(iv) Specific triode, pentode and beam tetrode characteristics

(A) Reverse grid current

Reverse grid current is the sum of gas current, leakage current and grid (primary) emission current. The test is normally carried out after pre-heating—see Sect. 3(i) above—since this is the condition which obtains under normal operation in equipment. Reverse grid current is measured by inserting a microammeter* in the grid circuit in series with a resistor, with maximum plate and screen voltages and dissipation and maximum cathode current. The circuit used is shown in Fig. 3.1 in which the microammeter is protected by a shorting key which is only opened when the reading is to be taken. The maximum value of the grid circuit resistance during the test as specified by JAN-1A should not exceed 100 000 ohms, although values up to 500 000 ohms are commonly used. The reading is normally taken after the reverse grid current has reached a steady value.

Alternatively, a suitable value of grid resistor (R_c) is connected in the grid circuit, with a switch for short-circuiting the resistor when desired. With the switch closed, the grid and plate voltages are adjusted to the desired values and the plate current is read. The switch is then opened and the grid bias readjusted so that the plate current returns to its former value. The reverse grid current may be computed from

$$I_c = \Delta E_c / R_c \quad (2)$$

where ΔE_c = change in grid voltage to maintain constant plate current.

When the mutual conductance is known (or as an approximation using the nominal value) the reverse grid current may be computed from

$$\text{Grid current in microamperes} = 1000 \Delta I_b / g_m R_c$$

where ΔI_b = change in plate current in milliamps.

g_m = mutual conductance in micromhos

and R_c = resistance of grid resistor in megohms.

Typical values of maximum reverse grid current in new valves, based on American JAN-1A Specifications (Ref. S2).

These values apply to types commonly used in radio receivers. They are only useful as a general guide, since commercial valves may be tested to slightly different specifications

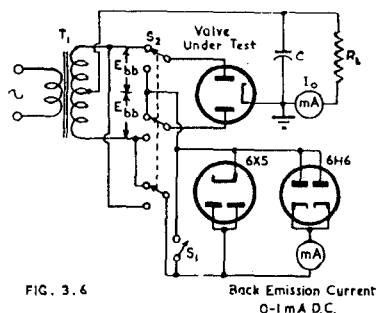

FIG. 3.6

Fig. 3.6. Back emission test.

*Alternatively, an electronic microammeter may be used, incorporating a less sensitive indicating instrument. One possible form uses a 6SN7-GT twin triode, cathode coupled; the maximum resistance in the grid circuit is 50 000 ohms for a 0-3 μ A range. This arrangement has the advantage that the instrument can be made self-protecting so that the indicating meter is not damaged by excessive gas current.

High- μ triode ($\mu < 65$)	0.5 to 0.6 μA
Medium- μ triode	1.0 to 2.0 μA
Twin triode—medium μ	1.0 to 1.5 μA each section
high μ ($\mu > 65$)	0.5 to 1.0 μA each section
R-F pentode	
sharp cut-off (generally)	0.5 to 1.0 μA^*
remote cut-off	1.0 to 2.0 μA
Power output	2.0 to 4.0 μA
Converter	1.0 to 2.0 μA

*Exceptions are: 6AK5 & 713A 0.1 μA , 6AS6 0.2 μA , 6AJ5 0.25 μA , 1231 & 7G7/1232 1.5 μA .

These reverse grid currents apply rigidly only when measured under the specified electrode conditions (for values see Ref. 65, Sec. 14). These are, in general, identical with the published typical operating condition or, if there is more than one, at the typical operating condition having the greatest plate dissipation.

The maximum value of grid current which may be used in any particular application without seriously affecting the performance, is dependent upon the actual value of grid circuit resistance—see Sect. 1(v)d.

(a) **Gas current (ionization current)**—Gas current cannot be readily measured directly†. It may be determined approximately by measuring the total reverse grid current under conditions of maximum dissipation (see above), and then subtracting the hot leakage current and grid emission current under the same conditions.

(b) **Cold and hot leakage**—Leakage currents may be measured with a voltage applied between the grid and each electrode in turn, with the other electrodes floating. Measurements may be made either with the valve cold ("cold leakage"), or immediately after the filament (or heater) has been switched off after testing for reverse grid current ("hot leakage"). The grid to cathode hot leakage current, with the grid biased as for the negative grid current test, may be too small to measure on the microammeter; in this case it may be regarded as zero in deriving the gas current. If any grid emission is present, the procedure will be as indicated in (c) below.

(c) **Grid (primary) emission**—Grid primary emission current may be derived by operating the valve under maximum rated voltages and dissipations for, say, 5 minutes, or until the characteristics have reached stable values, then by increasing the grid bias to the point of plate current cut-off without any other change in electrode voltages, and by measuring the negative grid current at this point. This negative grid current is then the sum of hot leakage and grid emission currents. There is no simple method of distinguishing between real grid emission current and those hot leakage currents which fall during the first few seconds as the valve cools. However, it is generally possible to distinguish hot leakage and grid emission by plotting the cooling curve of the reverse grid current versus time characteristic (this test cannot be applied to valves of the pentagrid type).

Grid current characteristics are described in Chapter 2 Sect. 2(iii).

(d) **Grid secondary emission**—The amount of secondary emission from the grid of a valve cannot be measured directly. Valves of the same type, however, may be compared as to the relative amount of secondary emission present by plotting, or tracing on a C.R.O., the positive grid characteristic. If the amount of secondary grid emission is sufficient for the characteristic to cut the axis, blocking may occur—see Sect. 3(iv)N.

(B) Grid current commencement voltage

The circuit of Fig. 3.1 is used except that the polarity of the grid microammeter is reversed. The grid voltage is then measured for which the grid current is positive and of the smallest value discernible on the microammeter (e.g., 0.2 μA).

(C) Positive grid current

This test applies usually to zero biased r-f pentodes, particularly filament types, to ensure that conduction does not occur during service when low screen voltages are used. The test is normally performed under low screen voltage conditions, with other

†Gas current may be measured by the method which converts the desired ion current to an alternating current by modulation of the ionizing electron stream while leaving undesired stray currents (e.g., leakage) unmodulated. See Ref. 40.

electrode conditions normal. It is a matter of experience that the grid current commencement voltage moves in a negative direction in some filament type pentodes as the screen voltage is reduced.

(D) Positive voltage electrode currents

The currents of the positive electrodes may be measured at the electrode voltages specified under typical (or any other) operating conditions, by using the circuit of Fig. 3.1. The valve may be damaged if it is operated, even momentarily, at electrode currents and dissipations in excess of the maximum ratings.

The electrode currents may tend to drift, particularly when the valve is operated at other than the cathode current at which it has been stabilized. If a series of curves is to be plotted, it is desirable to check one of the earlier readings at intervals during the test, to see whether the valve has drifted.

(E) Transconductance or mutual conductance*

Transconductance may be determined from the slope of a characteristic which has been plotted carefully. An approximation to the grid-plate transconductance, which generally errs on the high side, is to measure the plate current at equal grid-voltage increments on either side of the desired voltage, and to calculate the slope—see Chapter 2 Sect. 2(ii).

Grid-plate transconductance and mutual conductance may be measured by many methods, but the most satisfactory and most generally used laboratory method is the dynamic voltage ratio method developed by Tuttle (Ref. 2).

A simple adaptation which is satisfactory for all practical purposes is described below. In Fig. 3.7 a 1000 c/s generator is connected to a voltage divider and voltages E_2 and E_1 are applied to the plate (through R_s and C_1) and grid respectively of the valve under test. Resistor R_s is then adjusted to give a null point on the indicator. Condenser C_s is provided to balance out reactive currents arising from stray capacitances; the secondary of transformer T_1 should be connected in the direction which allows capacitive balancing.

At balance, the value of mutual conductance is given by

$$g_m = \frac{E_2}{E_1} \cdot \frac{1}{R_s} \quad (3)$$

One convenient form is shown in Fig. 3.7 where E_1 and E_2 are adjustable in steps of 10, while R_s is variable from 5000 minimum to 100 000 ohms maximum.

Range	Grid tap	Plate tap	E_2/E_1	R_s , min. ohms	R_s , max. ohms
1-10 μ mhos	C	B	1/10	10 000	100 000
10-100	B	B	1	10 000	100 000
100-1000	B	C	10	10 000	100 000
1000-20 000	A	C	100	5 000	100 000

Values of the other components may be :

$C_1 = 0.5 \mu\text{F}$, $C_s = 1 \mu\text{F}$, both 400 V working

C_2 = one gang condenser section

T_1 = step up transformer, 1 : 2 turns ratio

T_2 = electrostatically shielded output transformer, with primary resistance not greater than 50 ohms.

The reactances have been selected to give an error in mutual conductance not greater than 1 per cent. in each case.

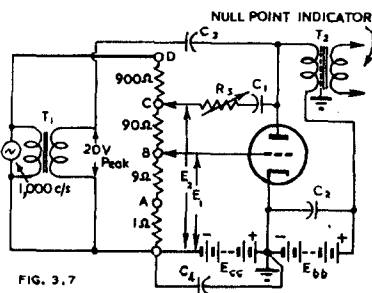

FIG. 3.7

Fig. 3.7. Dynamic voltage-ratio method of measuring mutual conductance (or transconductance).

*For definitions, see Chapter 2 Sect. 1.

Pentodes may be tested if a suitable screen supply is added to Fig. 3.7.

Further information on methods of measuring mutual or transconductance is given by Refs. 2, 15, 16, 17, 18, 21, 22, 59, 78, 79, 80, 81, 82, 83, 84, S12.

(F) Amplification factor

The amplification factor is usually tested by some form of bridge circuit as in Fig. 3.8. This is suitable for measurements of μ up to 1000. Suggested values of components are :

$R_1=10$ ohms, $R_2=90$ ohms, $R_3=900$ ohms, $R_4=10\,000$ ohms max., $L_1=5$ henrys min., $L_2=20$ henrys min. at max. plate current. $C_1=0.5\ \mu\text{F}$, $C_2=0.5\ \mu\text{F}$, C_3 may be two parallel sections of a gang condenser.

Choke L_1 should be of very low resistance, so that the voltage drop caused by any reverse or positive grid current does not affect the point of operation. Transformer T_1 should be electrostatically shielded.

The amplification factor is given by

$$\mu = \frac{R_4}{R}$$

where R =effective total grid resistance in grid arm of voltage divider (i.e., either R_1 or R_1+R_2 or $R_1+R_2+R_3$).

With R_4 adjustable from 1000 to 10 000 ohms, position 1 of S_1 will give a range of μ from 100 to 1000, position 2 from 10 to 100, and position 3 from 1 to 10. A satisfactory value of signal voltage is about 10 volts peak. Too high a value will result in operation over a non-linear portion of the characteristic, while also introducing the possibility of positive grid current with some types of valves operated at low grid bias.

Capacitance currents may be balanced out by adjusting the value of C_3 and by moving switch S_2 to the position giving capacitance balance.

FIG. 3.8

Fig. 3.8. Bridge test for measuring amplification factor.

FIG. 3.9

Fig. 3.9. Method of testing for plate resistance.

The amplification factor test of Fig. 3.8 may be used for pentodes with the addition of a suitable screen supply. For values of amplification factor over 1000 a higher ratio of the plate and grid arms of the bridge is required, that is R_4/R . This will result in some loss in accuracy at the higher values of μ due to capacitance effects.

References to measurement of mu factor and amplification factor : Refs. 2, 15, 16, 17, 18, 21, 22, 78, 79, 80, 81, 82, 84, S12.

(G) Plate resistance

Plate resistance may be measured conveniently by the dynamic voltage ratio method developed by Tuttle (Ref. 2) and an adaptation is shown in Fig. 3.9. The value of plate resistance is given by

$$r_p = \frac{R_1 R_2}{R_3} \quad (4)$$

where R_1 , R_2 and R_3 may have any convenient values of resistance.

One possible combination of resistances is :

Range of r_p	R_1 (fixed) ohms	R_2 (fixed) ohms	R_3 (variable) ohms
1000 to 10 000 ohms	10 000	1000	10 000 to 1000
10 000 to 100 000 ohms	100 000	1000	10 000 to 1000
0.1 to 1.0 megohm	100 000	10 000	10 000 to 1000
1 to 10 megohms*	100 000	100 000	10 000 to 1000

*On this range the accuracy is poor.

This circuit may be used for pentodes with the addition of a screen supply. Under these conditions C_2 should have a minimum capacitance of $1\ \mu\text{F}$ and C_4 a minimum capacitance of $0.1\ \mu\text{F}$ (paper dielectric, 400 V working) for a maximum error of 1% in each case, while choke L_1 should have an inductance of at least 12.5 henrys for a maximum error of 1% (except on the maximum range), for a frequency of 1000 c/s.

On the maximum range, the inductance of L_1 must be at least 125 henrys for a maximum error of 1 per cent., but the plate current through L_1 will normally be only a few milliamperes on this range. Thus two separate chokes will be required if the maximum range is to be used. Transformer T_1 should be electrostatically shielded, and its primary should have a resistance less than 50 ohms. Condenser C_3 is merely a blocking condenser of any convenient value, connected in series with the 1000 c/s source; it does not affect the readings.

Condenser C_3 is for the purpose of balancing out capacitance currents; it may be a single section of a gang condenser.

The combination of mutual conductance, amplification factor and plate resistance into a single unit introduces serious design difficulties and necessitates difficult compromises. A more elaborate combined bridge using Tuttle's method has been marketed by the General Radio Company and the theory is published in Ref. 2.

Plate resistance may also be measured by the well known bridge circuit (e.g., see Refs. 8, 9, 18, 21, 22, S12). The quadrature current may be balanced out by a small capacitor in the arm of the bridge adjacent to the arm containing the unknown.

References to the measurement of plate resistance: Refs. 2, 15, 16, 17, 18, 21, 22, 33, 78, 79, 80, 81, 82, 84.

FIG. 3.10

Fig. 3.10. Method of testing for a.c. amplification (after RMA).

FIG. 3.11

Fig. 3.11. Method for testing for power output.

(H) A.C. amplification

The standard R.M.A. test for a.c. amplification (Ref. S7) is shown in Fig. 3.10. This is applied to audio frequency voltage amplifier pentodes, and to a-f voltage amplifier high-mu triodes. This is a resistance-coupled amplifier test normally performed at zero bias with a 10 megohm grid resistor. The internal impedance of the signal source should not exceed 2500 ohms. The test is made at rated heater or filament voltage and normally with a plate load resistor of 0.5 megohm, and an appropriately by-passed screen resistor in the case of a pentode. In performing this test, it is important to specify whether the output voltage is to be read across the plate load resistor alone (as in the R.M.A. test of Fig. 3.10) or across a capacitively-coupled following grid resistor of specified value. It is also important, if accurate results are to be obtained, that the valve voltmeter used be true r.m.s. reading—that is, one having a square-law characteristic.

(I) Power output

Power output from the plate may be measured under the conditions indicated in Fig. 3.11. The peak value of the sinusoidal voltage E_g applied to the grid is normally

equal to the bias voltage E_{cc} , unless otherwise specified. The signal frequency is preferably either 400 or 1000 c/s, in order to reduce the size of L and C . The impedance of the choke L at the signal frequency should be at least, say, 7 times the impedance of the load, while the reactance of C should be less than, say, one seventh of the load impedance.

The power output meter for approximate and routine testing may be of the rectifier/d.c. meter type. In this case the load resistance will be incorporated in the power output meter as drawn in Fig. 3.11.

For accurate measurements, however, it is essential to measure either the true r.m.s. voltage across, or the current through, a load resistor of specified value and unity power factor. Generally the latter measurement is the more convenient as the current through the load may be measured by means of a thermo-couple ammeter.

The power output of a Class B amplifier may be measured either with push-pull operation or on each section separately. In the latter case the load resistance is one quarter that of the plate-to-plate value for push-pull operation, and the unit not under test is tied to the cathode. The power output from one section, owing to shifting of the loadline, is greater than half the power output with push-pull operation (Ref. 58), but the relationship must be established experimentally in each case. Alternatively, a resistive load may be connected directly in the plate circuit to give a closer approach to normal push-pull operation. The value of the resistance is arranged to be one quarter of the plate-to-plate load resistance with push-pull operation, and the plate supply voltage equal to the specified plate voltage for normal push-pull operation. Under these conditions the power output is given by (Ref. 58) :

$$P_o \approx 2.47 (I_b - 0.25I_{b0})^2 R_L \quad (4a)$$

where P_o = power output from one section, in watts

I_b = direct plate current in amperes, as measured by a d.c. meter

I_{b0} = plate current with no signal, in amperes,

R_L = load resistance per section, in ohms.

The value of I_{b0} may be taken, with sufficient accuracy for many purposes, as the published value.

In all cases with Class B amplifiers the specified value of input voltage is applied to the grid circuit in series with a specified value of resistance. The plate voltage source should have good voltage stability, an electronic voltage regulator being satisfactory. If a plate source impedance is specified, a series resistor of the appropriate value must be inserted in the plate supply circuit.

The relevance of a particular output measured under specified conditions is significant only in relation to the distortion present under those conditions.

(J) Distortion

Distortion in the power output test may be measured by one of several suitable methods, provided that the signal source is truly sinusoidal. The effect of harmonics from the signal source may be reduced by connecting a low-pass filter between the signal source and the grid.

The distortion may be measured by a harmonic analyser, of which several types have been described in the literature. When merely the value of the total harmonic distortion is desired, as in determining the undistorted output, those analysers which measure the root-mean-square value of all harmonics present are preferable to those which measure the separate harmonics.

The method of Suits (Ref. 85) is a particularly good example of the type of analyser which measures the harmonics separately. The Suits method requires only the simplest apparatus, and where laboratory facilities are limited this advantage may outweigh the disadvantages involved in the computation of the total harmonic distortion.

The Belfils analyser (Refs. 86, 87) utilizes an alternating-current Wheatstone-bridge balance for the suppression of the fundamental, and is particularly useful for direct measurement of the total harmonic distortion. For maximum convenience, the frequency of the audio-frequency source should be very stable. This instrument can be operated so that it is direct reading, by maintaining a constant input voltage.

In the McCurdy-Blye analyser (Ref. 88), low- and high-pass filters are used to separate the harmonics from the fundamental. This instrument is superior to the Belfils type in that the frequency of the source may vary somewhat without necessitating readjustment.

A differential analyser especially designed for power-output work has been described by Ballantine and Cobb (Ref. 89).

If an iron-cored choke is employed for shunt feed in the plate circuit (Fig. 3.11), care should be exercised in its selection or design to avoid the generation of harmonics in it due to the non-linear and hysteretic behaviour of the iron.

For measurement of distortion see Chapter 14 Sects. 2, 3; Chapter 37 Sect. 3.

(K) Microphony

There is no published standard test for microphony outside of Service or manufacturers' specifications. However an indication of the microphony of valves may be obtained using the same conditions as the R.M.A. standard audio frequency noise test (see below). It is reasonable to adjust the amplifier gain to be of the same order as the gain of the subsequent portion of the amplifier in which the valve is to operate. Nevertheless, valves unless specifically designed for low-level high-gain pre-amplifier use, should not be expected to be non-microphonic and free from noise at low levels when tested under such conditions.

In radio receiver factories the valves are usually tested in the chassis in which they are to operate, the set being tuned to a signal generator with internal modulation, and the volume control set at maximum. Any microphonic sounds which quickly die away are not considered as cause for removal of the valve, but a sustained howl is so considered. Such a valve may not be microphonic in another position in the chassis or in another model of receiver. Actions to be taken to reduce microphony have been described in Chapter 35 Sect. 3(iv). Notwithstanding the considerations above, all valves cannot be expected to be non-microphonic when placed directly in the acoustic field of, and close to, the loudspeaker in a receiver, particularly in small cabinets.

Ref. S2.

(L) Audio frequency noise

The R.M.A. standard for audio frequency noise test is with normal voltages applied to all electrodes, and the plate of the valve under test is coupled to the input of an amplifier with a frequency range of 100 to 2000 c/s (± 5 db of response at 400 c/s). A dynamic loudspeaker with a rating of at least 2.5 watts is connected to the output of the amplifier. The minimum external grid resistance is 100 000 ohms. The gain of the amplifier and the plate load resistance of the valve under test are to be as specified. The valve under test may be tapped lightly with a felt or cork mallet weighing not over $\frac{1}{2}$ ounce. Any objectionable noise heard in the loudspeaker, is cause for rejection (Ref. S7). See also Ref. S2.

(M) Radio frequency noise

The R.M.A. standard test for radio frequency noise is for normal voltages applied to all electrodes of the valve under test; the plate is coupled to the input of a r-f amplifier (of a radio receiver) at a frequency within the range of 50 to 1600 Kc/s. The minimum band-width is to be 5 Kc/s at 10 times signal. The audio frequency response is to be within ± 5 db of the response at 400 c/s over the frequency range from 100 to 2000 c/s. A suitable tuned transformer giving a resonant impedance of 50 000 to 200 000 ohms is to be used to couple the valve under test to the amplifier. The external grid circuit impedance of the valve under test is to be from 5000 to 25 000 ohms. Other conditions of test are as for the audio frequency noise test (Ref. S7). See also Ref. S2.

(N) Blocking

Tests on grid blocking are normally applied only to certain types subject to this characteristic. A valve may be tested for blocking by either of two methods. In the first method a high positive grid voltage (say 100 volts) is applied instantaneously with normal electrode voltages and the maximum value of grid resistance. The plate current should return to its initial value on the removal of the applied voltage.

The second method ("cross-over") is to apply a gradually increasing positive grid voltage with substantially zero grid circuit resistance, and to plot the grid current characteristic for positive values of grid voltage up to the point at which the grid current changes from positive to negative ("cross-over" point). See Chapter 2 Sect. 2(iii).

(O) Stage gain testing

A circuit such as that shown in Fig. 3.11A can be used to measure the gain of a r-f pentode operating under typical i-f amplifier conditions. Stage gain testing has the advantage of evaluating at the one time and under operating conditions at the appropriate frequency the effects of all valve characteristics which influence gain, such as mutual conductance, output impedance, input resistance, reverse grid current and even the effect of high screen or plate currents in increasing control grid bias or decreasing screen grid voltages

Fig. 3.11A. Method of testing for i-f stage gain.

In Fig. 3.11A the input and output circuits are typical high-impedance i-f transformers with secondary tuning of the first and primary tuning of the second, adjustable from the front panel of the tester to allow accurate alignment with varying capacitances in the valves under test. The 1 megohm resistor represents the plate impedance of a preceding converter stage and the 0.25 megohm resistor simulates the impedance of a diode detector. Screen and bias resistors are designed to give the required voltages with a valve of bogie characteristics, and the high impedance in the control grid circuit allows the effect of reverse grid current to be evaluated.

The output meter is calibrated to show stage gain in db for a given input at 455 Kc/s and limits are marked on the scale at a suitable number of db above and below the stage gain of a bogie valve.

(P) Electrode dissipation

The dissipation of an electrode is determined by subtracting the power output from that electrode—see Sect. 3(iv)I—from the d.c. power input to that electrode. Where the power output from an electrode is zero, the electrode dissipation is then equal to the d.c. power input.

(v) Specific converter characteristics

(A) Methods of operation including oscillator excitation

A converter valve essentially includes two sections, an oscillator and a mixer, which may be either separate units supplied by independent cathode streams as in a triode-hexode or combined to use a single cathode stream as in the pentagrid types. The characteristics of a converter depend both on the electrode voltages of the mixer and oscillator and on the excitation of the mixer by the oscillator.

For purposes of testing, the oscillator may be either self-excited or driven by an external source of alternating voltage of suitable amplitude; alternatively a limited range of characteristics may be determined under purely static conditions with direct voltages only applied to the electrodes. In general, the latter is not recommended for routine testing outside of valve factories, owing to the practical difficulties of correlating characteristics with published characteristics obtained under oscillating conditions.

(1) Oscillator self-excited

This is the normal method of operation in most radio receivers, and although it has much to commend it as a simultaneous test of both mixer and oscillator sections, the

oscillator circuit characteristics require to be specified exactly and closely controlled in order to obtain consistent results. For general service testing, less critical methods are therefore to be preferred. This method of testing, with a self-excited oscillator, requires a completely specified oscillator coil, particularly as regards the resonant impedances presented by the circuit to the valve which, together with the electrode voltages, determine the peak and average plate currents of the various electrodes. In practice, it is usually convenient to standardize the circuit by using a valve having specified characteristics under particular conditions (transconductance, amplification factor, plate current) and adjusting the resonant impedance of the tuned circuit by means of the shunting resistor to give a prescribed grid current.

The oscillator frequency is usually either an audio frequency or 1 Mc/s, the latter being more typical of normal operation

(2) Oscillator driven

This is a fairly commonly used test, because it has less dependence of the mixer on the oscillator characteristics. It suffers from the disadvantage, however, that inasmuch as the driving voltage is applied to the oscillator grid, it does not provide a satisfactory test of oscillator characteristics. With this method of testing, if grid current is regarded as a criterion of oscillator characteristics, the oscillator emission needs to be adequate only to supply the rectified current resulting from the excitation but may be quite inadequate to supply the high peak oscillator plate currents which may occur in normal operation, the values of which depend upon the impedance in the oscillator plate circuit.

For this reason, it is generally more satisfactory in service testing to use the driven method with prescribed excitation to test the mixer characteristics and to test the oscillator by means of either a transconductance test at a high plate current or a prescribed self-excited oscillator circuit test which calls for a reasonably high peak plate current, with rectified grid current as the criterion. In the latter case provided the oscillator circuit characteristics, that is the resonant impedances presented to the valve, are precisely specified the test is not critical as regards grid current.

(3) Static operation

With this method of testing, static voltages are applied to all electrodes and the electrode currents are measured.

(B) Specific characteristics

(a) Reverse signal grid current

This test is performed under the same general conditions as for triodes and pentodes, except that the method of operation may be with the oscillator self-excited, or with the oscillator driven, or with static operation.

(b) Signal grid current commencement

In general this test may be performed as for triodes and pentodes, except that the oscillator may be either self-excited or driven.

(c) Mixer positive voltage electrode currents

These may be measured, in general, as for triodes and pentodes, except that the oscillator may be either self-excited or driven.

(d) Mixer conversion transconductance*

Mixer conversion transconductance is determined from measurements of the magnitude of a beat-frequency component, $(f_1 - f_2)$ or $(f_1 + f_2)$, of the output current, and the magnitude of the input voltage of frequency f_1 where f_2 is the oscillator frequency. The method of measurement which has been standardized by JAN-1A (Ref. S2) and R.M.A. (Ref. S7), and which uses a driven oscillator, is to apply voltages of identical phase and frequency—usually mains frequency for convenience—to the specified electrodes (that is the signal and oscillator grids) with provision for a phase reversal of 180° of one with respect to the other. The change in direct plate current due to the phase reversal represents the difference-frequency plate-current component.

*Also referred to as conversion conductance. Mixer conversion transconductance is defined as the quotient of the magnitude of a single beat-frequency component $(f_1 - f_2)$ or $(f_1 + f_2)$ of the output electrode current by the magnitude of the control-electrode voltage of frequency f_1 , under the conditions that all direct electrode voltages and the magnitude of the electrode alternating voltage f_2 remain constant and that no impedances at the frequencies f_1 or f_2 are present in the output circuit, and that the magnitude of the signal voltage f_1 is very small.

This value divided by twice the peak value of the sinusoidal voltage applied to the signal input electrode is taken as the mixer conversion transconductance. Specified voltages are applied to the valve electrodes under specified circuit conditions and the oscillator excitation voltage is adjusted to the specified value or to give the specified oscillator grid current. Other methods of testing are acceptable if correlated with this method.

The relationship may be expressed in the form

$$g_c = \frac{I_{b1} - I_{b2}}{2E_{1m}} \quad (4b)$$

where g_c = conversion conductance in mhos

I_{b1} = plate current for the in-phase condition of signal and oscillator voltages
 E_1 and E_2 in amperes

I_{b2} = plate current for the out-of-phase condition of E_1 and E_2 , in amperes
 and E_{1m} = peak value of the signal voltage.

It should be clearly understood that the value of conversion transconductance measured by this method is dependent on the signal grid voltage and on the curvature of the mixer characteristics and consequently only approaches a true "differential" transconductance at the point of operation, as distinct from an average value, if the signal grid voltage amplitude is sufficiently small. In most cases, if the signal grid voltage does not exceed say 25 mV, exact correlation can be obtained for all types. At higher values, up to 100 mV, the error may be acceptable, depending upon the type and the condition of operation.

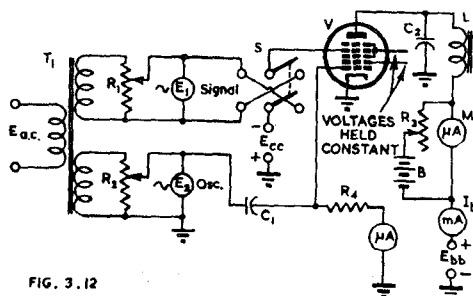

FIG. 3.12

Fig. 3.12. Phase reversal method of measuring conversion transconductance.

The circuit is shown in Fig. 3.12 in which one double-wound transformer, T_1 , with two secondary windings provides the signal and oscillator voltages, which are controlled by means of potentiometers R_1 and R_2 . A switch S permits phase reversal of the signal voltage. The grid coupling capacitor C_1 and grid resistor R_3 are provided, with a meter to measure oscillator grid current through R_4 . In the plate circuit of the valve under test there is a by-pass capacitor C_2 and iron-cored choke L to pass the direct current I_b from the plate voltage source E_{bb} . The increase in plate current is measured by the low resistance microammeter M after the standing current I_{b2} has been "bucked out" by the bucking battery B and rheostat R_5 which should have a minimum resistance at least 100 times that of the microammeter.

In order to obtain exact results, as indicated previously, very small signal voltages are required, which produce only small incremental readings of plate current and demand stabilized electrode voltage sources. In any particular case, the signal voltage may be increased until the error due to the large signal voltage becomes measurable, and tests should then be carried out at a somewhat lower signal voltage.

If a signal voltage of $1/2\sqrt{2}$ volt (0.5 volt peak) is used, the incremental plate current in milliamps then reads conversion transconductance in milliamps per volt. It seems that values of transconductance frequently quoted in published data are obtained using the above-mentioned value of signal voltage, as in many cases the true conversion transconductance under the conditions published differs from this value. As a result,

it is frequently difficult to calculate the exact performance of converter stages from published data of the converter used.

The shape of the curve of conversion transconductance plotted against oscillator grid current is very much influenced by the signal voltage used in the tests. The actual operating conversion transconductance in a practical case is a function of the input signal level.

The phase-shift method of testing conversion transconductance is the only **absolute** experimental method of measuring this characteristic, and accurate results can be obtained provided all electrode voltages, including signal and oscillator excitation voltages, are well stabilized, the electrode supply voltages free from hum, the excitation voltages sinusoidal, of low frequency and correct phase and the signal grid voltage sufficiently small.

Side-band method

The side-band method of measuring conversion transconductance is shown by the circuit of Fig. 3.13. The oscillator may be either self-excited at any convenient frequency, say 1 Mc/s as in Fig. 3.13, or may be driven. A signal voltage E_1 at audio frequency (say 1000 c/s) is applied to the control grid. The oscillator is adjusted to give the required grid current through the specified grid resistor R_2 . In the plate circuit there is a resonant circuit $L_1 C_1$, tuned to the oscillator frequency and shunted by a resistance R_1 , the value of which should be as low as possible and which should not exceed 10 000 ohms.

Fig. 3.13. Side-band method of measuring conversion transconductance.

The voltage across the resonant circuit comprising the oscillator frequency, the signal frequency and the two resulting sidebands are applied to a radio frequency amplifier followed by a diode detector across whose diode load is connected a valve voltmeter to indicate the amplitude of the audio frequency components. If an r-f amplifier is not used, the region of non-linearity of the diode characteristic results in the calibration of the system being dependent on the voltage developed across the tuned circuit and would thus be unsatisfactory for valves of low conversion conductance. However, the r-f amplifier may be omitted provided the signal applied to the diode is sufficiently high to ensure linear rectification. Where this is not so, the simplified circuit may not be suitable for measurements of low values of conversion conductance.

If the r-f amplifier is omitted, the signal voltage E_1 may be about 0.5 volt peak, and R_1 may be 10 000 ohms.

The tester must be calibrated against the standard phase reversal method and the circuit may be adjusted so that the meter is direct reading.

(c) Mixer plate resistance

This may be measured either with a self-excited or driven oscillator, the value of plate resistance being not affected by the method used. Measurement of plate resistance is performed as for a pentode, except for the excitation of the oscillator.

(f) Mixer transconductance

This may be measured as for a pentode valve, except that the oscillator should be either self-excited or driven.

(g) Oscillator grid current

The oscillator performance of a converter valve depends upon several valve and circuit parameters that are not simply defined.

The oscillator grid current may be used as the criterion of oscillator performance in a self-excited oscillator, operating under specified conditions. The circuit should be designed to draw typical peak and average total space currents. The Boonton Converter Oscillator test circuit is widely used to check oscillator performance, owing to its simplicity of design and ease of adjustment and control and, while not giving an exact criterion of oscillator performance, does provide a dynamic test of the usual parameters under conditions that simulate average receiver operation.

FIG. 3.14

Fig. 3.14. Self-excited oscillator, using the Hartley circuit, for testing oscillator performance.

The circuit (Fig. 3.14) is a series-fed Hartley having a fixed feedback ratio and having the tank circuit impedance variable so that the magnitude of oscillation may be adjusted. Normal voltages are applied to all electrodes.

It is necessary to specify the oscillator plate voltage, oscillator plate series resistor (if used), oscillator grid resistor (R_g) the inductance of each section of the coil (L_1 , L_2), the mutual inductance between the two sections (M), the capacitance shunted across the whole coil (C), the grid coupling capacitance (C_g), and the resonant impedance of the tuned circuit (R_d). Normally a coil having a higher reactance than the specified value of resonant impedance is used and is shunted by a variable resistance (R_1) to give the specified resonant impedance. Bias is obtained by means of a capacitor and a wire-wound gridleak. The wire-wound grid resistor is used because it has considerably higher impedance to radio frequencies than to direct current. The high radio-frequency impedance diminishes the shunting effect of the gridleak on the tuned circuit. The rectified grid current is read on a microammeter (suitably by-passed) in series with the grid resistor. Before the test oscillator is used, the relationship between the tuned impedance of the tank circuit and the setting of the variable resistor must be determined.

The R.M.A. standard (Ref. S7) and JAN-1A (Ref. S2, sheet dated 19 July, 1944) specify the component and coil design values as being: $C=100\ \mu\text{F}$ (mica); $C_g=200\ \mu\text{F}$ (mica); $R_1=50\ 000$ ohms potentiometer; $R_g=50\ 000$ ohms wire-wound resistor; $L_1=83\ \mu\text{H}$; $L_2=48\ \mu\text{H}$; $M=23.3\ \mu\text{H}$; coil diameter=1.25 in.; winding length=59/64 in.; wire No. 30 a.w.g. enamelled copper; turns=83; tap at 33 turns from anode end. See also Ref. S12.

The constants quoted above have been selected to simulate average circuit conditions in broadcast receivers for composite converters having transconductances less than $1500\ \mu\text{mhos}$ at zero bias. For valves having higher transconductances or for circuits above broadcast frequencies, the circuit with the constants given may not be satisfactory, as spurious oscillations may make it impossible to obtain correlation between test readings and receiver performance.

The ability of a valve to oscillate when the shunt impedance of a tank circuit is low is one criterion of the value of a valve as an oscillator. The oscillation test is made by applying the desired electrode potentials to the valve under test and reading the rectified grid current at some known setting of tank-circuit impedance. A valve that will not oscillate with the tank-circuit impedance below about 9000 ohms is considered to be a weak oscillator. A valve that will oscillate with a tank-circuit impedance as low as 3000 ohms is considered to be a strong oscillator. The minimum tuned impedance at which oscillation will start or cease as indicated by the rectified grid current will depend on the oscillator characteristics of the particular type and will vary from type to type.

(h) Oscillator plate current

The oscillator plate current may be read while the valve is being tested for grid current as a self-excited oscillator, or alternatively at zero grid voltage and specified plate voltage (usually 100 volts).

(i) Oscillator transconductance

The oscillator transconductance is usually measured at zero grid voltage and specified plate voltage (usually 100 volts).

(j) Oscillator amplification factor

The oscillator amplification factor is measured as for any triode, usually with a plate voltage of 100 volts and zero grid voltage.

(k) Oscillator plate resistance

The oscillator plate resistance is measured as for any triode, usually with a plate voltage of 100 volts and zero grid voltage.

(l) Signal grid blocking

Signal grid blocking may be treated as for the general case of grid blocking in Sect. 3(iv)N.

(m) Microphony

The general remarks in Sect. 3(iv)K regarding microphony apply also to converters.

(n) R-F noise

Converters may be tested for r-f noise under published electrode voltage and typical receiver circuit conditions, following the relevant recommendations of the R.M.A. r-f noise test—see Sect. 3(iv)M.

(vi) Tests for special characteristics

The following tests are not normally applied to receiving type valves and the undermentioned information is provided to assist designers in obtaining data of these characteristics for particular purposes.

(A) Short-circuit input admittance (y_{11})

At frequencies up to 10 Mc/s it is possible to use conventional bridge methods for the measurement of the four admittances, but at higher frequencies some version of the susceptance-variation or resistance-substitution method is necessary.

FIG. 3.15

Fig. 3.15. Semi-schematic diagram of equipment for measuring admittances by the susceptance-variation method (Ref. S12).

T is the 4 terminal transducer to be measured, Y_1 and Y_2 are calibrated variable-admittance elements which may be of various forms, such as coils or capacitors. V_1 and V_2 are signal-frequency voltage-measuring devices; these may be simply crystal or diode voltmeters or heterodyne receivers. Variable admittances Y_{c1} and Y_{c2} are used for coupling the input or output circuits to the signal oscillators.

(1) Susceptance-variation method of measurement (Refs. 51, S12)

In this method, the circuit is detuned with either the capacitor or the inductor adjustment to a point giving half the power output observed at resonance. The increment in susceptance, determined from the capacitance calibration curves, is then equal to the circuit conductance. In practice, the mean value obtained by using the half-power points on each side of resonance is used.

Using the circuit of Fig. 3.15 (Ref. S12)—

(a) Short-circuit the output terminals 2-2. This may be done either by detuning Y_2 sufficiently or by placing a suitable by-pass capacitor directly across terminals 2-2.

(b) Excite the input circuit by coupling the signal oscillator loosely through Y_{c1} to Y_1 .

(c) Adjust Y_1 for resonance as indicated by a maximum reading of V_1 . In order to insure that the coupling to the oscillator is sufficiently small, reduce the coupling until further reduction does not change the setting of Y_1 for resonance. Record the calibrated values of G_1 and B_1 for this setting.

(d) Vary Y_1 on either side of resonance until the voltage V_1 is reduced by a factor $1/\sqrt{2}$. Record the calibrated values of this total variation of Y_1 between half-power points as ΔG_1 and ΔB_1 . In order to insure that the oscillator and detector are not loading the circuit, reduce the coupling until further reduction does not change the susceptance variation ΔB_1 . The short-circuit input susceptance is then given by the relation

$$B_{11} = -B_1 \quad (5)$$

and the short-circuit input conductance by the relation

$$y_{11} = \frac{1}{2} \Delta B_1 [(1 + 2\eta^2)^{\frac{1}{2}} + \eta] - G_1 \quad (6)$$

$$\text{or } y_{11} \approx \frac{1}{2} \Delta B_1 [1 + \eta + \eta^2] - G_1 \quad (7)$$

or even further by the relation

$$y_{11} \approx \frac{1}{2} \Delta B_1 - G_1 \quad (8)$$

if η is negligible.

FIG. 3.16

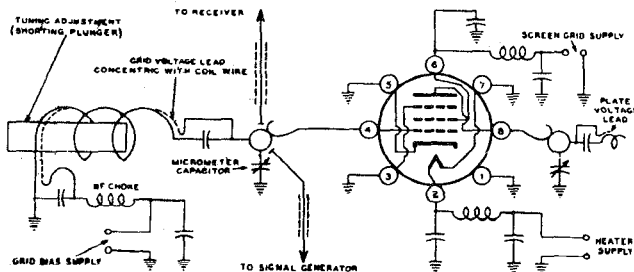

Fig. 3.16. Circuit diagram of equipment used for measurement of short-circuit input admittance (Ref. 51).

A practical form (Ref. 51) for the frequency range 50 to 150 Mc/s is shown in Figs 3.16 and 3.17. The valve under test is used as a part of a resonant circuit which includes a continuously-variable inductor and a small concentric-cylinder capacitor built on a micrometer head. The high-potential end of the inductor is connected to the high-potential electrode of the micrometer capacitor inside a cylindrical cavity open at the top. Fig. 3.17 also shows the positions of some of the by-pass capacitors used with the octal socket. These are button-type, silver-mica capacitors of approximately 500 $\mu\mu\text{F}$ capacitance. The socket is of the moulded phenolic type. Terminals 1, 3, 5 and 7 are connected directly to the mounting plate at a point directly below the terminal in each instance. Terminals 2 (heater) and 6 (screen grid) are by-passed to ground, and a lead is brought from each of these terminals through the mounting plate to a small r-f choke and a second by-pass capacitor. Terminal 8 (plate) is by-passed and fitted with a spring contacting the terminal for one of the circuits. Terminal 4 (grid) has only the contact spring. A similar arrangement is used with miniature valves. In this case, the socket is of the wafer type with mica-filled rubber insulation. Terminals 2, 3 and 7 are grounded and terminals 4, 5 and 6 are by-passed to ground. Terminals 1 (grid) and 5 (plate) have contact springs. The by-pass capacitors are closer to the mounting plate than in the case of the octal socket; the capacitors at terminals 4 and 6 overlap the capacitor to terminal 5. A 10 ohm resistor, mounted inside a cylindrical shield to minimize lead inductance, is connected between socket terminal 5 (plate) and the by-pass capacitor. This component was added to suppress a parasitic oscillation observed with certain type 6AK5 valves. The resistor was found to have no

FIG. 3.17

Fig. 3.17. Physical arrangement of circuit elements of Fig. 3.16 (Ref. 51).

measurable effect on input admittance readings obtained with valves, either of the 6AK5 type or of other types, not subject to the parasitic oscillation.

In order to obtain susceptance values, the circuit must first be calibrated for the capacitance required for resonance at each test frequency. The circuit is calibrated by determining the inductor settings for resonance with each of a number of small, disc-shaped, calibrating capacitors substituted for the valve. The insert in the lower left corner of Fig. 3.17 shows a cutaway view of the cavity with one of the calibrating capacitors in place. The length of the phosphor-bronze contact spring used with the calibrating capacitors is approximately the same as that used with the valve. Thus, the inductance of this lead is accounted for in the calibrating procedure. The reference terminals for the valve are the socket plate and the grid terminal of the socket or, possibly, a point on the grid terminal a little inside the body of the socket. The calculated inductance of the contact spring is 4.5 milli-microhenries per centimeter of length within about ± 25 per cent., but the difference in effective lengths of the springs for the socket connection and the calibrating connection is not more than 2 or 3 millimeters.

The range of the micrometer capacitor is sufficient for measurements of the circuit with the calibrating capacitors, with most cold valves, and with some valves under operating conditions. For other cases, adjustment of the inductor is required.

If the conductance being measured is small enough to be measured by the available range of the micrometer capacitor, the susceptance and conductance variations between $1/\sqrt{2}$ voltage points are given by

$$\Delta B = \omega \Delta C$$

$$\text{and } \Delta G = 0$$

where ω is the angular frequency of measurement and ΔC is the micrometer capacitance variation between the half-power points.

The calibration curves used at each test frequency are :

- (1) Capacitance for resonance
- (2) Slope of the capacitance curve
- (3) Conductance at resonance of the circuit with the calibrating capacitors.

These three quantities are plotted against the inductor adjustment readings. Since the conductance values for the calibrating capacitors themselves are too small to affect the calibration appreciably, the conductance curve corresponds, essentially, to the equipment.

(2) Resistance-substitution method of measurement

The resistance-substitution method applies only to the measurement of the conductive component of the admittance. The susceptive component must be measured by means of a calibrated susceptance element, as for the susceptance-variation method of measurement. Ideally, the resistance-substitution method involves, in the case of a two-terminal admittance, the removal of the electron-tube transducer from the calibrated admittance element and its replacement by a standard pure resistance of such a value that the voltage reading between the two terminals is the same as that obtained with the transducer in place. The calibrated susceptance element must be adjusted to resonance both before and after substitution of the resistance. If the measurement is of Y_{11} , the following relations are obtained :

$$B_{11} = -B_1 \quad (9)$$

as in (1) above, and

$$G_{11} = 1/R \quad (10)$$

where R is the standard resistance of a value that satisfies (10).

There are practical difficulties in obtaining standard resistors having negligible reactance at frequencies of the order of 100 Mc/s or higher. Wire-wound resistors are not usable at such frequencies. The most satisfactory types available are the metallized-glass or ceramic-rod resistors of relatively small physical size, having low-inductance terminals and very little distributed capacitance. A further difficulty arises from the fact that such resistors are obtainable only in discrete values of resistance. It would not be practicable to obtain the very large number of resistors needed to match the resistance of any electron-tube transducer. Hence, it is necessary to utilize a transformation property of the admittance-measuring equipment in order to match any arbitrary admittance with some one of a reasonably small set of standard resistors. A suitable resistance-substitution set consists of a transmission line of length l short-circuited at one end, having a characteristic admittance Y_0 and a propagation constant γ . If a known admittance Y is placed across the line at a distance x from the short-circuited end, the admittance Y_t at the open end of the line is given by the relation

$$Y_t = Y \left[\frac{\sinh \gamma x}{\sinh \gamma l} \right]^2 \left[\frac{1}{1 + \frac{Y \sinh \gamma x}{Y_0 \sinh \gamma l} \sinh \gamma (l-x)} \right] \quad (11)$$

Conversely, the admittance Y_t is the admittance that would have to be placed at the open end of the line to produce the same effect there as the known admittance Y at the position x . Equation (11) then represents the property of the transmission line of converting admittance Y at position x into admittance Y_t at position l . This expression can be simplified for a low-loss line having a characteristic admittance Y_0 large compared with the bridging admittance Y . Thus if $Y_0 \gg Y$,

$$\left| \frac{Y \sinh \gamma x}{Y_0 \sinh \gamma l} \sinh \gamma (l-x) \right| \ll 1, \quad (12)$$

and the real part of the propagation constant γ of the line is small,

$$\left[\frac{\sinh \gamma x}{\sinh \gamma l} \right]^2 \approx \left[\frac{\sinh \beta x}{\sinh \beta l} \right]^2 \quad (13)$$

where $\beta = 2\pi/\lambda$ Equation (11) then simplifies to

$$Y_t = Y \left[\frac{\sin \beta x}{\sin \beta l} \right]^2 \quad (14)$$

If Y is a pure conductance of value $1/R$, then Y_t is the pure conductance

$$G_T = \frac{1}{R} \left[\frac{\sin \beta x}{\sin \beta l} \right]^2 \quad (15)$$

In the measurement of the short-circuit input admittance Y_{11} , a low-loss transmission line of large characteristic admittance is coupled loosely to an oscillator near the short-circuited end. At the open end are a voltage-detecting device and a calibrated capacitor, by means of which B_{11} is obtained from (9). With the unknown transducer across the open end and the capacitor adjusted to obtain resonance, a voltage reading

is taken. The transducer is removed and one of the standard resistors placed across the line bridging the two conductors. The position of this resistor along the line is then adjusted and the system is readjusted for resonance with the calibrated capacitor until the voltage, as measured at the end of the line, is the same as before. By (15) we have

$$G_{11} = G_T = \frac{1}{R} \left[\frac{\sin \beta x}{\sin \beta l} \right]^2 \quad (16)$$

where R is the resistance of the standard placed x centimeters from the short-circuited end of the line. It is evident that a resistor must be selected having a resistance value near to but not larger than the reciprocal of G_{11} .

Since the transmission line should have low loss and low characteristic impedance, a coaxial line is desirable. The line will require a longitudinal opening or slot in order to permit one of the standard resistors to bridge the line at an adjustable position to satisfy the required voltage condition. A valve voltmeter is capacitively coupled to the open end of the line across which the electron-tube transducer may be attached. Socket and filter arrangements for wire-lead valves can be attached to this line. Radiation difficulties arising from the longitudinal opening in the line, together with the increasing difficulty in obtaining resistance standards at frequencies much above 300 Mc/s, appear to make this type of measuring equipment impracticable for measurements at higher frequencies on surface-lead valves. Ref. S12.

(B) Short-circuit feedback admittance (y_{12})

Susceptance-variation method of measurement

See (A)1 above for general description.

(a) With the input termination still set at the value for resonance obtained in step (c) in (A) above, excite the output circuit through Y_{C2} . In the event that oscillation difficulties are encountered, detune the output circuit Y_2 or load it until oscillation stops.

(b) Record the voltmeter readings V_1 and V_2 .

The magnitude of the feedback admittance is then given by the relation

$$|y_{12}| = \frac{|V_1|}{|V_2|} \frac{\Delta B_1}{2} \left[(1 + 2\eta^2)^{1/2} + \eta \right] \quad (17)$$

$$\text{or} \quad |y_{12}| \approx \frac{|V_1|}{|V_2|} \frac{\Delta B_1}{2} \left[1 + \eta + \eta^2 \right] \quad (18)$$

$$\text{or} \quad |y_{12}| \approx \frac{\Delta B_1 |V_1|}{2 |V_2|} \quad (19)$$

where ΔG_1 and ΔB_1 are the values obtained in the preceding measurement of y_{11} .

Ref. S12.

(C) Short-circuit output admittance (y_{22})

The short-circuit output admittance may be measured by following the procedure outlined for the short-circuit input admittance, the signal being coupled through Y_{C2} . If the subscripts 1 and 2 are interchanged, all of the above formulae concerning y_{11} may be used to relate y_{22} to the measured data.

Ref. S12.

(D) Short-circuit forward admittance (y_{21})

The magnitude of the forward admittance may be measured by following the procedure outlined previously for the measurement of the magnitude of y_{12} . If the subscripts 1 and 2 are interchanged, all of the formulae concerning y_{12} may be used to relate y_{21} to the measured data.

Ref. S12.

(E) Perveance

(1) Perveance of a diode

The perveance of a diode may be derived by plotting the current against the three-halves power of the voltage, when the slope of the curve will give the value of G . Voltages should be chosen sufficiently high so that such effects as those produced by

contact potential and initial electron velocity are unimportant. If this is not possible, a correction voltage ϵ should be added to the diode voltage, where

$$\epsilon = (3/2)I_b r_b - e_b$$

where r_b = anode resistance of diode.

Ref. S12.

(2) Perveance of a triode

The perveance of a triode may be derived as for a diode where the diode anode voltage is taken as the composite controlling voltage

$$e' = \frac{e_c + (e_b/\mu)}{1 + (1/\mu)} \quad (20)$$

Multi-grid valves may be considered, with sufficient accuracy for most purposes, as triodes with the screen grid as the anode and the screen grid voltage as the anode voltage.

Low voltage correction—The effects of initial electron velocity and contact potential may be represented by an internal correction voltage ϵ that is added to the composite controlling voltage, where

$$\epsilon = \frac{3I_b \mu}{2g_m(\mu + 1)} - \frac{\mu e_c + e_b}{\mu + 1} \quad (21)$$

The value of g_m to be used is that obtained with all the electrodes except the cathode and control grid tied together to form an anode which is held at the voltage ordinarily used for the screen grid.

Ref. S12.

(vii) Characteristics by pulse methods—point by point

The characteristics of valves in the region where electrode dissipations or currents exceed safe values may be obtained by pulse methods, in which the valve is allowed to pass current only for short intervals of such duration and recurrence frequency that it is not damaged.

FIG. 3.18

Fig. 3.18. Circuit for measuring electrode currents using single pulse generator method (I = peak-reading current indicator, E = peak-reading voltage indicator, V = moving coil voltmeter). If high accuracy is required, correction should be made for the voltage drop across the current indicators. The regulation of the electrode supplies is not important for point by point testing, provided that the shunt capacitors are sufficiently large.

(a) Single generator method

The valve is operated with the desired screen and plate voltages, but with the grid biased beyond cut-off, in the absence of pulses (Fig. 3.18). If secondary emission effects produce a negative impedance, the pulse generator must be shunted by a non-inductive load resistor of such value as to maintain an overall positive impedance at its terminals.

Refs. 38, S12.

(b) Multiple generator method

With this method, no direct voltages are applied but each electrode has its own pulse generator, all generators having their pulses synchronized. This method is not commonly employed with receiving type valves. Refs. 68, 72, S12.

References to characteristics by pulse methods : Refs. 38, 68, 72, 93, S12.

(c) Pulse generators

Pulse generators are of several types. In the capacitor discharge type a condenser is switched from charge to discharge through the valve under test. If there is no series impedance, the peak voltage applied to the valve is equal to the charging voltage. However, because of the very short duration of the pulse, an accurate current indicator is difficult to design.

Refs. 68, 69, S12.

A rectangular pulse shape is obtainable from a direct supply source in series with a high-vacuum triode (or several in parallel) whose grid is normally biased beyond cut-off. A rectangular control pulse, obtainable from a conventional source, is applied in the grid circuit to permit the triode to conduct only during the duration of the pulse. (Ref. S12). Alternatively an ignitron may be used (Ref. 38).

A half sine-wave, or portion of a half sine-wave, pulse is obtainable from an alternating source with gas triode or other control to provide the desired gap between pulses. Alternatively a d.c. source may be used with a gas triode and LC network. Ref. S12.

(d) Peak-reading voltage and current indicators

The input circuit must have a time constant that is large with respect to the time interval between successive pulses. The greatest accuracy is obtained with a rectangular waveform, good accuracy may be obtained from a half sine-wave, while the sharply peaked capacitor discharge method is the least accurate.

A peak-reading voltage indicator may be employed to indicate peak current by using it to measure the peak voltage drop across a non-inductive resistor of known resistance.

One form of indicator is a diode type valve voltmeter with a high resistance load shunted by a large capacitance. The use of this indicator for current-measuring purposes may result in serious errors if the electrode characteristic of the valve under test exhibits any negative slope.

A cathode ray oscillograph may be used directly to measure peak voltage, or peak voltage drop across a non-inductive resistor of known resistance, provided that there is no negative slope in the electrode characteristics. If negative slope is likely to occur, a linear horizontal sweep voltage, synchronised to the pulse generator frequency, may be used to spread out the current trace. In this manner the detection of possible errors is simplified. The vertical deflection corresponding to the maximum horizontal deflection is the one required ; for characteristics having only positive slopes, this vertical deflection will also be the maximum.

Amplifiers may be used provided that they are designed with sufficient bandwidth and sufficiently linear phase-frequency response for the high-frequency components of the pulse. The attenuator should be capacitively balanced, making the ratio of capacitance to resistance of all sections alike.

Reference to peak-reading indicators : Ref. S12.

(viii) Characteristics by curve tracer methods

A characteristic curve may be traced on the screen of a C.R. tube, using a suitable type of pulse generator for one electrode and fixed voltages for the other electrodes. The simplest characteristic for this purpose is the grid voltage versus plate current characteristic, either with zero plate load resistance or with a specified load resistor ("dynamic" characteristic).

A triangular or half sine-wave pulse generator characteristic is satisfactory. The grid is normally biased beyond cut-off, but is swung over the useful range of voltages by the pulse.

The plate voltage versus plate current characteristic may be traced by maintaining the grid (and screen, if any) at constant voltage and by applying the pulse voltage to the plate. This requires a peak voltage of several hundred volts for receiving valves, together with high peak currents. The grid voltage must be maintained constant, the regulation requirements being severe. The regulation requirements of the other electrodes are not important, if large capacitors are used.

A method of showing the two axes for any single characteristic is described in Ref. 73 which makes use of a standard vibrator.

References to curve tracer methods : 37, 39, 69, 70, 71, 72.

Display of valve characteristics

If it is desired to view a family of curves, the voltage of one electrode must be changed in steps for successive pulses. This may be accomplished by means of synchronous contactors (Refs. 34, 35, 36) or by electronic means (Ref. 39). Good regulation (high stability) for the electrode voltage supplies is very important.

See also Refs. 37, 90, 94, 96, S12.

SECTION 4 : ACCEPTANCE TESTING

(i) *Relevant characteristics* (ii) *Valve specifications* (iii) *Testing procedure.*

(i) Relevant characteristics

The relevant characteristics for acceptance testing are those characteristics that are subject to deterioration subsequent to manufacture, it being assumed that the valves have satisfactorily passed the valve manufacturing test specification. These relevant characteristics for acceptance testing may be divided into mechanical and electrical characteristics.

Mechanical characteristics that require checking for faults include loose bases and top caps, dry joints in connections, cracks in envelopes caused by glass strain, damage resulting from inherent strain or careless handling, damage to internal structure resulting in misalignment of electrodes, shorts and open circuits, loss of vacuum, noise and microphony from excessive handling causing damage to the mount and micas.

Electrical characteristics that require checking for faults include gas, a relevant dynamic test, emission and noise.

(ii) Valve specifications

The most widely known of the official specifications are those of the British (K1001) and American (JAN-1A) authorities covering types used in their respective areas.

(iii) Testing procedure

The testing procedure in each case is as laid down in the prescribed specifications. Where, however, valves do not require to be accepted to a prescribed specification, it is satisfactory to adopt the following procedure :

(a) Visually inspect all valves 100 per cent. for mechanical defects.

(b) Test all valves 100 per cent. for shorts and open circuits.

(c) Select at random from all the valves a representative sample (or samples) and test for a suitable dynamic characteristic using established statistical acceptance procedure. The test selected should give a satisfactory indication of the overall performance of the type in its normal application.

References to sampling inspection : Refs. 42, 43, 44.

SECTION 5: SERVICE TESTING AND SERVICE TESTER PRACTICE*

- (i) Purpose and scope of service testing and discussion of associated problems.
- (ii) Fundamental characteristics which should be tested.
- (iii) Types of commercial testers.
- (iv) Methods of testing characteristics in commercial service testers
 - (a) Shorts testing
 - (b) Continuity testing
 - (c) Heater to cathode leakage
 - (d) Emission testing
 - (e) Mutual conductance testing
 - (f) Plate conductance testing
 - (g) Reverse grid current testing
 - (h) Power output testing
 - (i) Conversion conductance testing
 - (j) Oscillator mutual conductance testing
 - (k) Noise testing
 - (l) A.C. amplification testing.
- (v) A.C. versus d.c. electrode voltages in testers.
- (vi) Pre-heating.
- (vii) Testing procedure.

(i) Purpose and scope of service testing and discussion of associated problems

Service testing is only carried out on valves which have previously been factory tested and which have also operated satisfactorily in a new receiver. The faults to be expected are those which may occur after manufacture.

Service testing is for the purpose of determining either

- (1) whether or not a valve in working condition has reached the point in life when it should be replaced, or
- (2) whether a valve with unknown history is faulty or not.

The determination of the point of life when a valve should be replaced is a very complex problem. This is a function of the application of the valve and of the standard of performance expected by the user. For example, a valve which still operates reasonably well as a resistance-coupled amplifier may yet give low gain as an r-f amplifier, and a valve which will still operate as an amplifier may fail to oscillate when used in the oscillator position. A receiver with old valves in the r-f and i-f stages may have very much less gain than it would have with new valves, but the effect may not be noticed by the user unless the set is used for the reception of weak signals.

A list of the generally accepted life test end-points is given in Sect. 2(iv)b.

The radio service-man is usually called upon to test a number of valves, frequently the whole valve complement of a receiver, to determine which (if any) is faulty. If one is obviously faulty, for example due to a short-circuit, open-circuit, gas, or extremely low emission, the problem is simple. In other cases it is helpful to test the valves in the original receiver, with a second complement of new valves for comparison, to make certain that the receiver itself is not faulty. If the original receiver is not accessible, the valves may be plugged into another receiver (preferably of the same model) for test.

Microphony should be checked in the original receiver. Motor-boating may be due to gas or grid emission, but it may also be caused by a faulty component in the receiver. Distortion is generally due to the power valve, but may also be caused by a defective filter by-pass capacitance in the receiver and in some cases by the signal diode or a defective resistor. Hum is usually caused by heater-to-cathode leakage or breakdown in the valve or a faulty filter capacitor in the circuit.

*The assistance of A. H. Wardale, Member I.R.E. (U.S.A.) and D. H. Connolly, A.S.T.C. is acknowledged.

(ii) Fundamental characteristics which should be tested

The fundamental characteristics which should be capable of being tested in a service tester are

(a) Shorts and continuity.

Testing for short circuits is essential.

Testing for continuity of the electrodes is highly desirable.

(b) Dynamic tests.

The dynamic tests which should be carried out in a service tester are :

Class of valve	Preferred test	Less desirable alternative
Rectifier (power diode)	Emission	Rectification test
Signal diode	Emission	—
Triode, low μ	Mutual conductance	—
Triode, high μ	A.C. amplification	—
Pentode, r-f	Mutual conductance	—
Pentode, battery a-f	A.C. amplification	—
Pentode, power	Power output	—
Converter	Conversion conductance	Mixer g_m
	Oscillator grid current	Oscillator g_m

See Sect. 3 for methods of testing these characteristics.

The dynamic test should be one in which the peaks and average plate currents approximate to the maximum current in normal operation.

(c) Other tests

Other tests which should be carried out in a service tester are :

Gas (amplifier types only).

Noise (amplifier types only).

Heater to cathode leakage (indirectly-heated types only).

(iii) Types of commercial testers

Commercial service testers are necessarily a compromise. They must be fairly simple to use, flexible with regard to future valve developments, as free as possible from damage to indicating instruments through faulty valves or misuse, speedy in operation and true in their indications.

The possible combinations of characteristics tested are :

Type of valve	Essential tests	Desirable tests
All	Shorts	Continuity Heater to cathode leakage
Vacuum types	At least one dynamic test	{ Emission Mutual conductance A.C. amplification Power output
	or for converters	{ Conversion conductance or Mixer g_m and Oscillator g_m
	together with	Noise Gas

Out of a representative group of 22 modern service testers examined, 17 incorporated some form of mutual conductance test, 7 incorporated an emission test other than for diodes and all 22 incorporated a diode emission test. One provided a plate conductance test. With regard to the remaining tests, 8 incorporated a heater to cathode leakage test, with 7 having a gas test and 7 having a noise test.

It seems to be generally admitted that an emission test alone is not a very satisfactory dynamic test for all amplifying valves. The better types of testers have both mutual conductance and diode emission ; they are deficient in that they do not provide a power output test for power valves, or a.c. amplification for high- μ triodes and a-f

pentodes. The method of testing for mutual conductance with a high grid swing is not the equivalent of a power output test. Neither mutual conductance nor emission testing is a satisfactory substitute for a.c. amplification testing of high- μ triodes or a-f pentodes.

It is obvious, therefore, that any ordinary commercial service tester does not give a true indication of the condition of all types of valves, and its readings should be used with discretion.

(iv) Methods of testing characteristics in commercial service testers

(a) Shorts testing

Testing for shorts should be carried out at mains frequency or on d.c., and the voltage applied to the neon lamp circuit should not exceed 110 volts r.m.s. The use of higher voltages results in some good valves being classed as filament-to-grid short circuits.

With a.c. supply, it is usual to design the circuit so that resistances over 0.5 megohm do not indicate as shorts; this is to avoid capacitance effects. With d.c. supplies there is no similar limitation, but different models vary considerably in their shorts testing sensitivity.

The most satisfactory switching arrangement is one which tests for shorts from any pin to all other pins tied together. The circuit of Fig. 3.4 may be used, except that the cathode need not be heated.

(b) Continuity testing

Continuity testing may be carried out in a manner closely resembling shorts testing, but with the cathode hot. Positive or alternating voltage is applied through the neon lamp to each electrode in turn; a glow indicates continuity.

The circuit of Fig. 3.4 may be used in a simple service tester, but a more elaborate tester such as the hexaphase (Fig. 3.2) is much more satisfactory for general use.

For further information on continuity testing see Sect. 3(ii)b.

(c) Heater to cathode leakage

The maximum leakage resistance from heater to cathode in new valves varies from 1 or 2 megohms for power valves to 5 megohms for ordinary 6.3 volt 0.3 ampere voltage amplifier valves and even higher for rectifier types having separate heaters and cathodes. A neon lamp will normally glow slightly when used in a shorts tester and applied between heater and cathode. A neon lamp may be de-sensitized either by shunting by a resistor (of the order of 0.1 to 0.5 megohm) or by a mica condenser (a value of 0.01 μ F gives a sensitivity of about 5 megohms—this is only useful with a.c. supply).

(d) Emission testing

Of the 7 commercial testers which included emission testing of amplifying valves, 5 used a.c. testing, 1 used half-wave rectified a.c. testing, and 1 used d.c. testing. Owing to the poor regulation obtainable from most service valve testers with d.c. supplies, other than batteries, it is doubtful whether this has any practical advantages over a.c. testing. With a.c. supply, the voltage in most service testers is 30 volts r.m.s.; this is only a compromise which is far from the optimum for all cases. For laboratory testing of emission see Sect. 3(ii)f.

(e) Mutual conductance testing

Of the 17 commercial testers having a mutual conductance test, 7 used some form of a.c. signal voltage applied to the control grid, and 6 used some grid shift method, the methods used by the other 4 being unknown.

All the American mutual conductance testers examined apply an a.c. signal to the grid, and measure the signal current in the plate circuit; all but one of these use a mains frequency signal, the exception being one with a 5 Kc/s signal and a tuned signal plate current meter.

In most cases this is not an accurate g_m test for all types of valves because the signal voltage on the grid is fairly high—between 4 and 5 volts r.m.s. in some cases—sufficient to run beyond grid cut-off in one direction and well on to the “flat top” in the other,

with short grid-base valves. Even those testers with reduced signal voltages have quite appreciable errors with some types of valves.

On the other hand, all but one of the examined English mutual conductance testers use a grid shift method. This introduces some errors due to plate supply regulation and curvature of the characteristics, but these can be allowed for in the calibration.

(f) Plate conductance testing

This is used by one American tester only as a reasonably close equivalent of the mutual conductance test, the amplification factor being assumed to be constant. Pentodes are triode-connected. A moderately high signal voltage is applied, this being possible with less error than with direct g_m measurement owing to the slight compensating change of μ with plate current.

(g) Reverse grid current testing

Of the post-war testers examined, all those of English design incorporate reverse grid current testing (often referred to as "gas testing") but this test was incorporated in only two of American design. The usual methods of testing are either by grid current meter or by a shorted grid resistor. For further details see Sect. 3(iv)A.

A valve which passes the reverse grid current test on a service tester may not operate satisfactorily in a receiver. The usable maximum value of negative grid current depends upon the application, the mutual conductance of the valve, the resistance in the grid circuit, the type of bias, the bias voltages, the total dissipation of the valve and its ventilation. The valve may be checked in the actual receiver after running for a period sufficiently long for the valve to reach its stable operating temperature; it may be tested by variation in the plate current of the valve under test when its grid resistor is shorted.

(h) Power output testing

This is not incorporated into any of the commercial service testers examined, but is the most satisfactory test for all power valves. Triode testing of pentode and beam power valves is quite satisfactory. Methods of testing are described in Sect. 3(iv)I.

(i) Conversion conductance

Only one of the testers examined provided a test for conversion conductance, the method being by phase reversal. For further details see Sect. 3(v)Bd.

A satisfactory alternative is to measure the transconductance of the mixer, this being the method commonly employed.

(j) Oscillator mutual conductance

None of the testers provided a test for oscillator grid current under self-oscillating conditions, although this is the most satisfactory form of test. For details see Sect. 3(v)Bg.

The method commonly employed is to measure the oscillator mutual conductance.

The measurement of oscillator grid current in a suitable receiver is a simple way of checking the oscillator section of a converter.

(k) Noise

The usual form of noise test is to connect the two neon lamp terminals to the aerial and earth terminals of a receiver, during the shorts test. For other forms of noise test see Sect. 3(iv)L and M.

(l) A.C. amplification

This test should be carried out with zero bias and a high value of grid resistor, as described in Sect. 3(iv)H. No test with fixed or self-bias is able to determine how a valve will operate with grid resistor bias.

(v) A.C. versus d.c. electrode voltages in testers

All but four of the commercial testers examined, which made provision for some form of g_m test, used d.c. electrode supplies. The general trend seems to be in the direction of using d.c. supply to all electrodes, and the additional circuit complications appear to be justified.

For comparison between laboratory testing of emission by a.c. or d.c. methods, see Sect. 3(ii)f.

(vi) Pre-heating

When more than one valve is to be tested, a pre-heating socket should be provided to save time. If not incorporated into the tester itself, the pre-heater may be a separate unit with one of each type of socket and a filament voltage switch and transformer. No voltages need normally be applied to the other electrodes except in cases when the valve is initially satisfactory but becomes defective during operation.

(vii) Testing procedure

Always test for shorts before carrying out any other test. When testing for emission, allow ample time for the valve to heat thoroughly before pressing the emission switch ; then press only long enough to give a reading. Do not leave the valve for more than three seconds on the emission test as otherwise the valve may be permanently damaged. The reading may be regarded as satisfactory provided that it is not below the limit and that it does not fall rapidly to the limit in the three second period.

When testing for mutual conductance, the switch may be pressed for any desired length of time, as no damage will be done to the valve provided that the valve is operated within its maximum ratings.

If a valve is gassy, the readings of emission and mutual conductance will be affected (usually increased for a slight amount of gas and decreased by excessive gas). If a valve is both gassy and of low emission, the true fault is " gas ".

If a valve indicates " no emission " while the heater is continuous, the fault may be excessive gas, air in the bulb, cathode coating " poisoned " by gas, or open-circuited cathode. Air in the bulb is indicated by a continuous heater, a cathode not visibly red, and a bulb which gradually becomes warm.

SECTION 1 : CURRENT AND VOLTAGE

(i) *Direct current* (ii) *Alternating current* (iii) *Indications of polarity and current flow.*

(i) Direct current

We speak of the flow of an electric current in more or less the same way that we speak of the flow of water, but we should remember that the conventional direction of current is opposite to the actual flow of electrons. In most electrical circuit theory however, it is sufficient to consider only the conventional direction of current flow. In Fig. 4.1 there is a battery connected to a load ; the current flows from the positive (+) terminal, through the load, to the negative (−) terminal, and then through the battery to the positive terminal.

FIG. 4-1

Fig. 4.1. Flow of current with battery and load.

Batteries (or cells) may be connected in series as in Fig. 4.2 and the total voltage is then equal to the sum of the voltages of the individual batteries (or cells). When calculating the voltage of any intermediate point with respect to (say) the negative terminal, count the number of cells passed through from the negative terminal to the tapping point, and multiply by the voltage per cell. When batteries are connected in series, each has to supply the full load current.

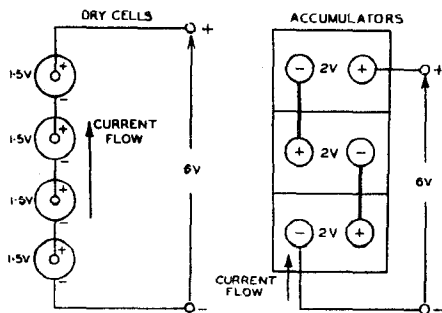

FIG. 4.2

Fig. 4.2. Cells in series.

Batteries (or cells) are occasionally connected in parallel as in Fig. 4.3. In this case the terminal voltage is the same as the voltage per battery (or cell). The current does not necessarily divide uniformly between the cells, unless these all have identical voltages and internal resistances.

Direct current may also be obtained from a d.c. generator, or from rectified and filtered a.c. supply. In all such cases there is a certain degree of ripple or hum which prevents it from being pure

d.c.; when the a.c. component is appreciable, the supply may be spoken of as "d.c. with superimposed ripple (or hum)" and must be treated as having the characteristics of both d.c. and a.c. When we speak of d.c. in a theoretical treatise, it is intended to imply pure, steady d.c.

(ii) Alternating current

The ordinary form of d.c. generator actually generates a.c., which is converted to d.c. by the commutator. If a loop of wire is rotated about its axis in a uniform magnetic field, an alternating voltage is generated across its terminals. Thus a.c. is just as fundamental as d.c. The usual power-house generates 3 phase a.c., but in radio receivers we are only concerned with one of these phases. A "sine wave" alternating current is illustrated in Fig. 4.4, where the vertical scale may represent voltage or current, and the horizontal scale represents time.* A cycle is the alternation from A to E, or from B to F, or from C to G.

FIG. 4.3

Fig. 4.3. Cells in parallel.

FIG. 4.4

Fig. 4.4. Form of sine-wave alternating current.

Most power supplies have frequencies of either 50 or 60 cycles per second (c/s). The period is the time taken by one cycle, which is $1/50$ or $1/60$ second, in these two cases.

*For mathematical treatment of periodic phenomena see Chapter 6 Sect. 4.

The precise shape of the wave is very important, and the sine wave has been adopted as the standard a.c. **waveform**, since this is the only one which always has the current waveform of the same shape as the voltage, when applied to a resistance, inductance or capacitance.† In practice we have to deal with various waveforms, some of which may be considered as imperfect ("distorted") sine waves, while others are of special shapes such as square waves, saw-tooth, or pulse types, or rectified sine waves. However, when we speak of a.c. in any theoretical treatise, it is intended to imply a distortionless sine wave. Other waveforms may be resolved by Fourier Analysis into a fundamental sine wave and a number of harmonic frequency sine waves, the latter having frequencies which are multiples of the fundamental frequency. This subject is treated mathematically in Chapter 6 Sect. 8.

When deriving the characteristics of any circuit, amplifier or network, it is usual to assume the application of a pure sine-wave voltage to the input terminals, then to calculate the currents and voltages in the circuit. In the case of a valve amplifier (or any other non-linear component) the distortion may be either calculated, or measured at the output terminals. If the device is to operate with a special input waveform (e.g. square wave), it is usual to resolve this into its fundamental and harmonic frequencies, and then to calculate the performance with the lowest (fundamental) frequency, an approximate middle** frequency, and the highest harmonic frequency—all these being sine waves.

(iii) Indications of polarity and current flow

In circuit diagrams the polarity of any battery or other d.c. voltage source is usually indicated by + and - signs; alternatively it may be indicated by an arrow, the head of the arrow indicating positive potential (e.g. Fig. 4.2). A similar convention may be used for the voltage between any points in the circuit (e.g. Fig. 4.14A). The direction of d.c. current flow is indicated by an arrow.

In the case of a.c. circuits a similar convention may be used, except that an arbitrary instantaneous condition is represented (Fig. 4.18A).

SECTION 2 : RESISTANCE

(i) *Ohm's Law for d.c.* (ii) *Ohm's Law for a.c.* (iii) *Resistances in series* (iv) *Resistances in parallel* (v) *Conductance in resistive circuits.*

(i) Ohm's Law for direct current

All substances offer some obstruction to the flow of electric current. Ohm's Law states that the current which flows is proportional to the applied voltage, in accordance with the equation

$$I = E/R \quad (1)$$

where R is the total resistance of the circuit. For example in Fig. 4.5 an ideal battery, having zero internal resistance, and giving a constant voltage E under all conditions, is connected across a resistance R . The current which flows is given by eqn. (1) above, provided that

I is expressed in amperes,

E is expressed in volts,

and R is expressed in ohms.*

Ohm's Law may also be arranged, for convenience, in the alternative forms

$$E = IR \quad (2)$$

$$\text{and } R = E/I \quad (3)$$

FIG. 4.5

Fig. 4.5. Circuit illustrating Ohm's Law for d.c.

†A sinewave has its derivative and integral of the same form as itself.

**Preferably the geometrical mean frequency which is given by $\sqrt{f_1 f_2}$ where f_1 and f_2 are the lowest and highest frequencies.

*It is assumed that the resistance remains constant under the conditions of operation. For other cases see Sect. 7(i).

In a circuit containing more than one battery (or other source of direct voltage), the effective voltage is determined by adding together those voltages which are in the same direction as the current, and subtracting any opposing voltages.

Ohm's Law also holds for any single resistor or combination of resistances. The voltage drop across any resistance R_1 , no matter what the external circuit may be, is given by

$$\text{Voltage drop} = IR_1 \quad (4)$$

where I is the current flowing through R_1 .

(ii) Ohm's Law for alternating current

Ohm's Law holds also for alternating voltages and currents, except that in this case the voltage (E) and the current (I) must be expressed in their **effective** or **root-mean-square** values of volts and amperes.

(iii) Resistances in series

When two or more resistors are connected so that the current through one is compelled to flow through the others, they are said to be in series, and the total resistance is the sum of their individual resistances. For example, in Fig. 4.6 the total resistance of the circuit is given by

$$R = R_1 + R_2 + R_3 \quad (5)$$

and the current is given by

$$I = E/R = E/(R_1 + R_2 + R_3).$$

It is interesting to note that R_1 , R_2 and R_3 form a **voltage divider**, across the battery E . Using eqn. (4):

$$\text{voltage drop across } R_1 = IR_1 = [R_1/(R_1 + R_2 + R_3)] \times E$$

$$\text{voltage drop across } R_2 = IR_2 = [R_2/(R_1 + R_2 + R_3)] \times E$$

$$\text{voltage drop across } R_3 = IR_3 = [R_3/(R_1 + R_2 + R_3)] \times E$$

$$\begin{aligned} \text{total voltage drop} &= IR_1 + IR_2 + IR_3 \\ &= I(R_1 + R_2 + R_3) = E. \end{aligned}$$

For example, if $E = 6$ volts, $R_1 = 10$ ohms, $R_2 = 10$ ohms and $R_3 = 10$ ohms, then

$$\begin{aligned} I &= E/(R_1 + R_2 + R_3) = 6/(10 + 10 + 10) \\ &= 6/30 = 0.2 \text{ ampere.} \end{aligned}$$

Voltage between points C and $D = 10 \times 0.2 = 2$ volts

$$B \text{ and } D = 20 \times 0.2 = 4 \text{ volts}$$

$$A \text{ and } D = 30 \times 0.2 = 6 \text{ volts.}$$

The voltage across any section of the voltage divider is proportional to its resistance (it is assumed that no current is drawn from the tapping points B or C).

FIG. 4.6

FIG. 4.7

Fig. 4.6. Resistances in series.

Fig. 4.7. Resistances in series, allowing for internal resistance of battery.

If the battery has any appreciable internal resistance the circuit must be modified to the form of Fig. 4.7 where R_i is the equivalent internal resistance. Here we have four resistances effectively in series and $I = E/(R_i + R_1 + R_2 + R_3)$. The

voltages between any of the points *A*, *B*, *C* or *D* will be less than in the corresponding case for zero internal resistance, the actual values being

$$\frac{R_1 + R_2 + R_3}{R_1 + R_1 + R_2 + R_3} \times \text{voltage for } R_1 = 0.$$

If R_1 is less than 1% of $(R_1 + R_2 + R_3)$, then its effect on voltages is less than 1%.

(iv) Resistances in parallel

When two resistances are in parallel (Fig. 4.8) the effective total resistance is given by

$$R = \frac{R_1 R_2}{R_1 + R_2} \quad (6)$$

When $R_1 = R_2$, $R = R_1/2 = R_2/2$.

When any number of resistances are in parallel (Fig. 4.9) the effective total resistance is given by

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \dots \quad (7)$$

When two or more resistors are in parallel, the total effective resistance may be determined by the graphical method of Fig. 4.10. This method* only requires a piece of ordinary graph paper (or alternatively a scale and set square). As an example, to find the total resistance of two resistors, 50 000 and 30 000 ohms, in parallel take any convenient base *AB* with verticals *AC* and *BD* at the two ends. Take 50 000 ohms on *BD* and draw the straight line *AD*; take 30 000 ohms on *AC* and draw *CB*; draw the line *XY* from their junction perpendicular to *AB*. The height of *XY* gives the required result, on the same scale.

FIG. 4.8

FIG. 4.9

Fig. 4.8. Two resistances in parallel. Fig. 4.9. Several resistors in parallel.

If it is required to determine the resistance of three resistors in parallel, the third being say 20 000 ohms, proceed further to join points *E* and *Y*, and the desired result is given by the height *PQ*. This may be continued indefinitely.

FIG. 4.10

Fig. 4.10. Graphical method for the determination of the effective resistance of two or more resistors in parallel (after *Wireless World*).

The same method may be used to determine suitable values of two resistors to be connected in parallel to give a specified total resistance. In this case, select one value (*C*) arbitrarily, mark *X* at the correct height and then find *D*; if not a suitable value, move *C* to the next available value and repeat the process until satisfactory.

*"Resistances in Parallel—Capacitances in Series," W.W. 48.9 (Sept. 1942) 205.
 "Diallist," "Series C and Parallel R," W.W. 51.4 (April 1945) 126.

When a network includes a number of resistors, some in series and some in parallel, firstly convert all groups in parallel to their effective total resistances, then proceed with the series chain.

(v) Conductance in resistive circuits

The conductance (G) of any resistor is its ability to conduct current, and this is obviously the reciprocal of the resistance—

$$G = 1/R \quad (8)$$

Applying Ohm's Law, we derive

$$I = EG \quad (9)$$

The unit of conductance is the mho (i.e. the reciprocal ohm).

When resistances are in parallel, their effective total conductance is the sum of their individual conductances—

$$G = G_1 + G_2 + G_3 + \dots \quad (10)$$

When a number of resistors are in parallel, the current through each is proportional to its conductance. Also,

$$\frac{I_1}{I_{total}} = \frac{G_1}{G_{total}} \quad (11)$$

SECTION 3 : POWER

(i) Power in d.c. circuits (ii) Power in resistive a.c. circuits.

(i) Power in d.c. circuits

The power converted into heat in a resistance is directly proportional to the product of the voltage and the current—

$$P = E \times I \quad (1)$$

where P is expressed in watts, E in volts and I in amperes. This equation may be rearranged, by using Ohm's Law, into the alternative forms—

$$P = I^2 R = E^2 / R \quad (2)$$

where R is expressed in ohms.

The total energy developed is the product of the power and the time. Units of energy are

(1) the watt-second or joule

(2) the kilowatt-hour (i.e. 1000 watts for 1 hour).

Fig. 4.11. One cycle of sine-wave voltage (e) and current (i) with zero phase angle. The instantaneous power (P) is always positive; the average power is half the peak power.

FIG. 4.11

(ii) Power in resistive a.c. circuits

The same general principles hold as for d.c., except that the voltage, current and power are varying. Fig. 4.11 shows one cycle of a sinewave voltage and current. The instantaneous power is equal to the product of the instantaneous voltage and

instantaneous current at any point in the cycle. The curve of instantaneous power (P) may be plotted point by point, and is always positive.

The heating of a resistor is obviously the result of the **average** or **effective power**, which is exactly half the peak power.

$$P_{peak} = E_{max} I_{max} \quad (3)$$

$$P_{av} = \frac{E_{max} I_{max}}{2} = \frac{E_{max}}{\sqrt{2}} \times \frac{I_{max}}{\sqrt{2}} \quad (4)$$

$E_{max}/\sqrt{2}$ is called the **effective** or **r.m.s. voltage**

$I_{max}/\sqrt{2}$ is called the **effective** or **r.m.s. current**.

The effective values of voltage and current are the values which have the same heating effect as with d.c. The initials r.m.s. stand for root mean square, indicating that it is the square root of the average of the squares over the cycle.

In a.c. practice, any reference to voltages or currents without specifying which value is intended, should always be interpreted as being r.m.s. (or effective) values. Measuring instruments are usually calibrated in r.m.s. values of currents and voltages.

The **form factor** is the ratio of the r.m.s. to the average value of the positive half-cycle. The following table summarizes the principal characteristics of several wave-forms, over the positive half-cycle in each case (see Chapter 30 for rectified waveforms) :

	Sine wave	Square wave	Triangular wave (isosceles)
Form factor (= r.m.s./average)	$\pi/2\sqrt{2} = 1.11$	1.00	$2/\sqrt{3} = 1.15$
Peak/r.m.s.	$\sqrt{2} = 1.414$	1.00	$\sqrt{3} = 1.73$
R.M.S./peak	$1/\sqrt{2} = 0.707$	1.00	$1/\sqrt{3} = 0.58$
Peak/average	$\pi/2 = 1.57$	1.00	2.0
Average/Peak	$2/\pi = 0.64$	1.00	0.5

SECTION 4 : CAPACITANCE

(i) *Introduction to capacitance* (ii) *Condensers in parallel and series* (iii) *Calculation of capacitance* (iv) *Condensers in d.c. circuits* (v) *Condensers in a.c. circuits.*

(1) Introduction to capacitance

A capacitor* (or condenser) in its simplest form, consists of two plates separated by an insulator (dielectric).

Any such condenser has a characteristic known as capacitance† whereby it is able to hold an electric charge. When a voltage difference (E) is applied between the plates, current flows instantaneously through the leads connecting the battery to the condenser (Fig. 4.12) until the latter has built up its charge, the current dropping gradually to zero. If the battery is removed, the condenser will hold its charge indefinitely (in practice there is a gradual loss of charge through leakage). If a conducting path is connected across the condenser plates, a current will flow through the conductor but will gradually fall to zero as the condenser loses its charge.

It is found that the charge (i.e. the amount of electricity) which a condenser will hold is proportional to the applied voltage and to the capacitance.

This may be put into the form of an equation :

$$Q = CE \quad (1)$$

where Q = quantity of electricity (the charge) in coulombs,

C = capacitance in farads,

and E = applied voltage.

*The American standard term is "Capacitor."

†It is assumed here that the condenser is ideal, without series resistance, leakage, or dielectric lag.

The unit of capacitance—the Farad (F)—is too large for convenience, so it is usual to specify capacitance as so many microfarads (μF) or micro-microfarads* ($\mu\mu\text{F}$). Any capacitance must be converted into its equivalent value in farads before being used in any fundamental equation such as (1) above—

$$1 \mu\text{F} = 1 \times 10^{-6} \text{ farad}$$

$$1 \mu\mu\text{F} = 1 \times 10^{-12} \text{ farad}$$

Note: The abbreviations mF or mmF should not be used under any circumstances to indicate microfarads or micro-microfarads, because mF is the symbol for milli-farads (1×10^{-3} farad). Some reasonable latitude is allowable with most symbols, but here there is danger of serious error and misunderstanding.

The energy stored in placing a charge on a condenser is

$$W = \frac{1}{2}(QE) = \frac{1}{2}(CE^2) = Q^2/2C \quad (2)$$

where W = energy, expressed in joules (watt-seconds)

Q = charge in coulombs

C = capacitance in farads

and E = applied voltage.

FIG. 4.12

FIG. 4.13

Fig. 4.12. Condenser connected to a battery.

Fig. 4.13. (A) Condensers in parallel. (B) Condensers in series.

(ii) Condensers in parallel and series

When two or more condensers are connected in parallel (Fig. 4.13A) the total capacitance is the sum of their individual capacitances:

$$C = C_1 + C_2 + C_3 + \dots \quad (3)$$

When two or more condensers are connected in series (Fig. 4.13B) the total capacitance is given by:

$$\frac{1}{C} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \dots \quad (4)$$

When only two condensers are connected in series:

$$C = \frac{C_1 C_2}{C_1 + C_2} \quad (5)$$

When two or more equal condensers (C_1) are connected in series, the total capacitance is

$$C = C_1/2 \text{ for 2 condensers}$$

and

$$C = C_1/n \text{ for } n \text{ condensers.}$$

Note: The curved plate of the symbol used for a condenser indicates the earthed (outer) plate of an electrolytic or circular paper condenser; when this is not applicable the curved plate is regarded as the one more nearly at earth potential.

(iii) Calculation of capacitance

Parallel plate condenser

When there are two plates, close together, the capacitance is approximately:

$$C = \frac{AK}{11.31d} \mu\text{F} \text{ when dimensions are in centimetres}$$

*The name picofarad (pF) is also used as an alternative.

or $C = \frac{AK}{4.45d} \mu\text{F}$ when dimensions are in inches

where A = useful area of one plate in square centimetres (or inches). The useful area is approximately equal to the area of the smaller plate when the square root of the area is large compared with the gap.

K = dielectric constant (for values of common materials see Chapter 38 Sect. 8. For air, $K = 1$).

d = gap between plates in centimetres (or inches).

Capacitance with air dielectric, plates 1 mm. apart

$C = 0.884 \mu\text{F}$ per sq. cm. area of one plate.

Capacitance with air dielectric, plates 0.10 inch apart

$C = 2.244 \mu\text{F}$ per sq. inch area of one plate.

When there are more than two plates, the "useful area" should be interpreted as the total useful area.

Cylindrical condenser (concentric cable)

$C = \frac{7.354K}{\log_{10} D/d} \mu\text{F}$ per foot length

where D = inside diameter of outside cylinder (inches)

d = outside diameter of inner cylinder (inches)

and K = dielectric constant of material in gap.

(iv) Condensers in d.c. circuits

An **ideal condenser** is one which has no resistance, no leakage, and no inductance. In practice, every condenser has some resistance, leakage and inductance, although these may be neglected under certain conditions of operation.

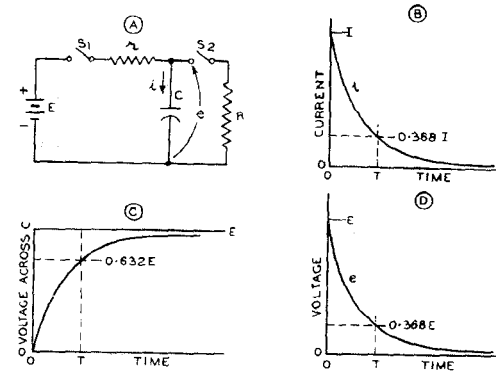

FIG. 4.14

Fig. 4.14. Condenser charge and discharge (A) Circuit (B) Discharge current characteristic (C) Charge voltage characteristic (D) Discharge voltage characteristic.

In Fig. 4.14A, C is an ideal condenser which may be charged by closing switch S_1 ; r represents the combined internal resistance of the battery E and the resistance of the leads in the circuit. When S_1 is closed, current (i) will flow as indicated in diagram B, the peak current being $I = E/r$ at time $t = 0$. The time for C to become fully charged is infinite—in other words the current never quite reaches zero, although it comes very close to zero after a short period. The equation for the current is of logarithmic form:

$$i = \frac{E}{r} e^{-t/rC} \quad (6)$$

where ϵ = base of natural logarithms (≈ 2.718)
 t = time in seconds after closing switch S_1
 E = battery voltage
 r = resistance in ohms
 and C = capacitance in farads.

The voltage (e) across the condenser is

$$e = E - ri = E(1 - \epsilon^{-t/rC}) \quad (7a)$$

and the curve (diagram C) is of the same shape as the current curve except that it is upside down. The voltage never quite reaches the value E , although it approaches it very closely.

The charge on the condenser is given by

$$q = Q(1 - \epsilon^{-t/rC}) \quad (7b)$$

where q = instantaneous charge on condenser

and $Q = EC$ = final charge on condenser

which follows the same law as the voltage (eqn. 7a).

If we now assume that the condenser C is fully charged, switch S_1 is opened, and switch S_2 is closed, the **discharge characteristic** will be given by

$$i = -\frac{E}{R}\epsilon^{-t/RC} \quad (8)$$

which is of the same form as diagram B, except that the current is in the opposite direction.

The curve of voltage (and also charge) against time for a discharging condenser is in diagram D, and is of the same shape as for current, since $e = Ri$. These charge and discharge characteristics are called **transients**.

In order to make a convenient measure of the time taken to discharge a condenser, we adopt the **time constant** which is the time taken to discharge a condenser on the assumption that the current remains constant throughout the process at its initial value. In practice, as explained above, the discharge current steadily falls with time, and under these conditions the time constant is the time taken to discharge the condenser to the point where the voltage or charge drops to $1/\epsilon$ or 36.8% of its initial value. The same applies also to the time taken by a condenser in process of being charged, to reach a voltage or charge of $(1 - 1/\epsilon)$ or 63.2% of its final value.

The time constant (T) is equal to

$$T = RC \quad (9)$$

where T is the time constant in seconds,

R is the total resistance in the circuit, either for charge or discharge, in ohms,

and C is the capacitance in farads.

This also holds when R is in megohms and C in microfarads.

(v) Condensers in a.c. circuits

When a condenser is connected to an a.c. line, current flows in the circuit, as may be checked by inserting an a.c. ammeter in series with the condenser. This does not mean that electrons flow through the condenser from one plate to the other; they are insulated from one another.

Suppose that a condenser of capacitance C farads is connected directly across an a.c. line, the voltage of which is given by the equation $e = E_m \sin \omega t$. The condenser will take sufficient charge to make the potential difference of its plates at every instant equal to the voltage of the line. As the impressed voltage continually varies in magnitude and direction, electrons must be continually passing in and out of the condenser to maintain its plates at the correct potential difference. This continual charging and discharging of the condenser constitutes the current read by the ammeter.

At any instant, $q = Ce$, where q is the instantaneous charge on the condenser. The current (i) is the rate of change (or differential* with respect to time) of the charge,

*See Chapter 6, Section 7.

$$\begin{aligned} \text{i.e.,} \quad i &= dq/dt \\ \text{But} \quad q &= Ce = CE_m \sin \omega t \end{aligned}$$

$$\text{Therefore } i = \frac{d}{dt} (CE_m \sin \omega t)$$

$$\text{Therefore } i = \omega CE_m \cos \omega t \quad (10)$$

Eqn. (10) is the equation of the current flowing through the condenser, from which we may derive the following facts :

1. It has a peak value of ωCE_m ; the current is therefore proportional to the applied voltage, also to the capacitance and to the frequency (since $f = \omega/2\pi$).
2. It has the same angular velocity (ω) and hence the same frequency as the applied voltage.
3. It follows a cosine waveform whereas the applied voltage has a sine waveform. This is the same as a sinewave advanced 90° in phase—we say that the current leads the voltage by 90° (Fig. 4.15).

Considering only the magnitude of the condenser charging current,

$$I_m = \omega CE_m \quad (\text{peak values})$$

$$\text{Therefore } I_{rms} = \omega CE_{rms} \quad (\text{effective values})$$

Where I and E occur in a.c. theory, they should be understood as being the same as I_{rms} and E_{rms} .

This should be compared with the equivalent expression when the condenser is replaced by a resistance (R) :

$$I_{rms} = \frac{E_{rms}}{R}$$

FIG. 4.15

Fig. 4.15. Alternating current through an ideal condenser.

diagram*. Fig. 4.16A shows a circuit with R and C in series across an a.c. line with a voltage $e = E_m \sin \omega t$. The instantaneous** values of voltage (e) and current (i) are shown with arrows to indicate the convention of positive direction. It is quite clear that the same current which passes through R must also pass through C . This causes a voltage drop RI across R and $(I/\omega C)$ across C where I is the r.m.s. value of the current. The relative phase relationships are given by the angular displacements in the vector diagram. These are determined trigonometrically by the peak values I_m , RI_m and $I_m/\omega C$; for convenience, the lengths of the vectors are marked in Fig. 4.16B according to the effective values I , RI and $I/\omega C$. The current vector is distinguished by a solid arrowhead; it may be to any convenient scale since there is no connection between the voltage and current scales. Since R is purely resistive, RI must be in phase with I , but the current through C must lead the voltage drop across C by 90° . This is shown on the vector diagram 4.16B where the direction of I is taken as the starting point; RI is drawn in phase with I and of length equal to the voltage drop on any convenient scale; $I/\omega C$ is drawn so that I leads it by 90° ; and the resultant (E) of RI and $I/\omega C$ is determined by completing the parallelogram. The resultant E is the vector sum of the voltage drops across R and C , which must

*A table of capacitive reactances is given in Chapter 38 Sect. 9 Table 42.

**See Chapter 6 Section 5(iv).

**It is illogical to show directions or polarities on the r.m.s. values of current (I) or voltage (E) since these are the effective values of alternating currents.

therefore be the applied (line) voltage. It will be seen that the current I leads the voltage E by an angle ϕ where

$$\tan \phi = \frac{I}{\omega C} \cdot \frac{1}{RI} = \frac{1}{\omega CR} = \frac{|X_c|}{R} \quad (10a)$$

If $R = 0$, then $\tan \phi = \infty$, and $\phi = 90^\circ$.

Since ϕ is the phase angle of the current with respect to the voltage, the angle ϕ in the circuit of Fig. 4.16A is positive.

The instantaneous current flowing through the circuit of Fig. 4.16A is therefore given by

$$i = I_m \sin(\omega t + \phi) \quad (10b)$$

where

$$\phi = \tan^{-1}(1/\omega CR).$$

The value of I_m in eqn. (10b) is given by

$$I_m = E_m/Z \quad (10c)$$

where Z is called the impedance.

Similarly in terms of effective values,

$$I = E/Z \quad (10d)$$

Obviously Z is a vector (or complex) quantity having phase relationship as well as magnitude, and is printed in bold face to indicate this fact. This may be developed further by the use of the j notation.

Fig. 4.16. (A) Resistance and capacitance across a.c. line (B) Vector diagram of voltage relationships (C) Vector diagram of impedance (Z) with its real component (R) and reactive component $-j(1/\omega C)$.

Using the j Notation

The operator j^* signifies a positive vector rotation of 90° , while $-j$ signifies a negative rotation of 90° . Instead of working out a detailed vector diagram, it is possible to treat a circuit problem very much more simply by using the j notation. For example in Fig. 4.16, we may equate the applied voltage E to the sum of the voltage drops across R and C :

$$E = RI - j \frac{I}{\omega C} \quad (11)$$

the $-j$ indicating 90° vector rotation in a negative direction, which is exactly what we have in diagram B.

It is sometimes more convenient to put $-jI/\omega C$ into the alternative form $+I/j\omega C$ which may be derived by multiplying both numerator and denominator by j (since $j^2 = -1$). Thus

$$E = RI + I/j\omega C \quad (12)$$

From (11) we can derive:

$$Z = E/I = R - j(1/\omega C) \quad (13)$$

For example, in Fig. 4.16A let $R = 100$ ohms and $C = 10 \mu F$, both connected in series, and let the frequency be 1000 c/s.

Then $\omega = 2\pi \times 1000 = 6280$

$$1/\omega C = 1/(6280 \times 10 \times 10^{-6}) = 15.9 \text{ ohms.}$$

and

$$Z = R - j(1/\omega C) = 100 - j 15.9 \quad (13a)$$

Eqn. (13a) indicates at a glance a resistance of 100 ohms in series with a negative reactance (i.e. a capacitive reactance) of 15.9 ohms. Values of capacitive reactances

*See Chapter 6 Sect. 5(iv).

for selected capacitances and frequencies are given in Chapter 38 Sect. 9 Table 42. Even if $R = 0$, we still write the impedance in the same form,

$$Z = 0 - j 15.9 \quad (13b)$$

Thus Z is a complex* quantity, that is to say it has a "real" part (R) and an "imaginary" part ($1/\omega C$) at 90° to R , as shown in Fig. 4.16C. The absolute magnitude (modulus) of Z is :

$$|Z| = \sqrt{R^2 + (1/\omega C)^2} \quad (14)$$

and its phase angle ϕ is given by

$$\tan \phi = - \frac{1}{\omega CR} \quad (15)$$

which is the same as we derived above from the vector diagram, except for the sign. The negative sign in eqn. (15) is because ϕ is the phase shift of Z with respect to R .

In a practical condenser, we may regard R in Fig. 4.16A as the equivalent series loss resistance of the condenser itself.

It is obvious from Fig. 4.16B that

$$\cos \phi = R/Z \quad (16a)$$

where Z is given by equation (13) above.

$\cos \phi$ is called the "Power factor."

If ϕ is nearly 90° , X is nearly equal to Z , apart from sign, and so

$$\cos \phi \approx R/|X| \quad (16b)$$

where $|X|$ indicates that the value of the reactance is taken apart from sign. With this approximation we obtain

$$\text{Power factor} = \cos \phi \approx \omega CR \quad (17)$$

Note that the power factor of any resistive component is always positive. A negative power factor indicates generation of power.

The total power dissipated in the circuit (Fig. 4.16A) will be

$$P = EI \cos \phi = EI \times \text{power factor} \quad (17a)$$

$$= I^2 R = \frac{E^2}{R[1 + X_c^2/R^2]} \quad (17b)$$

where P = power in watts

$$X_c = 1/\omega C$$

and $\cos \phi$ is defined by eqn. (16a) or the approximation (16b).

The **Q factor** of a condenser is the ratio of its reactance to its resistance—

$$Q = 1/\omega CR = \tan \phi \approx 1/(\text{power factor}) \quad (18)$$

SECTION 5 : INDUCTANCE

(i) *Introduction to inductance* (ii) *Inductances in d.c. circuits* (iii) *Inductances in series and parallel* (iv) *Mutual inductance* (v) *Inductances in a.c. circuits* (vi) *Power in inductive circuits.*

(i) Introduction to inductance

An inductor, in its simplest form, consists of a coil of wire with an air core as commonly used in r-f tuning circuits. Any inductor has a characteristic known as inductance whereby it sets up an electro-magnetic field when a current is passed through it. When the current is varied, the strength of the field varies ; as a result, an electro-motive force is induced in the coil. This may be expressed by the equation :

$$e = -N \frac{d\phi}{dt} \times 10^{-8} \text{ volts} \quad (1)$$

where e = e.m.f. induced at any instant

N = number of turns in the coil

ϕ = flux through the coil

*See Chapter 6, Sect. 6(i).

and $\frac{d\phi}{dt}$ = rate of change (differential with respect to time) of the flux.

The direction of the induced e.m.f. is always such as to oppose the change of current which is producing the induced voltage. In other words, the effect of the induced e.m.f. is to assist in maintaining constant both current and field.

We may also express the relationship in the form :

$$e = -L \frac{di}{dt} \quad (2)$$

where all the values are expressed in practical units—

e = e.m.f. induced at any instant, in volts

L = inductance, in henrys

i = current in amperes

and $\frac{di}{dt}$ = rate of change of current, in amperes per second.

The inductance L varies approximately* with the square of the number of turns in the coil, and may be increased considerably by using iron cores** (for low frequencies) or powdered iron (for radio frequencies). With iron cores the value of L is not constant, so that eqn. (2) cannot be used accurately in such cases.

The energy stored in a magnetic field is

$$\text{energy} = \frac{1}{2} LI^2 \quad (2a)$$

where energy is measured in joules (or watt seconds)

L is measured in henrys

and I is measured in amperes.

(ii) Inductances in d.c. circuits

When an inductance (L henrys) with a total circuit resistance (R ohms) is connected to a d.c. source of voltage (E), the current rises gradually to the steady value $I = E/R$. During the gradual rise, the current follows the logarithmic law

$$i = \frac{E}{R} (1 - e^{-Rt/L}) \quad (3)$$

where i = current in amperes at time t ,

e = base of natural logarithms ≈ 2.718 ,

and t = time in seconds after switch is closed.

The time constant (T) is the time in seconds from the time that the switch is closed until the current has risen to $(1 - 1/e)$ or 63.2% of its final value :

$$T = L/R \quad (4)$$

where L = inductance in henrys

and R = resistance in ohms.

The decay of current follows the law

$$i = \frac{E}{R} (e^{-Rt/L}) \quad (5)$$

The rise and decay of current are called **transients**.

(iii) Inductances in series and parallel

Inductances in series

The total inductance is equal to the sum of the individual inductances, provided that there is no coupling between them :

$$L = L_1 + L_2 + L_3 + \dots \quad (6)$$

Inductances in parallel

The total inductance is given by eqn. (7), provided that there is no coupling between them :

$$\frac{1}{L} = \frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \dots \quad (7)$$

*See Chapter 10 for formulae for calculating the inductance of coils.

**See Chapter 5 for iron cored inductances.

(iv) Mutual inductance

When two coils are placed near to one another, there tends to be coupling between them, which reaches a maximum when they are placed co-axially and with their centres as close together as possible.

If one such coil is supplied with varying current, it will set up a varying magnetic field, which in turn will induce an e.m.f. in the second coil. This induced e.m.f. in the secondary is proportional to the rate of current change in the first coil (primary) and to the mutual inductance of the two coils :

$$e_2 = -M \frac{di_1}{dt} \quad (8)$$

where e_2 = voltage induced in the secondary,

$\frac{di_1}{dt}$ = rate of change of current in the primary in amperes per second,

and M = mutual inductance of the two coils, in henrys.

(Compare Equations 2 and 8.)

M may be either positive or negative, depending on the rotation of, or connections to, the secondary. M is regarded as positive if the secondary voltage (e_2) has the same polarity as the induced voltage in a single coil.

The maximum possible (theoretical) value of M is when $M = \sqrt{L_1 L_2}$, being the condition of unity coupling, but in practice this cannot be achieved. The coefficient of coupling (k) is given by

$$k = M / \sqrt{L_1 L_2} \quad (9)$$

so that k is always less than unity.

If the secondary is loaded by a resistance R_2 (Fig. 4.17), current will flow through the secondary circuit.

FIG. 4.17

FIG. 4.18

Fig. 4.17. Two inductances coupled by mutual inductance (M) with the secondary loaded by a resistance.

Fig. 4.18. (A) Equivalent circuit diagram of practical inductance (B) Vector diagram of voltage relationships.

(v) Inductance in a.c. circuits

If an ideal inductance (L henrys) is connected across an a.c. line, the voltage of which is given by the equation $e = E_m \sin \omega t$, a current will flow having the same waveform as the line voltage, but the current will lag 90° behind the voltage. The inductance is said to have an **inductive reactance*** (X_L) equal to ωL , and the current will be

$$I_{rms} = E_{rms} / \omega L \quad (10)$$

We may helpfully compare this with the case of a condenser :

	Current	Reactance	Phase shift†
Capacitance :	$I_{rms} = \omega C E_{rms}$	$X_C = -1/\omega C$	$+90^\circ$
Inductance :	$I_{rms} = E_{rms} / \omega L$	$X_L = \omega L$	-90°

Every practical inductance has appreciable resistance, and we may draw the equivalent circuit of any normal inductor as an ideal inductance in series with a resistance

*A table of inductive reactances is given in Chapter 38 Sect. 9 Table 41.

†Of current with respect to voltage.

(Fig. 4.18A). If there is any other resistance in the circuit, it may be added to the resistance of the inductor to give the total resistance R .

If an alternating voltage is applied across L and R in series (Fig. 4.18A) the vector diagram may be drawn as in (B). The current vector I is first drawn to any convenient scale; the vector of voltage drop across R is then drawn as RI in phase with I ; the vector of voltage drop across L is then drawn as ωLI so that I will lag behind it by 90° —hence ωLI is drawn as shown; the parallelogram is then completed to give the resultant $E = ZI$ with a phase angle such that $\tan \phi = \omega L/R$.

Using the j notation we may write :

$$E = RI + j\omega LI \quad (11)$$

where $+j$ indicates 90° vector rotation in a positive direction.

From (11) we can derive :

$$Z = E/I = R + j\omega L \quad (12)$$

For example, if $R = 150$ ohms, $L = 20$ henrys and $f = 1000$ c/s, then

$$\omega = 2\pi \times 1000 = 6280$$

$$\omega L = 6280 \times 20 = 125\,600 \text{ ohms}$$

and

$$Z = 150 + j\,125\,600 \quad (12a)$$

Eqn. (12a) indicates at a glance a resistance of 150 ohms in series with a positive reactance (i.e. an inductive reactance) of 125 600 ohms. Values of inductive reactances are given in Chapter 38 Sect. 9 Table 41.

The magnitude (modulus) of Z is :

$$|Z| = \sqrt{R^2 + (\omega L)^2} \quad (13)$$

and its phase angle is given by

$$\tan \phi = \omega L/R \quad (14)$$

as also shown by the vector diagram.

(vi) Power in inductive circuits

The power drawn from the line in Fig. 4.18A is the integral over one cycle of the instantaneous values of $e \times i$. As shown by Fig. 4.19, during parts of each cycle energy is being taken by the circuit, while during other parts of the cycle energy is being given back by the circuit. The latter may be regarded as negative power being taken by the circuit, and is so drawn. The expression for the power is

$$\begin{aligned} P &= E_m \sin \omega t \times I_m \sin (\omega t - \phi) \\ &= E_m I_m \sin \omega t \cdot \sin (\omega t - \phi) \\ &= E_m I_m \sin \omega t (\sin \omega t \cos \phi - \cos \omega t \sin \phi) \\ &= E_m I_m (\sin^2 \omega t \cos \phi - \sin \omega t \cos \omega t \sin \phi). \end{aligned}$$

Now the average value of $(\sin \omega t \cos \omega t)$ over one cycle is zero*,

Therefore $P = E_m I_m (\sin^2 \omega t \cos \phi)$

$$\begin{aligned} &= \frac{1}{2} E_m I_m (1 - \cos 2\omega t) (\cos \phi) \\ &= E_{rms} I_{rms} \cos \phi \end{aligned} \quad (15)$$

(since the average value of $\int_0^{2\pi} \cos 2\omega t = 0^*$)

where P is expressed in watts, E and I in volts and amperes.

Fig. 4.19. Power in an inductive circuit with applied sine-wave voltage (e).

*See Chapter 6 Sect. 7(iii) (Definite Integrals).

From eqn. (15) the power is equal to the product of the effective voltage and current multiplied by $\cos \phi$, which is called the **Power Factor**, its value being given by $\cos \phi = R/\sqrt{R^2 + (\omega L)^2}$.

When the load is purely resistive, $L = 0$ and the power factor = 1; the power is therefore $P = E_{rms} I_{rms}$.

From (15) we may derive for the general case :

$$P = EI \cos \phi = EI \cdot R/\sqrt{R^2 + (\omega L)^2}$$

$$\text{Therefore } P = I \cdot I\sqrt{R^2 + (\omega L)^2} \times R/\sqrt{R^2 + (\omega L)^2} = I^2 R \quad (16a)$$

$$\text{or } P = \frac{E^2}{R[1 + (\omega L)^2/R^2]} \quad (16b)$$

$$\text{Therefore } R = P/I^2 \quad (17)$$

where P = power in watts

ωL = inductive reactance in ohms

R = resistance in ohms

and I = current in amperes.

In other words, the total power taken from the line in the circuit of Fig. 4.18A is the power dissipated by the effective total resistance R . There is no loss of power in an ideal inductance with zero resistance, although it draws current from an a.c. line, because the power factor is zero ($\phi = 90^\circ$, therefore $\cos \phi = 0$). The product of $I \times E$ in this case is called the **wattless power** or **reactive power**, or more correctly the **reactive volt-amperes**.

The power factor at any given frequency gives the ratio of the resistance of a coil to its impedance and may be used as a figure of merit for the coil. A good coil should have a very small power factor.

The power factor is almost identical with the inverse of the coil magnification factor Q (Chapter 9), and the error is less than 1% for values of Q greater than 7 :

$$Q = \omega L/R = \tan \phi$$

$$\text{Power factor} = \cos \phi = R/Z$$

$$\tan \phi \approx 1/\cos \phi \text{ (error } < 1\% \text{ for } \phi > 82^\circ)$$

Therefore Power Factor $\approx 1/Q$ for $Q > 7$.

SECTION 6 : IMPEDANCE AND ADMITTANCE

(i) *Impedance a complex quantity* (ii) *Series circuits with L , C and R* (iii) *Parallel combinations of L , C and R* (iv) *Series-parallel combinations of L , C and R* (v) *Conductance, susceptance and admittance* (vi) *Conversion from series to parallel impedance.*

(i) Impedance, a complex quantity

Impedance has already been introduced in Sections 4 and 5, in connection with series circuits of C and R or L and R . Impedance is a complex quantity, having both a resistive and a reactive component. We are therefore concerned, not only with its magnitude, but also with its phase angle.

(ii) Series circuits with L , C and R

When a resistance, an inductance and a capacitance are connected in series across an a.c. line (Fig. 4.20A), the same current will flow through each.

In using the j notation, remember that j simply means 90° positive vector rotation (the voltage drop for an inductance) and $-j$ means 90° negative vector rotation (the voltage drop for a capacitance).

In terms of the effective values

where E = applied voltage

and I = current through circuit, we have :

Voltage drop through $R = RI$

„ „ „ $L = j\omega LI$

„ „ „ $C = (-j/\omega C)I$

The total voltage drop is equal to the applied voltage,

therefore $E = [R + j(\omega L - 1/\omega C)] I$

Hence $Z = R + j(\omega L - 1/\omega C)$ (1)

Here R is the resistive component of Z , while $(\omega L - 1/\omega C)$ is the reactive component.

It may therefore be written as

$$Z = R + jX \text{ where } X = (\omega L - 1/\omega C).$$

For example, let $R = 500$ ohms, $L = 20$ henrys, and $C = 1 \mu\text{F}$, all connected in series across an a.c. line with a frequency of 50 c/s.

Then $\omega = 2\pi \times 50 = 314$

$$1/\omega C = 1/(314 \times 10^{-6}) = 3180 \text{ ohms}$$

$$X = \omega L - 1/\omega C = 6280 - 3180 = 3100 \text{ ohms}$$

(the positive sign indicates that this is inductively reactive) and

$$Z = R + jX = 500 + j3100.$$

If L had been 5 henrys, then X would have been

$$1570 - 3180 = -1610 \text{ ohms}$$

which is capacitively reactive.

The phase angle is given by $\tan \phi = X/R$. The magnitude of the impedance is given by

$$|Z| = \sqrt{R^2 + (\omega L - 1/\omega C)^2} \quad (1a)$$

Fig. 4.20. (A) Circuit of R , L and C in series across a.c. line (B) Vector diagram of voltage relationships.

This may be illustrated by means of a vector diagram (Fig. 4.20 B) where I is drawn to any convenient scale. The voltage-drop vectors are then drawn, to the selected voltage scale, RI in phase with I , $j\omega LI$ at 90° in advance of I and $-jI/\omega C$ lagging 90° behind I . The simplest method of combining the three vectors is to take either ωLI or $I/\omega C$, whichever is the greater, and then to subtract the other from it, since these two are exactly in phase opposition. In diagram B, ωLI is the greater, so that $I/\omega C$ is subtracted from ωLI to give $(\omega L - 1/\omega C)I$. The two remaining vectors, RI and $j(\omega L - 1/\omega C)I$ are then combined by completing the parallelogram, to give the resultant ZI which, of course, must be equal to the applied voltage E .

A special case arises when $\omega L = 1/\omega C$ in eqn. (1); the reactive component becomes zero and $Z = R$. This is the phenomenon of **series resonance** which is considered in greater detail in Chapter 9.

Special cases of equation (1)

R and L only :	Put $1/\omega C = 0$,	$Z = R + j\omega L$
R and C only :	Put $\omega L = 0$,	$Z = R - j/\omega C = R + 1/j\omega C$
L and C only :	Put $R = 0$,	$Z = j(\omega L - 1/\omega C)$
R only :		$Z = R + j0$
L only :		$Z = 0 + j\omega L$
C only :		$Z = 0 - j/\omega C = 1/j\omega C$

Note that $Q = |\tan \phi| = |X|/R$.

A table of inductive reactances is given in Chapter 38 Sect. 9(i) Table 41.

A table of capacitive reactances is given in Chapter 38 Sect. 9(ii) Table 42.

A table and two charts to find X , R or Z , when a reactance and resistance are connected in series, any two values being known, is given in Chap. 38 Sect 9(iv) Table 44.

Series Combinations of L , C and R

Series combination	Impedance $Z = R + jX$	Magnitude of impedance $ Z = \sqrt{R^2 + X^2}$	Phase angle $\phi = \tan^{-1}(X/R)$	Admittance* $Y = 1/Z$
R	ohms R	ohms R	radians 0	mhos $1/R$
L	$+j\omega L$	ωL	$+\pi/2$	$-j(1/\omega L)$
C	$-j(1/\omega C)$	$1/\omega C$	$-\pi/2$	$j\omega C$
$R_1 + R_2$	$R_1 + R_2$	$R_1 + R_2$	0	$1/(R_1 + R_2)$
$L_1(M)L_2$	$+j\omega(L_1 + L_2 \pm 2M)$	$\omega(L_1 + L_2 \pm 2M)$	$+\pi/2$	$-j/\omega(L_1 + L_2 \pm 2M)$
$C_1 + C_2$	$-j\frac{1}{\omega}\left(\frac{C_1 + C_2}{C_1 C_2}\right)$	$\frac{1}{\omega}\left(\frac{C_1 + C_2}{C_1 C_2}\right)$	$-\frac{\pi}{2}$	$j\omega\left(\frac{C_1 C_2}{C_1 + C_2}\right)$
$R + L$	$R + j\omega L$	$\sqrt{R^2 + \omega^2 L^2}$	$\tan^{-1} \frac{\omega L}{R}$	$\frac{R - j\omega L}{R^2 + \omega^2 L^2}$
$R + C$	$R - j\frac{1}{\omega C}$	$\sqrt{\frac{\omega^2 C^2 R^2 + 1}{\omega^2 C^2}}$	$-\tan^{-1} \frac{1}{\omega RC}$	$\frac{\omega^2 C^2 R + j\omega C}{\omega^2 C^2 R^2 + 1}$
$L + C$	$+j\left(\omega L - \frac{1}{\omega C}\right)$	$\left(\omega L - \frac{1}{\omega C}\right)$	$\pm\frac{\pi}{2}$	$-\frac{j\omega C}{\omega^2 LC - 1}$
$R + L + C$	$R + j\left(\omega L - \frac{1}{\omega C}\right)$	$\sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}$	$\tan^{-1}\left(\frac{\omega L - 1/\omega C}{R}\right)$	$\frac{R - j(\omega L - 1/\omega C)}{R^2 + (\omega L - 1/\omega C)^2}$

*See Sect. 6(v) below.

General case with a number of arms connected in series, each arm being of the form $R + X$

Arm (1): $Z_1 = R_1 + jX_1$ (i.e. R_1 in series with X_1)

Arm (2): $Z_2 = R_2 + jX_2$

Arm (3): $Z_3 = R_3 + jX_3$ etc.

then the total impedance is given by

$$Z = (R_1 + R_2 + R_3 + \dots) + j(X_1 + X_2 + X_3 + \dots)$$

(iii) Parallel combinations of L , C and R

When a number of resistance and reactive elements are connected in parallel across an a.c. line, the same voltage is applied across each. For example in Fig. 4.20C there are three parallel paths across the a.c. line, and the current through each may be determined separately.

Let E_o = r.m.s. value of line voltage.

Then r.m.s. current through $L = I_1 = E_o/\omega L$

” ” ” ” $C = I_2 = E_o\omega C$

” ” ” ” $R = I_3 = E_o/R$.

The phase relationships between these currents are shown in Fig. 4.20D. There is 180° phase angle between the current through L and that through C , so that the resultant of these two currents is $(I_2 - I_1)$. The vector resultant of $(I_2 - I_1)$ and I_3 is given by I_o in Fig. 4.20D. Thus the current through L and C may be considerably greater than the total line current I_o .

Fig. 4.20.C Circuit of R , L and C in parallel across a.c. line.

Fig. 4.20.D Vector diagram of voltage relationships.

The impedance of the parallel combination may be derived by considering L and C as being replaced by a single reactive element having a reactance of $1/(\omega C - 1/\omega L)$. Note that with parallel connection, the convention is that the phase of the capacitive element is taken as positive. Thus

$$\begin{aligned} I_o &= I_3 + j(I_2 - I_1) \\ &= \frac{E_o}{R} + jE_o\left(\omega C - \frac{1}{\omega L}\right) \end{aligned}$$

$$\begin{aligned} \text{Therefore } Z &= \frac{E_o}{I_o} = \frac{1}{\frac{1}{R} + j\left(\omega C - \frac{1}{\omega L}\right)} \times \frac{\frac{1}{R} - j\left(\omega C - \frac{1}{\omega L}\right)}{\frac{1}{R} - j\left(\omega C - \frac{1}{\omega L}\right)} \\ &= \frac{\frac{1}{R} - j\left(\omega C - \frac{1}{\omega L}\right)}{\left(\frac{1}{R}\right)^2 + \left(\omega C - \frac{1}{\omega L}\right)^2} \end{aligned} \quad (2)$$

Parallel combinations of L , C and R

Parallel combination	Impedance $Z = R + jX$	Magnitude of impedance $ Z = \sqrt{R^2 + X^2}$	Phase angle $\phi = \tan^{-1} (X/R)$	Admittance* $Y = 1/Z$
R_1, R_2	ohms $\frac{R_1 R_2}{R_1 + R_2}$	ohms $\frac{R_1 R_2}{R_1 + R_2}$	radians 0	mhos $\frac{R_1 + R_2}{R_1 R_2}$
C_1, C_2	$-j \frac{1}{\omega(C_1 + C_2)}$	$\frac{1}{\omega(C_1 + C_2)}$	$-\frac{\pi}{2}$	$+j\omega(C_1 + C_2)$
L_1, R	$\frac{\omega^2 L^2 R + j\omega L R^2}{\omega^2 L^2 + R^2}$	$\frac{\omega L R}{\sqrt{\omega^2 L^2 + R^2}}$	$\tan^{-1} \frac{R}{\omega L}$	$\frac{1}{R} - j \frac{j}{\omega L}$
R, C	$\frac{R - j\omega R^2 C}{1 + \omega^2 R^2 C^2}$	$\frac{R}{\sqrt{1 + \omega^2 R^2 C^2}}$	$\tan^{-1}(-\omega R C)$	$\frac{1}{R} + j\omega C$
L, C	$+j \frac{\omega L}{1 - \omega^2 L C}$	$\frac{\omega L}{1 - \omega^2 L C}$	$\pm \frac{\pi}{2}$	$j \left(\omega C - \frac{1}{\omega L} \right)$
$L_1(M)L_2$	$+j \omega \frac{L_1 L_2 - M^2}{L_1 + L_2 \mp 2M}$	$\omega \frac{L_1 L_2 - M^2}{L_1 + L_2 \mp 2M}$	$\pm \frac{\pi}{2}$	$-j \frac{1}{\omega} \left(\frac{L_1 + L_2 \mp 2M}{L_1 L_2 - M^2} \right)$
L, C, R	$\frac{1}{\left(\frac{1}{R} \right)^2 - j \left(\omega C - \frac{1}{\omega L} \right)} + \left(\omega C - \frac{1}{\omega L} \right)^2$	$\frac{R}{\sqrt{1 + R^2 \left(\omega C - \frac{1}{\omega L} \right)^2}}$	$\tan^{-1} - R \left(\omega C - \frac{1}{\omega L} \right)$	$\frac{1}{R} + j \left(\omega C - \frac{1}{\omega L} \right)$

Note that $Q = |\tan \phi|$.

*See Sect. 6(v) below.

The magnitude of the impedance of a reactance X in parallel with a resistance R is given by

$$|Z| = \frac{RX}{\sqrt{X^2 + R^2}} \quad (3a)$$

$$= \frac{\omega LR}{\sqrt{\omega^2 L^2 + R^2}} \quad \text{when } X = \omega L \quad (3b)$$

$$= \frac{R}{\sqrt{1 + \omega^2 R^2 C^2}} \quad \text{when } X = 1/\omega C \quad (3c)$$

$$= \frac{R}{\sqrt{1 + R^2 (\omega C - 1/\omega L)^2}} \quad \left\{ \begin{array}{l} \text{when } L \text{ and } C \\ \text{are in parallel} \end{array} \right\} \quad (3d)$$

A table and a chart to find X , R or Z when a reactance and resistance are connected in parallel, is given in Chapter 38 Sect. 9(iii) Table 43.

A simple graphical method for determining the resultant impedance of a reactance and a resistance in parallel is given in Fig. 4.20E where OA and OB represent R and X respectively and OD is drawn at right angles to the hypotenuse. The length OD represents the scalar value of the resultant impedance, while the angle DOA is equal to the phase angle ϕ between the applied voltage and the resultant current.

For other graphical methods for impedances in parallel see Reed, C.R.G. (letter) W.E. 28.328 (Jan. 1951) 32; Benson, F. A. (letter) W.E. 28.331 (April 1951) 128.

FIG. 4.20 E

Fig. 4.20E. Impedances in parallel.

(iv) Series-parallel combinations of L , C and R

Some simple combinations of L , C and R are described in (A) to (E) below. The general procedure for other combinations is described in (F) below.

(A) Parallel tuned circuit with losses in both L and C (Fig. 4.21A)

$$\text{Impedance of branch (1): } Z_1 = R_1 + j\omega L \quad (4a)$$

$$\text{Impedance of branch (2): } Z_2 = R_2 - j/\omega C \quad (4b)$$

Let Z = total impedance of Z_1 and Z_2 in parallel.

$$\text{Then } Z = \frac{Z_1 Z_2}{Z_1 + Z_2} = \frac{(R_1 + j\omega L)(R_2 - j/\omega C)}{(R_1 + R_2) + j(\omega L - 1/\omega C)} \quad (4c)$$

Multiplying both numerator and denominator by $(R_1 + R_2) - j(\omega L - 1/\omega C)$, we have

$$Z = \frac{(R_1 R_2 + j\omega L R_2 - jR_1/\omega C + L/C)[R_1 + R_2 - j(\omega L - 1/\omega C)]}{(R_1 + R_2)^2 + (\omega L - 1/\omega C)^2} \quad (5)$$

$$\text{Let } Z = \frac{A + jB}{(R_1 + R_2)^2 + (\omega L - 1/\omega C)^2} \quad (6)$$

and let us now determine the values of A and B :

$$\begin{aligned} \text{Numerator} &= R_1^2 R_2 + jR_1 R_2 \omega L - jR_1^2/\omega C + R_1 L/C + R_1 R_2^2 + jR_2^2 \omega L \\ &\quad - jR_1 R_2/\omega C + R_2 L/C - jR_1 R_2 \omega L + R_2 \omega^2 L^2 - R_1 L/C \\ &\quad - j\omega L^2/C + jR_1 R_2/\omega C - R_2 L/C + R_1/\omega^2 C^2 + jL/\omega C^2 \\ &= R_1^2 R_2 + R_1 R_2^2 + R_2 \omega^2 L^2 + R_1/\omega^2 C^2 + j[R_2^2 \omega L - R_1^2/\omega C \\ &\quad - \omega L^2/C + L/\omega C^2]. \end{aligned}$$

$$\text{Therefore } A = R_1 R_2 (R_1 + R_2) + R_2 \omega^2 L^2 + R_1/\omega^2 C^2 \quad (7)$$

$$\text{and } B = R_2^2 \omega L - R_1^2/\omega C - (L/C)(\omega L - 1/\omega C) \quad (8)$$

which values should be used in eqn. (6).

Note that A divided by the denominator (eqn. 6) is the effective resistance of the total circuit, while B divided by the denominator is the effective reactance.

The magnitude of the impedance may be obtained most readily from eqn. (4c) by replacing Z_1 and Z_2 in the numerator only by $Z_1 \angle \phi_1$ and $Z_2 \angle \phi_2$ respectively.

$$Z = \frac{(Z_1 \angle \phi_1)(Z_2 \angle \phi_2)}{(R_1 + R_2) + j(\omega L - 1/\omega C)} = \frac{Z_1 Z_2 \angle (\phi_1 + \phi_2)}{(R_1 + R_2) + j(\omega L - 1/\omega C)} \quad (9)$$

$$\text{where } Z_1 = \sqrt{R_1^2 + \omega^2 L^2}$$

$$\text{and } Z_2 = \sqrt{R_2^2 + 1/\omega^2 C^2}$$

$$\text{whence } |Z| = \left[\frac{(R_1^2 + \omega^2 L^2)(R_2^2 + 1/\omega^2 C^2)}{(R_1 + R_2)^2 + (\omega L - 1/\omega C)^2} \right]^{\frac{1}{2}} \quad (10)$$

The phase angle is given by $\tan^{-1} B/A$

$$\text{i.e. } \phi = \tan^{-1} \left[\frac{R_2^2 \omega L - R_1^2 / \omega C - (L/C)(\omega L - 1/\omega C)}{R_1 R_2 (R_1 + R_2) + R_2 \omega^2 L^2 + R_1 / \omega^2 C^2} \right] \quad (11)$$

When $LC\omega^2 = 1$, eqn. (10) may be reduced to

$$|Z| = \frac{L}{C} \cdot \frac{[1 + (C/L)(R_1^2 + R_2^2) + (C^2/L^2) R_1^2 R_2^2]^{\frac{1}{2}}}{R_1 + R_2} \quad (12)$$

$$\text{or } |Z| \approx (L/C)(R_1 + R_2) \quad (13)$$

with an error $< 1\%$ provided $Q > 10$

where $Q = \omega L/(R_1 + R_2)$.

Fig. 4.21. (A) Network incorporating 4 elements for impedance calculations (B) Simplified network with 3 elements.

(B) Parallel tuned circuit with loss in L only (Fig. 4.21B)

This is a special case of (A) in which $R_2 = 0$.

It may be shown that eqn. (5) becomes

$$Z = \frac{R - j\omega [CR^2 + L(\omega^2 LC - 1)]}{\omega^2 C^2 R^2 + (\omega^2 LC - 1)^2} \quad (14)$$

The magnitude of the impedance derived from eqn. (10) becomes

$$|Z| = \left[\frac{R^2 + \omega^2 L^2}{\omega^2 C^2 R^2 + (\omega^2 LC - 1)^2} \right]^{\frac{1}{2}} \quad (15)$$

The phase angle derived from eqn. (11) becomes

$$\phi = \tan^{-1} \frac{\omega[L(1 - \omega^2 LC) - CR^2]}{R} \quad (16)$$

(a) The effective reactance of eqn. (14) is zero (i.e. the power factor is unity) when

$$CR^2 = L(1 - \omega^2 LC)$$

$$\text{i.e. when } \omega^2 L^2 C = L - CR^2$$

$$\text{i.e. when } \omega = \sqrt{\frac{1}{LC} - \frac{R^2}{L^2}} \quad (17)$$

which can be written in the form

$$\text{when } \omega = \frac{1}{\sqrt{LC}} \sqrt{1 - \frac{CR^2}{L}} = \omega_0 \sqrt{1 - \frac{CR^2}{L}} \quad (18)$$

where $\omega_0 = 1/\sqrt{LC}$ is the value of ω when the resistance R is zero.

This condition, namely that the effective reactance is zero, which may also be expressed as the condition of unity power factor, is one of several possible definitions of **parallel resonance**. This is the definition used in Chapter 9. It should be noted that the expression giving the value of ω is not independent of the resistance in the circuit as is the case with series resonance.

If $LC\omega^2 = 1$, which is the condition for resonance if the resistance is zero, the impedance is given very closely, when R is small, by

$$Z \approx L/CR \quad (19)$$

The remaining possible definitions of parallel resonance are conditions to give maximum impedance. The condition of maximum impedance is sometimes called *anti-resonance*. Maximum impedance occurs under slightly different conditions for the variables C , L and ω^* .

(b) Condition of maximum total impedance when C is the variable

The maximum value of Z which can be obtained is

$$|Z|_{\max} = \frac{R_1^2 + \omega^2 L^2}{R_1} = R_1(1 + Q^2) \quad (20)$$

where $Q = \omega L/R_1$

$$\text{which occurs when } C = \frac{L}{R_1^2 + \omega^2 L^2} \quad (21)$$

This is also the condition giving unity power factor.

(c) Condition of maximum total impedance when L is the variable

The maximum value of Z which can be obtained is

$$|Z|_{\max} = \frac{2R_1}{\sqrt{1 + 4\omega^2 C^2 R_1^2} - 1} \quad (22)$$

$$\text{which occurs when } L = \frac{1 + \sqrt{1 + 4\omega^2 C^2 R_1^2}}{2\omega^2 C} \quad (23)$$

$$\text{or when } C = \frac{L}{\omega^2 L^2 - R_1^2} \quad (24)$$

If L is the variable and Q is maintained constant, the maximum value of Z which can be obtained is

$$|Z|_{\max} = Q/\omega C \quad (25)$$

$$\text{which occurs when } L = \frac{Q^2}{\omega^2 C(1 + Q^2)} \quad (26)$$

(d) Condition of maximum total impedance when the applied frequency is the variable

The maximum value of Z which can be obtained is

$$|Z|_{\max} = \frac{L}{C\sqrt{R_1^2 - \frac{L}{C}\left(\sqrt{2R_1^2 \frac{C}{L}} + 1 - 1\right)^2}} \quad (27)$$

which occurs when

$$\omega = 2\pi f = \sqrt{\frac{\sqrt{(2R_1^2 C/L)} + 1}{LC} - \frac{R_1^2}{L^2}} \quad (28)$$

In practice, for all normal values of $Q (= \omega L/R)$ as used in tuned circuits, these four cases are almost identical and the frequency of parallel resonance is approximately the same as that for series resonance.

We may summarise the resonance frequencies for the various conditions given above:

Series resonance	$LC\omega^2 = 1$
Parallel resonance (a)	$LC\omega^2 = 1 - CR^2/L$
(b)	$LC\omega^2 = 1 - CR^2/L$
(c)	$LC\omega^2 = 1 + CR^2/L$
(d)	$LC\omega^2 = \sqrt{1 + 2CR^2/L} - CR^2/L$

*See R. S. Glasgow (Book) "Principles of Radio Engineering" (McGraw-Hill Book Co., New York and London, 1936) pp. 35-44.

Note that $CR^2/L = 1/Q^2$ under conditions (a) and (b)

$CR^2/L \approx 1/Q^2$ under conditions (c) and (d).

For further information on tuned circuits see Chapter 9.

(C) Circuit of Fig. 4.21C

This is a special case of Fig. 4.21A in which

$(1/\omega C) = 0$. From eqn. (6)

$$Z = \frac{R_1 R_2 (R_1 + R_2) + R_2 \omega^2 L^2 + j \omega L R_2^2}{(R_1 + R_2)^2 + \omega^2 L^2} \quad (29)$$

From eqn. (10),

$$|Z| = R_2 \left[\frac{R_1^2 + \omega^2 L^2}{(R_1 + R_2)^2 + \omega^2 L^2} \right]^{\frac{1}{2}} \quad (30)$$

From eqn. (11)

$$\phi = \tan^{-1} \frac{\omega L R_2}{R_1 (R_1 + R_2) + \omega^2 L^2} \quad (31)$$

(D) Circuit of Fig. 4.21D

Impedance of arm (1) = $Z_1 = R_1 + j(\omega L_1 - 1/\omega C_1)$

„ „ (2) = $Z_2 = R_2 + j(\omega L_2 - 1/\omega C_2)$

Let $X_1 = \omega L_1 - 1/\omega C_1$

and $X_2 = \omega L_2 - 1/\omega C_2$

then $Z_1 = R_1 + jX_1$; $Z_2 = R_2 + jX_2$.

$$Z = \frac{Z_1 Z_2}{Z_1 + Z_2} = \frac{(R_1 + jX_1)(R_2 + jX_2)}{(R_1 + R_2) + j(X_1 + X_2)}$$

$$= \frac{(R_1 R_2 - X_1 X_2) + j(R_1 X_2 + R_2 X_1)}{(R_1 + R_2) + j(X_1 + X_2)}$$

which may be put into the form

$$Z = \frac{R_1(R_2^2 + X_2^2) + R_2(R_1^2 + X_1^2) + j[X_1(R_2^2 + X_2^2) + X_2(R_1^2 + X_1^2)]}{(R_1 + R_2)^2 + (X_1 + X_2)^2} \quad (32)$$

The magnitude of the impedance may be derived by the method used for deriving eqn. (10)—

$$|Z| = \left[\frac{(R_1^2 + X_1^2)(R_2^2 + X_2^2)}{(R_1 + R_2)^2 + (X_1 + X_2)^2} \right]^{\frac{1}{2}} \quad (33)$$

The phase angle may be derived from eqn. (32)—

$$\phi = \tan^{-1} \frac{X_1(R_2^2 + X_2^2) + X_2(R_1^2 + X_1^2)}{R_1(R_2^2 + X_2^2) + R_2(R_1^2 + X_1^2)} \quad (34)$$

(E) Circuit of Fig. 4.21E

1. Determine the impedance (Z_1) of L_1 , C_1 and R_1 in series, using eqn. (1)—

$$Z_1 = R_1 + j(\omega L_1 - 1/\omega C_1) \quad (35)$$

2. Determine the impedance (Z_2) of L_2 , C_2 and R_2 in parallel using eqn. (2) but separating the resistive and reactive components—

$$Z_2 = \frac{\frac{1}{R_2}}{\left(\frac{1}{R_2}\right)^2 + \left(\omega C_2 - \frac{1}{\omega L_2}\right)^2} - j \frac{\left(\omega C_2 - \frac{1}{\omega L_2}\right)}{\left(\frac{1}{R_2}\right)^2 + \left(\omega C_2 - \frac{1}{\omega L_2}\right)^2} \quad (36)$$

3. Determine the combined impedance (Z) by adding the resistive and reactive components of (14) and (15)—

$$Z = A + jB \quad (37)$$

$$\text{where } A = R_1 + \frac{\frac{1}{R_2}}{\left(\frac{1}{R_2}\right)^2 + \left(\omega C_2 - \frac{1}{\omega L_2}\right)^2}$$

$$\text{and } B = \omega L_1 - \frac{1}{\omega C_1} - \frac{\omega G_2 - \frac{1}{\omega L_2}}{\left(\frac{1}{R_2}\right)^2 + \left(\omega C_2 - \frac{1}{\omega L_2}\right)^2}.$$

The magnitude of the impedance is given by

$$|Z| = \sqrt{A^2 + B^2} \quad (38)$$

The phase angle ϕ is given by

$$\phi = \tan^{-1}(B/A) \quad (39)$$

where A and B have the same values as for eqn. (37).

FIG. 4.21C

FIG. 4.21D

FIG. 4.21E

Fig. 4.21. (C) (D) (E) Series-parallel networks for impedance calculations.

(F) General procedure to find the impedance of a two-terminal network

1. If possible, divide the network into two or more parallel branches, each of which is connected to the two terminals but has no other connection with any other branch.
2. Find the impedance of each branch, using the methods described in A, B and C above.

3. Determine the impedance (Z) of the network from the relation

$$\frac{1}{Z} = \frac{1}{Z_1} + \frac{1}{Z_2} + \frac{1}{Z_3} + \dots \quad (40)$$

Note : If there are more than two parallel branches it is more convenient to work in terms of admittance—see Sect. 6(v) below.

Alternatively, if the circuit cannot be divided into parallel branches, treat it as a series circuit, firstly determining the resistive and reactive components of each section, and then adding all the resistive and all the reactive values separately, as in (E).

(v) Conductance, susceptance and admittance

In an arm* containing both reactance and resistance in series, the **conductance** (G_1) of the arm is given by

$$G_1 = \frac{R_1}{R_1^2 + X_1^2} \text{ mhos} \quad (41)$$

where $X_1 = (\omega L_1 - 1/\omega C_1)$.

When there are a number of such arms in parallel, the resultant conductance is the sum of their separate conductances, that is

$$G = G_1 + G_2 + G_3 + \dots$$

The **susceptance** (B_1) of the arm under similar conditions, is given by

$$B_1 = \frac{X_1}{R_1^2 + X_1^2} \text{ mhos} \quad (42)$$

where $X_1 = (\omega L_1 - 1/\omega C_1)$.

[Inductive susceptance is regarded as positive. Capacitive susceptance is regarded as negative.]

When there are a number of such arms in parallel, the resultant susceptance is the sum of their separate susceptances,

$$B = B_1 + B_2 + B_3 + \dots \quad (43)$$

When any arm includes only resistance, the conductance of the arm is $1/R_1$ and the susceptance zero,

$$\text{i.e. } G_1 = 1/R_1 \quad B_1 = 0.$$

*An arm is a distinct set of elements in a network, electrically isolated from all other conductors except at two points.

When any arm has only inductance, the conductance of the arm is zero and the susceptance is $1/\omega L_1$,

$$\text{i.e. } G_1 = 0$$

$$B_1 = 1/\omega L_1$$

When any arm has only capacitance, the conductance of the arm is zero, and the susceptance is $-\omega C$,

$$\text{i.e. } G_1 = 0$$

$$B_1 = -\omega C$$

The following relationships hold between R , X , G and B

$$R = \frac{G}{G^2 + B^2}; \quad X = \frac{B}{G^2 + B^2} \quad (44)$$

The admittance (Y_1) of any arm containing resistance and reactance in series is given by

$$Y_1 = G_1 - jB_1 \quad (45)$$

$$\text{i.e. } Y_1 = G_1 - jB_1 = \frac{R_1 - jX_1}{R_1^2 + X_1^2} = \frac{1}{R_1 + jX_1} = \frac{1}{Z_1}, \quad (46)$$

indicating that **the admittance is the reciprocal of the impedance**.

Thus the value of the admittance may always be derived from the impedance—

$$Y = \frac{1}{Z} = \frac{1}{R + jX} \cdot \frac{R - jX}{R - jX} = \frac{R - jX}{R^2 + X^2} \quad (46a)$$

$$\text{Similarly } Z = \frac{1}{Y} = \frac{1}{G - jB} \cdot \frac{G + jB}{G + jB} = \frac{G + jB}{G^2 + B^2} \quad (46b)$$

The negative sign in front of jB in eqn. (45) deserves special attention—

Admittance of inductive arm (R and L in series):

$$Y = G - jB = \frac{R - j\omega L}{R^2 + \omega^2 L^2} \quad (47)$$

Admittance of capacitive arm (R and C in series):

$$Y = G + jB = \frac{R + j/\omega C}{R^2 + 1/\omega^2 C^2} = \frac{\omega^2 C^2 R + j\omega C}{\omega^2 C^2 R^2 + 1} \quad (48)$$

The admittance of any arm containing resistance, capacitance and inductance in series (Fig. 4.20A) is given by

$$Y = G - jB \quad (49)$$

$$\text{where } G = \frac{R}{R^2 + X^2}$$

$$X = (\omega L - 1/\omega C)$$

$$\text{and } B = \frac{X}{R^2 + X^2} = \frac{(\omega L - 1/\omega C)}{R^2 + (\omega L - 1/\omega C)^2}$$

$$\text{therefore } Y = \frac{R - j(\omega L - 1/\omega C)}{R^2 + (\omega L - 1/\omega C)^2} \quad (50)$$

Values of admittance for various series combinations are included in the table in Sect. 6(iii).

Admittance of parallel-connected impedances

$$\begin{aligned} L \text{ and } R \text{ in parallel: } \quad G &= G_1 + G_2 = 0 + 1/R = 1/R \\ B &= B_1 + B_2 = 1/\omega L + 0 = 1/\omega L \\ \text{therefore } Y &= G - jB = (1/R) - j(1/\omega L) \end{aligned}$$

Similarly

$$\begin{aligned} C \text{ and } R \text{ in parallel: } \quad Y &= G - jB = (1/R) + j\omega C \\ L \text{ and } C \text{ in parallel: } \quad Y &= G - jB = j(\omega C - 1/\omega L) \\ L, C \text{ and } R \text{ in parallel: } \quad Y &= G - jB = (1/R) + j(\omega C - 1/\omega L) \end{aligned}$$

See also table of Parallel Combinations of L , C and R —Column 5, in Sect. 6(iii).

Admittance of series-parallel-connected impedances

When there are a number of arms in parallel, each arm including resistance and reactance in series,

Arm (1) : $Z_1 = R_1 + jX_1$ or $Y_1 = G_1 - jB_1$

Arm (2) : $Z_2 = R_2 + jX_2$ or $Y_2 = G_2 - jB_2$

Arm (3) : $Z_3 = R_3 + jX_3$ or $Y_3 = G_3 - jB_3$ etc.

where $X_1 = (\omega L_1 - 1/\omega C_1)$ etc.

then the total admittance is given by the vector sum

$$Y = Y_1 + Y_2 + Y_3 + \dots \\ = (G_1 + G_2 + G_3 + \dots) - j(B_1 + B_2 + B_3 + \dots) \quad (51)$$

The following examples may alternatively be handled by the use of eqn. (46a) provided that the value of Z is known.

Example (A) : Fig. 4.21A

Arm (1) is inductive : $Y_1 = G_1 - jB_1$

$$G_1 = \frac{R_1}{R_1^2 + X_1^2}; B_1 = \frac{X_1}{R_1^2 + X_1^2} \quad (X_1 = \omega L)$$

Arm (2) is capacitive : $Y_2 = G_2 + jB_2$

$$G_2 = \frac{R_2}{R_2^2 + X_2^2}; B_2 = \frac{X_2}{R_2^2 + X_2^2}, \quad (X_2 = -1/\omega C)$$

Fig. 4.21F. Chart for conversion between resistance and reactance, and conductance and susceptance

$$Z = (R \pm jX) 10^n, \quad Y = (G \mp jB) 10^{-n}.$$

On collecting the terms we get

$$\begin{aligned} Y &= (G_1 + G_2) - j(B_1 + B_2) \\ &= \frac{R_1 + \omega^2 C^2 R_1 R_2 (R_1 + R_2) + \omega^4 L^2 C^2 R_2}{(R_1^2 + \omega^2 L^2)(1 + \omega^2 C^2 R_2^2)} \\ &\quad + j\omega \left[\frac{CR_1^2 - L + \omega^2 LC(L - CR_2^2)}{(R_1^2 + \omega^2 L^2)(1 + \omega^2 C^2 R_2^2)} \right] \end{aligned} \quad (52)$$

Example (B) : Fig. 4.21B.

This is a special case of (A) in which $R_2 = 0$. From eqn. (52)

$$Y = \frac{R - j\omega[L(1 - \omega^2 LC) - CR^2]}{R^2 + \omega^2 L^2} \quad (53)$$

Example (C) : Fig. 4.21C.

This is a special case of Example (A) in which $X_2 = (1/\omega C) = 0$.

$$Y = \frac{R_1(R_1 + R_2) + \omega^2 L^2 - j\omega LR_2}{R_2(R_1^2 + \omega^2 L^2)} \quad (54)$$

Example (D) : Fig. 4.21D.

$$\begin{aligned} Y_1 &= G_1 - jB_1 = \frac{R_1}{R_1^2 + X_1^2} - j \frac{X_1}{R_1^2 + X_1^2} \\ Y_2 &= G_2 - jB_2 = \frac{R_2}{R_2^2 + X_2^2} - j \frac{X_2}{R_2^2 + X_2^2} \\ Y &= \frac{R_1}{R_1^2 + X_1^2} + \frac{R_2}{R_2^2 + X_2^2} - j \left[\frac{X_1}{R_1^2 + X_1^2} + \frac{X_2}{R_2^2 + X_2^2} \right] \\ &= \frac{R_1 R_2 (R_1 + R_2) + R_1 X_2^2 + R_2 X_1^2 - j[R_1^2 X_2 + R_2^2 X_1 + X_1 X_2 (X_1 + X_2)]}{(R_1^2 + X_1^2)(R_2^2 + X_2^2)} \end{aligned} \quad (55)$$

Chart for conversion between resistance and reactance, conductance and susceptance.

Fig. 4.21F can be used in conversions between resistance and reactance, and conductance and susceptance.

Example 1. The impedance of a circuit is $1 + j 0.3$; determine its admittance.

Method : $Z = 1.0 + j 0.3$. Enter the chart on the semi-circle $R = 1.0$ and follow it until it meets the arc $X = 0.3$. The corresponding values of G and B are 0.917 and 0.275. Thus $Y = 0.917 - j 0.275$.

Example 2. The admittance of a circuit is $0.000\ 004 + j 0.000\ 013$; determine its impedance.

Method : $Y = 0.000\ 004 + j 0.000\ 013 = (0.4 + j 1.3) \times 10^5$.

Enter the chart on the lines $G = 0.4$ and $B = 1.3$.

The intersection is at $R = 0.22$, $X = 0.7$. Thus

$$Z = (0.22 - j 0.7)10^5 = 22\ 000 - j 70\ 000.$$

At series resonance, $\omega L = 1/\omega C$ and $X = 0$, so that $Y = G = 1/R$.

The admittance at any frequency is given graphically by the **Admittance Circle Diagram** (Fig. 4.22) in which the vector OY represents the admittance, where Y is any point on the circle. The diameter of the circle is equal to $1/R$ and the admittance at series resonance, when the frequency is f_0 , is represented by OA .

As the frequency of the voltage applied to the series tuned circuit (Fig. 4.20A) is increased from zero to in-

Fig. 4.22. Admittance circle diagram.

finity, so the point Y moves from O (at zero frequency) through C to A (at resonance) and thence through E to O again (at an infinite frequency). The angle ϕ is the angle by which the current i leads the applied voltage e ; when ϕ is negative the current lags behind the voltage. Thus when OY lies in the upper portion of the circle the circuit is capacitive, and when it lies in the lower portion of the circle the circuit is inductive.

Fig. 4.22.A Series form of impedance; (B) Equivalent parallel form.

FIG. 4.22 A

FIG. 4.22 B

When Y is at the point C, the admittance will be represented by OC and ϕ will be 45° ; the reactive and resistive components of the impedance will therefore be equal. At zero frequency ϕ will be $+90^\circ$ and the admittance will be zero: at infinite frequency ϕ will be -90° and the admittance will also be zero.

(vi) Conversion from series to parallel impedance

It is possible to convert from the series form $Z = R_s + jX_s$ as shown in Fig. 4.22A

Fig. 4.22C. Chart for conversion between series resistance and reactance and equivalent parallel resistance and reactance.

to the equivalent parallel form (B) and vice versa.

$$R_p = \frac{R_s X_p^2}{R_s^2 + X_p^2} = \frac{X_p}{\frac{X_p}{R_p} + \frac{R_p}{X_p}} \quad (56)$$

$$X_s = \frac{X_p R_p^2}{R_p^2 + X_p^2} = \frac{R_p}{\frac{X_p}{R_p} + \frac{R_p}{X_p}} \quad (57)$$

The following approximations hold with an error within 1%:

$$(1) \text{ If } R_p > 10X_p, \quad \text{or if } R_s < 0.1 X_s, \\ \text{then } R_p \approx X_p^2/R_p; \quad X_s \approx X_p \quad (58)$$

$$\text{and } R_p \approx X_s^2/R_s; \quad X_p \approx X_s. \quad (59)$$

$$(2) \text{ If } R_p < 0.1 X_p, \quad \text{or if } R_s > 10X_s, \\ \text{then } R_s \approx R_p; \quad X_s \approx R_p^2/X_p \quad (60)$$

$$\text{and } R_p \approx R_s; \quad X_p \approx R_s^2/X_s \quad (61)$$

Fig. 4.22C can be used to make this conversion.

Example 1. Find the parallel circuit equivalent to a series connection of a 10 ohm resistor (R_p) and an inductor with a reactance of 3 ohms (X_s).

Method: Enter the chart vertically from $R_s = 10$ and horizontally from $X_s = 3$. These lines intersect at $R_p = 10.9$ and $X_p = 36$, so the equivalent parallel connection requires a 10.9 ohm resistor and an inductor with a reactance of 36 ohms.

Example 2. Find the series circuit equivalent to a parallel connection of a 30 000 ohm resistor and a capacitor with a reactance of -8000 ohms.

Method: Enter the chart on the arcs $R_p = 30$ and $X_p = 8$. The intersection is at $R_s = 2$ and $X_s = 7.5$, so the appropriate series elements are $R_s = 2000$ ohms and $X_s = -7500$ ohms.

(i) Introduction to networks

A network is any combination of impedances ("elements")—whether resistances, inductances, mutual inductances or capacitances. Ohm's law may be applied either to the voltage drop in any element, or in any branch, or to the voltage applied to the whole network, involving the total network current and total network impedance, provided that the impedances of the elements are constant. Other laws and theorems which may be used for the solution of network problems are described below.

In network analysis it is assumed that the impedances of elements remain constant under all conditions; that is that the elements are **linear devices**. Some types of resistors and capacitors and all air-cored inductors are linear, but iron-cored inductors and amplifying valves are **non-linear**. Other non-linear devices include granule-type microphones, electrolytic condensers, glow lamps, barretters (ballast tubes), electric lamp filaments, temperature-controlled resistances such as thermistors*, and thyrite.† However, it is usually found that satisfactory results may be obtained by applying the average characteristics of the non-linear devices under their operating conditions. Further consideration of non-linear components is given in Sect. 7(xii).

*Thermistors are resistors with a high negative temperature coefficient. See Sect. 9(i)n.

†Thyrite is a conductor whose resistance falls in the ratio 12.6:1 every time the voltage is doubled, over a current ratio 10 000 000 to 1. See K. B. McEachron "Thyrite, a new material for lightning arresters" General Electric Review (U.S.A.) 33.2 (Feb. 1930) 92.

Rectifiers, whether thermionic or otherwise, are non-linear devices ; they are frequently represented by an equivalent circuit having a fixed series resistance in the conducting direction and infinitely high resistance in the other. This approximation is very inaccurate at low levels where they have effective resistance varying as a function of the applied voltage, while some rectifiers pass appreciable current in the reverse direction.

Most elements (resistors, capacitors and inductors) transmit energy equally in either direction and are referred to as "bilateral", but thermionic valves operate only in one direction ("unilateral") ; when the latter form part of a network it is necessary to exercise care, particularly if they are represented by equivalent circuits.

Hints on the solution of network problems

A complete solution of a network involves the determination of the current through every element (or around every mesh). With simple networks the normal procedure is to apply Kirchhoff's Laws—Sect. 7(ii)—until all the currents and their directions have been determined. The voltage drop across any element may then be derived from a knowledge of the impedance of the element and the current through it.

As a first stage it is important to simplify the circuit, and to draw an equivalent circuit diagram for analysis.

If in any arm there are two or more resistors connected in series, the equivalent circuit diagram should be drawn with

$$R = R_1 + R_2 + \dots$$

Similarly with inductance $L = L_1 + L_2 + \dots$

and with capacitance

$$C = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \dots}$$

If in any part of the circuit there are two or more elements of the same kind in parallel (whether R , L , or C) the resultant should be determined and applied to the equivalent circuit diagram.

An exception to this rule is where it is merely required to calculate the output voltage from a passive resistive 4-terminal network. In this case it is sometimes helpful to arrange the network in the form of a potential divider, or sequence of dividers, and to use the method of Sect. 7(iii).

It is very important to mark on the equivalent circuit diagram the directions or polarities of the applied voltages (whether direct or alternating) and the assumed directions of the currents ; if any one of the latter is incorrect, this will be shown by a negative sign in the calculated value. A clockwise direction for the flow of current around any mesh is conventional.

In some cases it may be found simpler to reduce a passive 4-terminal network to an equivalent T or π section—see Sect. 7(x)—than to analyse it by means of Kirchhoff's Laws.

Definitions

An **element** is the smallest entity (i.e. a distinct unit) which may be connected in a network—e.g. L , C or R .

An **arm** is a distinct set of elements, electrically isolated from all other conductors except at two points.

A **series arm** conducts the main current in the direction of propagation.

A **shunt arm** diverts a part of the main current.

A **branch** is one of several parallel paths.

A **mesh** is a combination of elements forming a closed path.

A **two-terminal network** is one which has only two terminals for the application of a source of power or connection to another network.

A **four-terminal network** is one which has four terminals for the application of a source of power or connections to other networks. The common form of four-terminal network has two input and two output terminals ; this term is used even when one input terminal is directly connected to one output terminal, or both earthed.

A **passive network** is one containing no source of power.

An **active network** is one containing one or more sources of power (e.g. batteries, generators, amplifiers).

The **input circuit** of a network is that from which the network derives power.

The **output circuit** of a network is that into which the network delivers power.

Impedance matching—two impedances are said to be matched when they have the same magnitude and the same phase angle.

Reference may also be made to I.R.E. Standard 50IRE4.S1 published in Proc. I.R.E.39.1 (Jan. 1951) 27.

Examples

An amplifier is a four-terminal active network.

An attenuator is a four-terminal passive network.

A conventional tone control is a two-terminal passive network.

Differentiating and Integrating Networks

Based on the fundamental mathematical analysis of the circuit, the following terms are sometimes used in connection with 4-terminal networks.

Differentiating Networks—(1) Series resistance and shunt inductance
or (2) Series capacitance and shunt resistance

Integrating Networks —(1) Series inductance and shunt resistance
or (2) Series resistance and shunt capacitance.

(ii) Kirchhoff's Laws

(1) **The algebraic sum of all the instantaneous values of all currents flowing towards any junction point in a circuit is zero at every instant.**

This is illustrated for d.c. in Fig. 4.23. It will be seen that all junctions and corner points are lettered for reference. The polarities of the two batteries and their voltages are marked. The currents are marked in the obvious directions or, if this is not clear, then arbitrarily in either direction (clockwise around each loop is preferred). Both currents and voltages are referred to by the point lettering,

e.g. i_{ab} is the current flowing from a to b

i_{ba} is the current flowing from b to a

e_{bc} is the potential of point b with respect to point c .

Applying Kirchhoff's first law, at point b

$$i_{ab} + i_{fb} - i_{bc} = 0$$

or $i_{ab} + i_{fb} = i_{bc}$ which is really obvious.

Positive current is taken as flowing towards the junction point; negative current as flowing away from it.

FIG. 4.23

FIG. 4.24

Fig. 4.23. Network incorporating 3 elements and 2 d.c. voltage sources.

Fig. 4.24. Network incorporating 4 elements and one a.c. voltage source.

This law is illustrated for a.c. in Fig. 4.24 which follows the same general rules as for d.c. The instantaneous generator voltage e is shown in an arbitrary direction and the directions of the currents are then determined.

At point b ,

$$i_{ab} - i_{bf} - i_{bc} = 0$$

following the general procedure as in the d.c. case.

(2) **The total rise or fall of potential at any instant in going around any closed circuit is zero.**

This is illustrated for d.c. in Fig. 4.23, taking each closed circuit in turn and proceeding clockwise in each case. Any voltage source is here regarded as positive if it assists in sending current clockwise around the closed circuit (i.e. voltage rise). The voltage across any impedance is regarded as negative if the current arrow is in the same direction as the direction of travel around the closed circuit (i.e. voltage drop).

$$\text{Circuit } d a b c d: +6 - 16 i_{ab} - 10 i_{bc} = 0 \quad (1)$$

$$\text{Circuit } d a b f g c d: +6 - 16 i_{ab} + 8 i_{fb} - 4 = 0 \quad (2)$$

$$\text{Circuit } f b c g f: +4 - 8 i_{fb} - 10 i_{bc} = 0 \quad (3)$$

Applying Kirchhoff's first law to point b ,

$$i_{ab} + i_{fb} = i_{bc} \quad (4)$$

To find the values of the three unknown currents, it is necessary to apply three suitable equations.

[Similarly for all other cases—the total number of equations must be equal to the number of unknowns. The number of equations based on Kirchhoff's first law should be one less than the number of junction points; those based on his second law should equal the number of independent closed paths.]

Equations (1), (3) and (4) would be sufficient, since (2) merely duplicates parts of (1) and (3).

$$\text{From (4): } i_{ab} = i_{bc} - i_{fb}$$

$$\text{Applying in (1): } +6 - 16(i_{bc} - i_{fb}) - 10 i_{bc} = 0$$

$$\text{Therefore } +6 - 16 i_{bc} + 16 i_{fb} - 10 i_{bc} = 0$$

$$\text{Therefore } +6 - 26 i_{bc} + 16 i_{fb} = 0 \quad (5)$$

$$\text{Adding twice (3): } +8 - 20 i_{bc} - 16 i_{fb} = 0$$

$$\text{Therefore } +14 - 46 i_{bc} = 0$$

$$\text{Therefore } i_{bc} = 14/46 \text{ ampere.}$$

The other currents may be found by applying this value in (5) and then in (4).

Kirchhoff's Second Law is illustrated for a.c. in Fig. 4.24. Here again, as in all cases, it is assumed that we move around each loop of the network in a clockwise direction.

The voltage across—

$$\left. \begin{array}{l} \text{a resistance is } -Ri \\ \text{an inductance is } -j\omega Li \\ \text{a capacitance is } +j(1/\omega C)i \end{array} \right\} \text{ where } i \text{ is in the clockwise direction around the loop.}$$

$$\text{Circuit } d a b c d: e - R_1 i_{ab} + j(1/\omega C_1) i_{bc} = 0$$

$$\text{Therefore } R_1 i_{ab} - j(1/\omega C_1) i_{bc} = e \quad (6)$$

$$\text{Circuit } b f g c b: -j\omega L_1 i_{bf} - R_2 i_{bf} - j(1/\omega C_1) i_{bc} = 0$$

$$\text{Therefore } (j\omega L_1 + R_2) i_{bf} + j(1/\omega C_1) i_{bc} = 0 \quad (7)$$

Applying Kirchhoff's first law to junction b :

$$\begin{aligned} i_{ab} - i_{bf} - i_{bc} &= 0 \\ \text{Therefore } i_{ab} &= i_{bf} + i_{bc} \end{aligned} \quad (8)$$

Adding (6) and (7)

$$\begin{aligned} R_1 i_{ab} + (j\omega L_1 + R_2) i_{bf} &= e \\ R_1 i_{bf} + R_1 i_{bc} + (j\omega L_1 + R_2) i_{bf} &= e \\ \text{Therefore } R_1 i_{bc} + (R_1 + R_2 + j\omega L_1) i_{bf} &= e \end{aligned} \quad (9)$$

$$\begin{aligned} \text{Multiplying (7) by } (-jR_1\omega C_1), \text{ remembering that } j^2 &= -1, \\ R_1 i_{bc} + (R_1\omega^2 L_1 C_1 - jR_1 R_2\omega C_1) i_{bf} &= 0 \end{aligned} \quad (10)$$

Subtracting (10) from (9),

$$[(R_1 + R_2 - R_1\omega^2 L_1 C_1) + j(\omega L_1 + R_1 R_2\omega C_1)] i_{bf} = e \quad (11)$$

which gives the value of i_{bf} when e is known.

The value of i_{bc} may be found by substituting this value of i_{bf} in eqn. (7); i_{ab} may then be determined by eqn. (8).

(iii) Potential Dividers

The fundamental form of potential divider (also known as voltage divider or potentiometer) is shown in Fig. 4.25. Here a direct line voltage E is "divided" into two

voltages E_1 and E_2 , where $E = E_1 + E_2$. If no current is drawn from the junction (or tap) B, the voltage across BC is given by

$$E_2 = \left(\frac{R_2}{R_1 + R_2} \right) E, \quad (1)$$

$$\text{and } I_1 = I_2 = E/(R_1 + R_2) \quad (2)$$

FIG. 4.25

Fig. 4.25. Potential divider across a d.c. line.

On load

When a current I_3 is drawn from B, the simplest analysis is to consider the effective load resistance R_3 which will draw a current I_3 at a voltage E_2' , i.e. $R_3 = E_2'/I_3$. We now have resistances R_2 and R_3 in parallel, and their total effective resistance is therefore

$$R' = R_2 R_3 / (R_2 + R_3).$$

In this case the voltage divider is composed of R_1 and R' in series, and the voltage at the point B is given by

$$\begin{aligned} E_2' &= \left(\frac{R'}{R_1 + R'} \right) E \\ &= \left(\frac{R_2 R_3}{R_1 R_2 + R_1 R_3 + R_2 R_3} \right) E \\ E_2' &= \left(\frac{R_2}{R_1 + R_2} \right) E - \left(\frac{R_1 R_2}{R_1 + R_2} \right) I_3 \end{aligned} \quad (3)$$

The first term on the right hand side is the no-load voltage E_2 ; the second term is the further reduction in voltage due to I_3 —this being a linear equation.

FIG. 4.26

Fig. 4.26. Graphical method for determining the output voltage from a potential divider.

FIG. 4.27

Fig. 4.27. A potential divider with a load in the form of another potential divider.

Eqn. (3) may be plotted* as in Fig. 4.26 where, as a typical example, $E = 250$ V, $R_1 = 10\,000$ and $R_2 = 15\,000$ ohms, so that $(R_1 + R_2) = 25\,000$ ohms. E_2 , for

*Cundy, P. F. "Potential Divider Design," W.W. 50.5 (May 1944) 154.

no load, is obviously 150 volts (point B) while point C is for the condition of maximum current (I_{max}) and zero voltage. The latter may be determined by putting $E_2' = 0$ in eqn. (3) which gives

$$I_{max} = E/R_1 \quad (4)$$

In this condition we have, effectively, a resistance R_1 only, in series with a load of zero resistance.

If points B and C in Fig. 4.26 are joined by a straight line, we may then determine the voltage for any value of load current (I_3) between zero and maximum. For example, with a load current of 10 mA, the voltage will be 90 V (point D).

It is sometimes useful to calculate on the basis of a drop in voltage (based on the no-load voltage E_2) of so many volts per milliamp of load current; in this case the drop is 150 volts for 25 mA, or 6 volts per milliamp. This rate of voltage drop is actually the negative slope of the line BC.

The equivalent series source resistance (R_s) is given by

$$R_s = \frac{E_2}{I_{max}} = \frac{150}{25 \times 10^{-3}} = 6000 \text{ ohms.}$$

This may be put into the alternative form

$$R_s = \frac{R_1 R_2}{R_1 + R_2} \quad (5)$$

“**Regulation**” is defined differently in American and British practice.

American definition: The percentage voltage regulation is the difference between the full-load and no-load voltages, divided by the *full-load* voltage and multiplied by 100.

British definition: The percentage voltage regulation is the difference between the full-load and no-load voltages, divided by the *no-load* voltage and multiplied by 100.

In the example above for a current of 10 mA,

$$\text{Regulation} = \frac{150 - 90}{150} \times 100 = 40\% \text{ by British definition.}$$

The line BD in Fig. 4.26 may be called the “**regulation characteristic**” for the conditions specified above.

To find the load current corresponding to a specified value of E_2' , eqn. (3) may be re-arranged in the form

$$I_3 = \frac{E}{R_1} - E_2' \left(\frac{R_1 + R_2}{R_1 R_2} \right) \quad (6)$$

$$\text{or } I_3 = I_{max} - E_2' \left(\frac{R_1 + R_2}{R_1 R_2} \right) \quad (7)$$

Special Case 1

If it is known that the voltage drops from E_2 at no load to E_2' for a load current I_3 , then the voltage E_x corresponding to a load current I_x is given by

$$E_x = E_2 - (E_2 - E_2')(I_x/I_3) \quad (8)$$

Special case 2

If the voltages across the load (E_x, E_y) for two different values of load current (I_x, I_y) are known, the voltage at zero load current is given by

$$E_2 = \frac{E_x I_y - E_y I_x}{I_y - I_x} \quad (9)$$

This is often useful for determining the no load voltage when the voltmeter draws appreciable current. A method of applying this with a two range voltmeter has been described*, and the true voltage is given by

*Lafferty, R. E. “A correction formula for voltmeter loading” (letter) Proc. I.R.E. 34.6 (June 1946) 358.

$$E_2 = \frac{(S - 1) E_z}{S - (E_z/E_v)} \quad (10)$$

where S = ratio of the two voltmeter scales used for the two readings E_z and E_v ,
 E_z = voltmeter reading on the higher voltage scale,
 E_v = voltmeter reading on the lower voltage scale.
 If $S = 2$, then

$$E_2 = \frac{E_z}{2 - (E_z/E_v)} \quad (11)$$

Complicated divider network

When a voltage divider has another voltage divider as its load (Fig. 4.27) the best procedure is to work throughout in resistances and voltages, and to leave currents until after the voltages have been determined. The final equivalent load resistance (R_6) must be determined before commencing calculations, then proceed—

$$R_1 \text{ in parallel with } R_5 : \quad R' = R_1 R_5 / (R_1 + R_5)$$

$$R_3 \text{ in series with } R' : \quad R'' = R_3 + R'$$

$$R'' \text{ in parallel with } R_2 : \quad R''' = R_2 R'' / (R_2 + R'')$$

$$\text{Then } E_2 = \left(\frac{R'''}{R_1 + R'''} \right) E \quad (12)$$

$$\text{and } E_4 = \left(\frac{R'}{R_3 + R'} \right) E_2 \quad (13)$$

A somewhat similar procedure may be adopted in any divider network.

(iv) Thévenin's Theorem (pronounced "tay-venin's")

This theorem* may be expressed in various ways, of which one is :

FIG. 4.26

Fig. 4.28. (A) An impedance connected to two terminals of a network (B) Thevenin's equivalent circuit.

FIG. 4.29

Fig. 4.29. (A) an impedance, carrying a current I_L , connected to two terminals of a network; (B) Norton's equivalent circuit.

The current in any impedance, Z_L , connected to two terminals of a network consisting of any number of impedances and generators (or voltage sources) is the same as though Z_L were connected to a simple generator, whose generated voltage is the open-circuited voltage at the terminals in question, and whose impedance is the impedance of the network looking back from the terminals, with all generators replaced by impedances equal to the internal impedances of these generators.

In Fig. 4.28, (A) shows an impedance Z_L whose two ends are connected to the terminals 1, 2 of any network. Diagram (B) shows Thevenin's equivalent circuit, with a generator E' and series impedance Z_{12} where :

E' is the voltage measured at the terminals 1, 2, with Z_L removed,
 and Z_{12} is the impedance of the network measured across the terminals 1, 2, when looking backwards into the network, with all generators out of operation and each replaced by an impedance equal to its internal impedance.

*For the proofs of this and subsequent theorems, see W. L. Everitt, Ref. 1 pp. 47-57.

(v) Norton's Theorem

This is similar in many ways to Thevenin's Theorem, but provides a constant current generator and a shunt impedance.

The current in any impedance Z_R , connected to two terminals of a network, is the same as though Z_R were connected to a constant current generator whose generated current is equal to the current which flows through the two terminals when these terminals are short-circuited, the constant-current generator being in shunt with an impedance equal to the impedance of the network looking back from the terminals in question.

In Fig. 4.29, (A) shows an impedance Z_L through which flows a current I_L , connected to a network. Diagram (B) shows Norton's equivalent circuit, with a constant current generator delivering a current I' to an impedance Z_{12} in shunt with Z_L . As in diagram A, the current through Z_L is I_L .

Here $I' = E'/Z_{12}$
where E' and Z_{12} are the same as in Fig. 4.28B (Thevenin's Theorem).

(vi) Maximum Power Transfer Theorem

The maximum power will be absorbed by one network from another joined to it at two terminals, when the impedance of the receiving network is varied, if the impedances (looking into the two networks at the junction) are conjugates* of each other.

This is illustrated in Fig. 4.30 where E is the generated voltage, Z_g the generator internal impedance and Z_L the load impedance. In the special case where Z_g and Z_L are pure resistances,

Z_g will become R_g

Z_L will become R_L

and maximum power transfer will occur when $R_L = R_g$.

In the general case, $Z_g = R_g + jX_g$ and $Z_L = R_L + jX_L$ while for maximum power transfer $R_L = R_g$ and $X_L = -X_g$.

In other words, if Z_g is inductive, Z_L should be capacitive, and vice versa.

If the magnitude of the load impedance may be varied, but not the phase angle, then the maximum power will be absorbed from a generator when the absolute value of the load impedance is equal to the absolute value of the impedance of the supply network.

See Ref 3 (References to networks). Sect. 7(xv).

(vii) Reciprocity Theorem

In any system composed of linear bilateral impedances, if an electromotive force E is applied between any two terminals and the current I is measured in any branch, their ratio (called the "transfer impedance") will be equal to the ratio obtained if the positions of E and I are interchanged.

In Fig. 4.31 a generator supplies a voltage E to a network, and an ammeter A reads the current I_2 . The transfer impedance is E/I_2 . If now E and A are reversed, the new transfer impedance will have the same value as previously. In other words, E being unchanged, the ammeter reading in the new position will be the same as previously.

This theorem proves that a network of bilateral impedances transmits with equal effectiveness in both directions, when generator and load have the same impedance.

(viii) Superposition Theorem

In any network consisting of generators and linear impedances, the current flowing at any point is the sum of the currents which would flow if each generator were considered separately, all other generators being replaced at the time by impedances equal to their internal impedances.

This theorem considerably simplifies the analysis of any network containing more than one generator. It is important to note the linearity requirements, as the theorem

*Two impedances are conjugates of each other when their resistive components are equal, and their reactive components are equal in magnitude but opposite in sign.

breaks down under other conditions. It is therefore only applicable to valves when these are being operated to give negligible distortion.

Fig. 4.30. A generator, with internal impedance Z_g , connected to a load Z_L , to illustrate the maximum power transfer.

Fig. 4.31. A generator E supplying voltage to a network, with an ammeter A to read the current I_2 . The reciprocity theorem states that, when A and E are reversed, the transfer impedance E/I_2 will be unchanged.

Fig. 4.32. (A) An impedance Z in a network with current I and voltage drop ZI (B) Equivalent circuit having identical results so far as current and voltage drop are concerned, with a generator developing a voltage $E = ZI$. This illustrates the Compensation Theorem.

(ix) Compensation Theorem

An impedance in a network may be replaced by a generator of zero internal impedance, whose generated voltage at any instant is equal to the instantaneous potential difference produced across the replaced impedance by the current flowing through it.

This is illustrated in Fig. 4.32 where in (A) a current I is flowing through an impedance Z with a voltage drop IZ . This is equivalent to an identical network, as in (B), where Z has been replaced by a generator of zero internal impedance, whose generated voltage (E) is equal in magnitude to IZ , and is in a direction opposing the flow of current.

(x) Four-terminal networks

The most common fundamental types of four terminal networks are illustrated in Fig. 4.33, where (A) is a T section, (B) is a Π section and (C) a Lattice section. Both A and B are called 3 element networks, and C a 4 element network, from the number of arms containing impedances. In conventional operation, the left-hand terminals 1, 2, are regarded as the input terminals, to which is connected some generator, or other network containing a generator. Terminals 3, 4, are normally regarded as the output terminals, across which is connected a load impedance Z_L .

If we are concerned only with the observable impedances between terminals, it is possible—by selecting suitable values—to convert a T section to a Π section, and vice versa, but only for one particular frequency. This equivalence is independent of the character of the generator or load.

Equivalent T section

$$Z_1 = \frac{Z_A Z_B}{Z_A + Z_B + Z_C}$$

$$Z_2 = \frac{Z_B Z_C}{Z_A + Z_B + Z_C}$$

$$Z_3 = \frac{Z_A Z_C}{Z_A + Z_B + Z_C}$$

Equivalent Π section

$$Z_A = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_1 Z_3}{Z_2}$$

$$Z_B = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_1 Z_3}{Z_3}$$

$$Z_C = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_1 Z_3}{Z_1}$$

(14)

The bridged T section of Fig. 4.33E may be reduced to the equivalent T section of Fig. 4.33F, or vice versa, by using the same equivalent values as for equivalent T and Π sections (above).

Any complex four-terminal network can be reduced, at a single frequency, to a single T or Π section. The procedure is to measure (or calculate) the three constants : Z_{o1} = the impedance at the input terminals when the output terminals are open-circuited.

Z_{o2} = the impedance at the output end looking back into the network with the input terminals open-circuited.

Z_{s1} = the impedance at the input end with the output terminals short-circuited.

When these are known, the constants for the equivalent T and Π sections are :

Equivalent T section

$$Z_1 = Z_{o1} - \sqrt{Z_{o2}(Z_{o1} - Z_{s1})}$$

$$Z_2 = Z_{o2} - \sqrt{Z_{o2}(Z_{o1} - Z_{s1})}$$

$$Z_3 = \sqrt{Z_{o2}(Z_{o1} - Z_{s1})}$$

Equivalent Π section

$$\left. \begin{aligned} Z_A &= \frac{Z_{s1}Z_{o2}}{Z_{o2} - \sqrt{Z_{o2}(Z_{o1} - Z_{s1})}} \\ Z_B &= \frac{Z_{s1}Z_{o2}}{\sqrt{Z_{o2}(Z_{o1} - Z_{s1})}} \\ Z_C &= \frac{Z_{s1}Z_{o2}}{Z_{o1} - \sqrt{Z_{o2}(Z_{o1} - Z_{s1})}} \end{aligned} \right\} \quad (15)$$

It would also be possible to derive expressions for the equivalent sections, using Z_{s2} in place of Z_{s1} , where Z_{s2} = impedance at the output end with the input terminals short-circuited.

A lattice network may be reduced to an equivalent T or Π network (see any suitable text-book) but it is interesting to note that it is essentially a "bridge" circuit. Fig. 4.33 (C) may be re-drawn as in (D) without any change being made.

Four-terminal networks are considered further in Sect. 8 ; they may also be treated as multi-mesh networks as in Sect. 7(xi) below.

(xi) Multi-Mesh Networks

A typical flat multi-mesh network is shown in Fig. 4.33G. A "flat" network is defined as one which can be flattened out without having any lines crossing over each other ; the treatment in this handbook is limited to flat networks. Junctions at which the current can divide are called branch points (A, B, C, D, E). In Fig. 4.33G there are 5 meshes, and the circulating mesh current of each is marked (I_1, I_2 , etc.) in the conventional clockwise direction. The simplest form of solution is by means of the **Mesh Equations**. The basis for the use of these equations is given in Ref. 4, Sect. 7(xv). Impedances in the network are numbered Z_{10}, Z_{20} , etc., when they form part of one mesh only (mesh 1, mesh 2, etc.). Impedances which are common to two meshes are numbered Z_{12}, Z_{13} , etc., and are called **mutual impedances**, the

FIG. 4.33

Fig. 4.33. Four Terminal Networks (A) T Section (B) Π Section (C) Lattice Section (D) Lattice Section redrawn in the form of a bridge (E) Bridged T Section (F) T Section equivalent to Bridged T.

suffixes indicating the meshes to which they are common. The applied alternating voltages are also numbered E_1, E_2 , etc. where the suffix indicates the mesh number. If there is more than one voltage source in any mesh, E_1 etc. will indicate the vector sum of these voltages.

There must be the same number of mesh equations as there are meshes in the network. The mesh equations are written in the general form for n meshes as

$$\left. \begin{aligned} Z_{11}I_1 + Z_{12}I_2 + Z_{13}I_3 + \dots Z_{1n}I_n &= E_1 \\ Z_{21}I_1 + Z_{22}I_2 + Z_{23}I_3 + \dots Z_{2n}I_n &= E_2 \\ \vdots &\vdots \\ Z_{n1}I_1 + Z_{n2}I_2 + Z_{n3}I_3 + \dots Z_{nn}I_n &= E_n \end{aligned} \right\} \quad (16)$$

where each Z is of the form $R + j(\omega L - 1/\omega C)$ and Z_{11}, Z_{22} , etc. is called the **self-impedance** of the individual mesh, i.e., the impedance round the mesh if all other branches of the network other than those included in the mesh in question were open-circuited.

For example, in Fig. 4.33G—

$$\begin{aligned} Z_{11} &= Z_{10} + Z_{13} + Z_{12} \\ &= R_{10} + jX_{10} + R_{13} + jX_{13} + R_{12} + jX_{12} \\ &= R_{10} + j(\omega L_{10} - 1/\omega C_{10}) + R_{13} + j(\omega L_{13} - 1/\omega C_{13}) \\ &\quad + R_{12} + j(\omega L_{12} - 1/\omega C_{12}) \end{aligned}$$

$$\text{i.e. } Z_{11} = (R_{10} + R_{13} + R_{12}) + j[(\omega L_{10} + \omega L_{13} + \omega L_{12}) - (1/\omega C_{10} + 1/\omega C_{13} + 1/\omega C_{12})] \quad (17)$$

Note that Z_{21} is the same as Z_{12} etc. and that the signs of the mutual impedances may be positive or negative (see below).

An impedance that is common to two branches is considered to be a positive **mutual impedance** when the arrows representing the corresponding mesh currents pass through the impedance in the same direction; or a negative mutual impedance if the arrows pass through the impedance in opposite directions.

Thus in Fig. 4.33G the arrows representing the corresponding mesh currents pass through the impedances Z_{13}, Z_{13}, Z_{24} and Z_{34} in opposite directions, so that these constitute negative mutual impedances, and have negative signs in eqn. (16).

A **mutual inductance** may be defined as positive or negative according to whether it acts with a polarity the same as, or opposite to, that of a corresponding common inductance*.

FIG. 4.33 G

Fig. 4.33G. Typical multi-mesh network.

FIG. 4.33 H

Fig. 4.33H. Simple 2-mesh network.

A simple example is the 2-mesh network of Fig. 4.33H. Applying eqn. (16) we have

$$Z_{11} = R_{10} + j[\omega L_{10} - 1/\omega C_{12}] \quad (18)$$

$$Z_{22} = R_{20} + j[\omega L_{20} - 1/\omega C_{12}] \quad (19)$$

$$Z_{12} = Z_{21} = j(1/\omega C_{12}) \quad (20)$$

Since there are two meshes, there will be two mesh equations—

$$\left. \begin{aligned} Z_{11}I_1 + Z_{12}I_2 &= E_1 \\ Z_{21}I_1 + Z_{22}I_2 &= 0 \end{aligned} \right\} \quad (21)$$

*The opposite definition is also used.

These linear simultaneous equations may be solved by elimination, but any more complicated network would have to be solved by the use of Determinants, for which see any suitable mathematical textbook.

The total current in any common branch may be determined by the difference between the two mesh currents.

The method of handling **mutual inductance** is illustrated by the 2-mesh network of Fig. 4.33I. Here

$$Z_{11} = (R_{10} + R_{12}) + j(\omega L_{10} + \omega L_{12} - 1/\omega C_{10}) \quad (22)$$

$$Z_{22} = (R_{12} + R_{20}) + j(\omega L_{12} + \omega L_{20} - 1/\omega C_{20}) \quad (23)$$

$$Z_{12} = Z_{21} = R_{12} + j(\omega L_{12} \pm \omega M_{12}) \quad (24)$$

and the two mesh equations will be as eqn. (21).

The polarity of M_{12} in eqn. (24) must be determined in accordance with the accepted convention, as described in connection with eqn. (16).

A solution of eqn. (16) by means of Determinants shows that in the general case the Determinant D is given by

$$D = \begin{vmatrix} Z_{11} & Z_{12} & \dots & Z_{1n} \\ Z_{21} & Z_{22} & \dots & Z_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ Z_{n1} & Z_{n2} & \dots & Z_{nn} \end{vmatrix} \quad (25)$$

and the current I_k in the k^{th} mesh that flows as the result of the voltage E_j acting in the j^{th} mesh is

$$I_k = E_j \frac{B_{jk}}{D} \quad (26)$$

where B_{jk} is the principal minor of D multiplied by $(-1)^{j+k}$. This minor is formed by cancelling the j^{th} row and the k^{th} column and then moving the remainder together to form a new determinant with one less row and column than D , where D is the determinant defined by eqn. (25). The row cancelled corresponds to the mesh containing the input voltage, the column cancelled to the mesh containing the required current.

Fig. 4.33 I. Two-mesh network incorporating mutual inductance.

The **input impedance** of a passive network with a single applied voltage (Fig. 4.33J) is given by

$$\text{Input impedance} = E_1/I_1 = D/B_{11} \quad (27)$$

where E_1 = voltage applied to input terminals

I_1 = input current

D = determinant defined by eqn. (25)

and B_{11} is the minor of D obtained by cancelling the first row and column.

The **transfer impedance** of a 4-terminal network (Fig. 4.33K) is defined as the ratio of the voltage applied to the input terminals to the resulting current through the load impedance connected to the output terminals (i.e., the n^{th} mesh).

FIG. 4.33 J

FIG. 4.33 K

Fig. 4.33J. Illustrating input impedance of network.

Fig. 4.33K. Four terminal network illustrating input and transfer impedances.

$$\text{Transfer impedance} = E_1/I_L = D/B_{1n} \quad (28)$$

where D = determinant defined by eqn. (25)

and B_{1n} is the minor of D obtained by cancelling the first row and n^{th} column, and applying the factor $(-1)^{n+1}$.

(xii) Non-linear components in networks

In radio engineering the principal non-linear components in networks are valves, although certain resistors and iron-cored inductances are also non-linear. The non-linearity can only be neglected when the voltage swing across any non-linear component is so limited that the characteristic is substantially constant over the range of operation.

In a non-linear component the impedance is not constant, but varies with the applied voltage*. Each such impedance must be treated as having an impedance which is a function of voltage, i.e.

$$Z = F(e).$$

The mathematical theory of circuits containing non-linear components is complicated and, in the general form, outside the scope of this handbook. Those who are interested are referred to the list at the end of this subsection.

The treatment of non-linearity in valve characteristics is covered in Chapter 27 for detection and Chapter 25 for frequency conversion. Distortion through curvature of valve characteristics is covered in Chapter 2 Sect. 9 and Chapter 13.

(xiii) Phase-shift networks

The bridge type phase-shift network of Fig. 4.34 has the advantage of providing full range phase shifting from 0 to 180°, with constant attenuation (6db) for all degrees of phase shift†.

Fig. 4.34 (A) A phase-shift network providing full range phase shifting from 0 to 180° with 6 db attenuation for all degrees of phase shift (B) vector diagram of voltage relationships.

It may be shown, when $R_1 = R_1' = 1/\omega C$, that

$$\left| \frac{E_O}{E} \right| = \frac{1}{2} \quad \text{and} \quad \phi = \tan^{-1} \left(\frac{2R_1R_x}{R_x^2 - R_1^2} \right)$$

which is illustrated by the vector diagram Fig. 4.34B, where E_{R1} and $E_{R1'}$ are equal, and both equal to E_O ; E_{Rx} and E_C are at right angles, but their vector sum is E . Point P is therefore on the circumference of a semi-circle.

*It is assumed here that the impedance is not a function of time; this occurs in the case of barretters and lamp filaments.

(xiv) Transients in Networks

The treatment of networks earlier in this Section has been on the basis of a steady applied direct voltage, or a steady alternating voltage, or a combination of the two. It is also important to know the transient currents which may flow during the period from the application of a voltage until the steady state has been reached or during the period from the disconnection of the voltage until a steady state has been reached, or due to some sudden change in operating conditions after the steady state has been reached.

The simple cases of a capacitance and inductance each in series with a resistance, on direct charge and discharge, have been covered in Sects. 4 and 5. These charge and discharge characteristics are of a logarithmic form, and non-oscillatory. However, in any network including L , C and R , the transient characteristics tend to be oscillatory. These oscillatory transients may be more or less heavily damped, and normally become of negligible value after a short period of time. On the other hand, they may continue as sustained oscillations.

Amplifiers, particularly those with feedback, should have a sufficiently damped oscillatory transient in the output circuit when the input is increased instantaneously from zero to some predetermined steady voltage (this is called "unit step" input). In practice it is more convenient to use a periodic rectangular wave input, with the time period of the "flat top" sufficiently long to allow for the decay of damped oscillatory transients. A C.R.O. is commonly used for observation of such a waveform.

Alternatively, an impulse having very short time duration may be applied to the network or amplifier. This differs from unit step input in that the input voltage returns to zero almost instantaneously.

The complete mathematical analysis of all but very simple networks is very complicated and specialized, and outside the scope of this Handbook.

For further information see Refs. 4, 7 and 8.

SECTION 8 : FILTERS

(i) *Introduction to filters* (ii) *Resistance-capacitance filters, high-pass and low-pass* (iii) *Special types of resistance-capacitance filters* (iv) *Iterative impedances of four-terminal networks* (v) *Image impedances and image transfer constant of four-terminal networks* (vi) *Symmetrical networks* (vii) *"Constant k" filters* (viii) *M Derived filters* (ix) *Practical filters* (x) *Frequency dividing networks* (xi) *References to filters.*

(i) Introduction to filters

A filter is any passive* network which discriminates between different frequencies, that is to say it provides substantially constant "transmission" over any desired range of frequencies and a high degree of attenuation for all other frequencies.

Filters are conveniently grouped as under :

Low pass filters—transmission band from zero (or some very low) frequency to a specified frequency. Attenuation for all higher frequencies.

High pass filters—transmission band from some specified frequency to very high frequencies. Attenuation for all lower frequencies.

Band pass filters—transmission band from one to another specified frequency. Attenuation for all lower and higher frequencies.

Band elimination filters—"traps."

Practical filters, particularly of the simple variety, have only a gradual change in attenuation. The sharper the required change in attenuation, the more complicated becomes the filter.

Some very simple filters are :

1. The grid coupling condenser and grid resistor of an amplifier (high pass resistance-capacitance filter).
 2. The series condenser and variable resistor of a conventional tone control (low pass resistance-capacitance, with adjustable attenuation).
 3. The smoothing filter of a power supply, including one or two inductances and two or three capacitances (low pass filter).
 4. An overcoupled i-f transformer (tuned band pass filter).
 5. A tuned aerial coil or r-f transformer (tuned narrow band pass filter).
- See Chapter 6 for mathematics.

(ii) Resistance—capacitance filters

Fig. 4.35A shows a r.c. high pass filter as for grid coupling in an amplifier. This is essentially a voltage divider in which C forms a reactive, and R a resistive, arm.

If the generator has zero resistance and if there is no loading on the output, the ratio of output to input voltages is given by

$$\frac{E_o}{E_i} = \frac{R}{R + jX_c} \quad \text{where } X_c = -1/2\pi fC.$$

Therefore $\left| \frac{E_o}{E_i} \right| = \frac{R}{\sqrt{R^2 + X^2}} = \frac{1}{\sqrt{1 + (X/R)^2}} \quad (1)$

If we select a frequency (f_1) at which $|X_c| = R$, then $|E_o/E_i| = 0.707$ which is practically equivalent to an attenuation of 3 db. This frequency is the reference point used for design ; it is called the theoretical cut-off frequency. Its value is given by†

$$f_1 = 1/(2\pi RC) \text{ c/s} \quad (2)$$

where R and C are in ohms and farads (or in megohms and microfarads). The value RC is called the **time constant** and is measured in seconds (see Sect. 4(iv)) so that

*i.e. not including a valve or generator.

†A nomogram to determine the value of f_1 is given by E. Frank "Resistance Capacitance Filter Chart" Elect. 18.11 (Nov. 1945) 164.

FIG. 4.35

Fig. 4.35. (A) is a resistance capacitance high-pass filter; (B) is a two section filter; (C) is a modified form of A, providing attenuation within top and bottom limits; (D) is the vector diagram of A.

the low frequency response of an amplifier is sometimes defined by specifying a time constant of so many microseconds. If the time constant is, say 3000 microseconds,

$RC = 3000 \times 10^{-6}$ seconds, so that

$$f_1 = 1/(2\pi \times 3000 \times 10^{-6}) = 53 \text{ c/s.}$$

Fig. 4.36 shows the attenuation in db plotted against frequency for $R = 1$ megohm and selected values of C . It will be seen that the slope of the attenuation characteristics approaches 6 db per octave (i.e. the attenuation increases by 6 db every time the frequency is halved), and is very close indeed to this value for attenuations beyond 10 db. Each of these characteristics is exactly the same shape as the other, only moved bodily sideways.

FIG. 4.36

Fig. 4.36. Attenuation in decibels versus frequency for a resistance-capacitance coupling or filter (Fig. 4.35A) in which the total resistance (R) = 1 megohm. If applied to a resistance-coupled valve amplifier, $R = R_g + r_p R_L / (r_p + R_L)$. If r_p is less than 10 000 ohms, the error in neglecting the second term is less than 1%. If the valve is a pentode, R may be taken as $(R_g + R_L)$ with a sufficient accuracy for most purposes.

If $R = 0.5$ megohm, multiply values of C by 2 and similarly in proportion for other resistances.

One of these attenuation characteristics is shown in Fig. 4.36A together with the straight line AB which is the tangent to the curve and has a constant slope of 6 db/octave (or 20 db/decade). The point of intersection between AB and the zero db line is point A which corresponds to the theoretical cut-off frequency f_1 . For ease in calculation, the "straight-line" approximate characteristic CAB is sometimes used in calculations in place of the actual attenuation characteristic, the maximum error being 3 db.

In Fig. 4.35(B) there are two such filters in cascade and further sections may also be added. A two-section filter in which $R_1 = R_2$ and $C_1 = C_2$ will have somewhat more than twice the attenuation in decibels of a single section filter, and the ultimate slope of the attenuation characteristic will approach 12 db/octave.

Fig. 4.36A. Actual and approximate attenuation characteristics, using the theoretical cut-off frequency f_1 as the reference frequency.

If C in diagram (A) is shunted by a resistance R' , as in Fig. 4.35(C), the effect is to limit the attenuation to that given by R' and R as a voltage divider, i.e., $E_o/E_i = R/(R + R')$. The shape of the attenuation characteristic at low values of attenuation is very little affected by R' .

The reactance of C in Fig. 4.35A causes a phase difference between E_o and E_i , as shown by the vector diagram (D). The phase angle is given by

$$\cos \phi = E_o/E_i \quad (3)$$

For an attenuation of 3 db, $E_o/E_i = 0.707$ and $\phi = 45^\circ$; thus E_o leads E_i by 45° .

Fig. 4.37 shows a typical **r.c. low-pass filter**, as used for tone control, decoupling in multistage amplifiers, or smoothing filters for power supplies when a large voltage drop in the filter is permissible. It is readily seen that this is the same as Fig. 4.35A except that R and C have been interchanged. The theoretical cut-off frequency f_1 , at which $X_c = R$, is therefore unchanged and equal to $1/(2\pi RC)$. Provided that the generator impedance is zero, and that there is no load across the output terminals, the ratio of output to input voltages is given by

$$\frac{E_o}{E_i} = \frac{jX_c}{R + jX_c} \text{ where } X_c = -1/2\pi fC$$

Fig. 4.37. Is a low pass resistance-capacitance filter

FIG. 4.38

FREQUENCY C/S

Fig. 4.38. Shows the attenuation characteristics for the low-pass filter of Fig. 4.37 for the values of R and C shown below:

R (ohms)	C (μF)				
	Curve A	B	C	D	E
400,000	10	20	40	80	160
200,000	20	40	80	160	320
100,000	40	80	160	320	640
50,000	80	160	320	640	1280
20,000	200	400	800	1600	3200
10,000	400	800	1600	3200	6400

$$\text{Therefore } \left| \frac{E_o}{E_i} \right| = \frac{X_c}{\sqrt{R^2 + X_c^2}} = \frac{1}{\sqrt{1 + (R/X_c)^2}} \quad (4)$$

If the generator has a resistance R_g , then R in the eqn. (4) should include R_g .

Attenuation characteristics derived from this equation are given in Fig. 4.38 in a form capable of adaptation to most problems involving limited attenuation.

The rate of attenuation approaches 6 db/octave, and the shape of the curve is a mirror-image of that for the high-pass filter (Figs. 4.35A and 4.36).

If the filter is used as a smoothing filter, the ratio E_o/E_i is frequently 0.1 or less and under these conditions (with a maximum error of 1%)—

$$\left| \frac{E_o}{E_i} \right| \approx \frac{1}{2\pi fRC} \quad (5)$$

FIG. 4.39

FIG. 4.40

Fig. 4.39 is a two section low pass resistance-capacitance filter.

Fig. 4.40 is a Parallel T Network for the complete elimination of a particular input frequency from the output voltage.

If additional filtering is required, it is possible to use two or more filter sections (Fig. 4.39). Provided that $R_1 > 10X_{c1}$; $R_2 > 10X_{c1}$ and $R_2 > 10X_{c2}$, the voltage ratio is given (with a maximum error of 3%) by

$$\left| \frac{E_o}{E_i} \right| \approx \frac{1}{40f^2 \times R_1 R_2 C_1 C_2} \quad (6)$$

(iii) Special types of resistance-capacitance filters

An important method of eliminating a particular input frequency from the output voltage is the **Parallel T Network** as in Fig. 4.40. In the usual symmetrical form*,

$$R_1 = R_2 = 2R_o; \quad C_1 = C_2 = \frac{1}{2}C_o; \quad \text{and} \quad R_1 = 1/(2\pi f C_1);$$

infinite attenuation is obtained at a frequency f where

$$f = 1/(2\pi R_1 C_1) \quad (7)$$

irrespective of the loading of the output terminals.

The mathematical analysis of the general case has been published†, showing that the unsymmetrical case provides an improvement in the discrimination.

The case with finite generator resistance and terminated into a resistive load has also been analysed‡.

(iv) Iterative impedances of four-terminal networks

A four-terminal network or filter is shown in Fig. 4.41 with a generator E_o , having a series generator impedance Z_o , applied to the input terminals, 1, 2, and a load impedance Z_L across the output terminals 3, 4. The input impedance under these conditions, looking into the network from terminals 1, 2 is shown as Z_{k1} . The output impedance, looking into the network from terminals 3, 4 is shown as Z_{k2} . When Z_L is adjusted to be equal to Z_{k1} we have a special case which is of interest when similar filter sections are to be connected together in a chain so that each section is a load on the one preceding it. Under those conditions we call Z_{k1} an **iterative impedance** of the network

We must also adjust Z_o to be equal to Z_{k2} , this being the second iterative impedance.

If the network is a single T section, as in Fig. 4.42, and if $Z_1 = Z_2$, then

$$Z_{k1} = Z_{k2} = \sqrt{Z_1(Z_1 + 2Z_3)} \quad (8)$$

and the two iterative impedances are equal.

If the network is a single L section (as in Fig. 4.42 but with $Z_2 = 0$) then the iterative impedances are given by

$$Z_{k1} = \sqrt{\frac{Z_1^2}{4} + Z_1 Z_3} + \frac{Z_1}{2} \quad (8a)$$

$$Z_{k2} = \sqrt{\frac{Z_1^2}{4} + Z_1 Z_3} - \frac{Z_1}{2} \quad (8b)$$

If we now define a quantity P , called the iterative transfer constant, such that

$$P = \log_e (I_1/I_2) \quad (9a)$$

where I_1 = input current

and I_2 = output current

the formulae for the L section may be written in the alternative forms

$$Z_{k1} = \frac{Z_1 \epsilon^P}{\epsilon^P - 1} = Z_3 (\epsilon^P - 1) \quad (9b)$$

$$Z_{k2} = Z_{k1} \epsilon^{-P}$$

$$\text{where } \cosh P = 1 + \frac{Z_1}{2Z_3} = \frac{Z_1 + 2Z_3}{2Z_3}.$$

(See Chapter 38 Sect. 21 Table 73 for hyperbolic sines, cosines and tangents.)

†Wolf, A. "Note on a parallel-T resistance-capacitance network," Proc. I.R.E. 34.9 (Sept. 1946) 659. See also Hastings, A. E. "Analysis of a resistance-capacitance parallel-T network and applications," Proc. I.R.E. 34.3 (March 1946) 126P; McGaughan, H. S. "Variation of an RC parallel-T null network," Tele-Tech. 6.8 (Aug. 1947) 48.

‡Cowles, L. C. "The parallel-T resistance-capacitance network" Proc. I.R.E. 40.12 (Dec. 1952) 1712. Corr. 42.10 (Oct. 1954) 1547.

For a T network with iterative impedances,

$$P = \cosh^{-1}[(Z_1 + Z_2 + 2Z_3)/2Z_3] \quad (10)$$

If a number of networks are connected in a chain, with each section having the same two iterative impedances Z_{k1} and Z_{k2} as Fig. 4.43, we may regard the combined networks as equivalent to a single network having iterative impedances Z_{k1} and Z_{k2} respectively. The iterative transfer constant (P) is then given by

$$P = (A_1 + A_2 + A_3) + j(B_1 + B_2 + B_3) \quad (11)$$

where P_1 = propagation constant of the first section of the network

$$= A_1 + jB_1$$

$$P_2 = A_2 + jB_2 \text{ etc.}$$

$$A_1 = \text{attenuation constant (nepers)}$$

and B_1 = phase constant (radians).

(v) Image impedances and image transfer constant of four-terminal networks

An alternative way of expressing the constants of a network is by the use of image impedances. A T network is shown in Fig. 4.44 with generator and load impedances Z_{I1} and Z_{I2} respectively. It is possible to adjust Z_A , Z_B and Z_C to give an input impedance (looking into the network from terminals 1, 2 with load connected) equal

Fig. 4.41 shows a four terminal network with generator and load.

FIG. 4.41

Fig. 4.42 is a single T section network applicable to Fig. 4.41.

FIG. 4.42

Fig. 4.43 is a combination of three networks in cascade, with iterative impedance relationships.

FIG. 4.43

Fig. 4.44 is a single T section network terminated in its image impedances.

FIG. 4.44

to Z_{I1} , and at the same time to give an output impedance (looking from terminals 3, 4 with generator connected) equal to Z_{I2} . Under these conditions the impedance on each side of terminals 1, 2 is an "image" of the other (since they are both identical)

and similarly with the impedances on each side of terminals 3, 4. The two image impedances are given by

$$Z_{I1} = \sqrt{\frac{(Z_A + Z_C)(Z_A Z_B + Z_A Z_C + Z_B Z_C)}{(Z_B + Z_C)}} \quad (12a)$$

$$Z_{I2} = \sqrt{\frac{(Z_B + Z_C)(Z_A Z_B + Z_A Z_C + Z_B Z_C)}{(Z_A + Z_C)}} \quad (12b)$$

Similarly a Π network as shown in Fig. 4.44A may have the values of the elements adjusted so that the network is terminated in its image impedances. The two image impedances are then given by

$$Z_{I1} = Z_1 \sqrt{\frac{(Z_2 + Z_3)Z_3}{(Z_1 + Z_3)(Z_1 + Z_2 + Z_3)}} \quad (13a)$$

$$Z_{I2} = Z_2 \sqrt{\frac{(Z_1 + Z_3)Z_3}{(Z_2 + Z_3)(Z_1 + Z_2 + Z_3)}} \quad (13b)$$

The two image impedances may also be expressed in terms of the open-circuit and short-circuit impedances (Sect.7(ix))

$$Z_{I1} = \sqrt{Z_{01}Z_{s1}} \quad (14)$$

$$Z_{I2} = \sqrt{Z_{02}Z_{s2}} \quad (15)$$

FIG. 4.44 A

FIG. 4.44 B

Fig. 4.44A is a single Π section network terminated in its image impedances.

Fig. 4.44B is a single L section network terminated in its image impedances.

The transfer of power is indicated by the **image transfer constant** θ whose value is given by

$$\theta = \frac{1}{2} \log \epsilon \frac{E_1 I_1}{E_2 I_2} = \log \epsilon \frac{I_1}{I_2} \sqrt{\frac{Z_{I1}}{Z_{I2}}} = \log \epsilon \sqrt{\frac{I_1}{I_2} \cdot \frac{I_2'}{I_1'}} \quad (16)$$

provided that the network is terminated in its image impedances,

where E_1 and I_1 are voltage and current at terminals 1, 2

E_2 and I_2 are voltage and current at terminals 3, 4

I_1' and I_2' are currents at terminals 1, 2 and 3, 4 respectively with transmission in the reversed direction.

FIG. 4.45

Fig. 4.45 is a combination of three networks in cascade, with image impedance relationships.

When every section of a filter is working between its image impedances, there are no reflection effects. Fig. 4.45 shows a three section group connected on an image impedance basis. This is equivalent to a single network having image impedances Z_{I1} and Z_{I4} respectively,

$$\theta = (\alpha_1 + \alpha_2 + \alpha_3) + j(\beta_1 + \beta_2 + \beta_3) = \alpha + j\beta \quad (16a)$$

where $\theta_1 = \alpha_1 + j\beta_1$, etc.

The real part ($\alpha_1 + \alpha_2 + \alpha_3 = \alpha$) of the image transfer constant θ is called the **image attenuation constant**, and the imaginary part ($\beta_1 + \beta_2 + \beta_3 = \beta$) is called the **image phase constant**.

Where the values of the elements of the T and Π networks are known, the value of the image transfer constant is given by

T Network (Fig. 4.44) :

$$\tanh \theta = \sqrt{\frac{(Z_A Z_B + Z_A Z_C + Z_B Z_C)}{(Z_A + Z_C)(Z_B + Z_C)}} \quad (16b)$$

Π Network (Fig. 4.44A) :

$$\tanh \theta = \sqrt{\frac{Z_3(Z_1 + Z_2 + Z_3)}{(Z_1 + Z_3)(Z_2 + Z_3)}} \quad (16c)$$

If the image impedances and transfer constant are known, the impedances of T, Π and L networks are given by

For T Section (Fig. 4.44) :

$$Z_C = \frac{\sqrt{Z_{I1} Z_{I2}}}{\sinh \theta} \quad (17a)$$

$$Z_B = \frac{Z_{I2}}{\tanh \theta} - Z_C \quad (17b)$$

$$Z_A = \frac{Z_{I1}}{\tanh \theta} - Z_C \quad (17c)$$

For a Π Section (Fig. 4.44A) :

$$Z_3 = \sqrt{Z_{I1} Z_{I2}} \sinh \theta \quad (17d)$$

$$Z_2 = \frac{1}{\frac{1}{Z_{I2} \tanh \theta} - \frac{1}{Z_3}} \quad (17e)$$

$$Z_1 = \frac{1}{\frac{1}{Z_{I1} \tanh \theta} - \frac{1}{Z_3}} \quad (17f)$$

For an L Section (Fig. 4.44B) :

$$Z_A = \sqrt{Z_{I1}(Z_{I1} - Z_{I2})} \quad (17g)$$

$$Z_C = Z_{I2} \sqrt{\frac{Z_{I1}}{Z_{I1} - Z_{I2}}} \quad (17h)$$

$$\cosh \theta = \sqrt{(Z_{I1}/Z_{I2})} \quad (17i)$$

(vi) Symmetrical networks

When a network is symmetrical, that is when it may be reversed in the circuit with respect to the direction of propagation without alterations in the voltages and currents external to the network, the two iterative impedances become equal to each other and to the two image impedances :

$$Z_K = Z_{K1} = Z_{K2} = Z_I = Z_{I1} = Z_{I2} \quad (18)$$

(this is sometimes called the characteristic impedance)

$$\text{Also } P = \theta = \alpha + j\beta \quad (19)$$

where α = image attenuation constant

and β = image phase constant.

(vii) "Constant k " filters

A "constant k " filter is one in which

$$Z_1 Z_2 = k^2 \quad (20)$$

where Z_1 and Z_2 are the two arms of a filter section, and k is a constant, independent of frequency. Fig. 4.46 shows a symmetrical T type section terminated in its image impedances, which is a "constant k " filter provided that $Z_1 Z_2 = k^2$. The constant k^2 has the dimensions of a resistance squared, so that we replace k^2 by R^2 in the following analysis. This requirement is fulfilled when Z_1 and Z_2 are reciprocal reactances ; the simplest case is when Z_1 is a capacitance with zero resistance and Z_2 an inductance

with zero resistance or vice versa. Some popular combinations are given below :

Original (Z_1)	Reciprocal (Z_2)
L	$C = L/R^2$
$L + r$ in series	$C = L/R^2$ in shunt with R^2/r
$C + r$ in series	$L = R^2 C$ in shunt with R^2/r
$L + C$ in series	$C' = L/R^2$ in shunt with $L' = R^2 C$
$r + L + C$ in series	R^2/r in shunt with $C' = L/R^2$ and with $L' = R^2 C$

FIG. 4.46

FIG. 4.47

Fig. 4.46 is a symmetrical T section terminated in its image impedances.

Fig. 4.47 is a symmetrical Π section terminated in its image impedances.

Z_I is called the **mid-series image impedance** in a symmetrical T section (Fig. 4.46) while Z_I' is called the **mid-shunt image impedance** in a symmetrical Π section (Fig. 4.47) :

T section : mid-series image impedance

$$Z_I = \sqrt{Z_1 Z_2 + (Z_1^2/4)} = R \sqrt{1 + (Z_1/2R)^2} \quad (21)$$

Π section : mid-shunt image impedance

$$Z_I' = \sqrt{\frac{Z_1 Z_2}{1 + Z_1/4Z_2}} = \frac{R}{\sqrt{1 + (Z_1/2R)^2}} \quad (22)$$

Therefore $Z_I Z_I' = R^2 = Z_1 Z_2$ (23)

If Z_1 is a pure reactance (X_1),

$$\text{then } Z_I = R \sqrt{1 - (X_1/2R)^2} \quad (24)$$

$$\text{and } Z_I' = \frac{R}{\sqrt{1 - (X_1/2R)^2}} \quad (25)$$

The image transfer constant θ for either T or Π sections is given by

$$\cosh \theta = 1 + (Z_1/2Z_2) \quad (25a)$$

Half sections have exactly half the image transfer constant of a full section.

$$\text{In the pass band : } \alpha = 0 \quad (25b)$$

$$\cos \beta = 1 + (Z_1/2Z_2) \quad (25c)$$

$$\text{In the stop band : } \cosh \alpha = |1 + (Z_1/2Z_2)| \quad (25d)$$

$$\text{Phase shift} = 0 \text{ or } \pm 180^\circ \quad (25e)$$

FIG. 4.48

Fig. 4.48 is a half section terminated in its image impedances.

Fig. 4.48 is a half-section terminated in its image impedances, which in this case are unequal. Two such half-sections, with the second one reversed left-to-right, are equivalent to a single T section.

$$Z_I = \sqrt{Z_1 Z_2 + (Z_1^2/4)} \quad (25f)$$

$$Z_I' = \sqrt{\frac{Z_1 Z_2}{1 + (Z_1/4Z_2)}} \quad (25g)$$

An ideal filter in which the reactances have zero loss has zero attenuation for all frequencies that make $(Z_1/4Z_2)$ between 0 and -1 ; this range of frequencies is called

the **pass band**. All other frequencies are attenuated and are said to lie in the **stop band** (or attenuation band) of the filter.

Low pass filter—constant k type

Fig. 4.49 shows three forms of simple low-pass filters of the constant k type. In each case

$$Z_1 = j\omega L$$

and $Z_2 = 1/j\omega C$.

Now $Z_1 Z_2 = R^2$, therefore $L/C = R^2$, where R may have any convenient value. The mid-series image impedance is

$$Z_I = R\sqrt{1 - (\omega L/2R)^2} = R\sqrt{1 - (f/f_0)^2} \quad (26)$$

where $f_0 = 1/\pi\sqrt{LC}$, f_0 = cut-off frequency.

When $f = f_0$, $Z_I = 0$ and there is infinite attenuation if L and C have no resistance. The mid-shunt image impedance is

$$Z_I' = \frac{R}{\sqrt{1 - (\omega L/2R)^2}} = \frac{R}{\sqrt{1 - (f/f_0)^2}} \quad (27)$$

When $f = f_0$, Z_I' becomes infinite.

Fig. 4.49. Three varieties of low-pass constant k filters: (A) T section (B) Half section (C) Π section.

With both T and Π arrangements, the ideal filter has zero attenuation for frequencies less than f_0 , a sharp cut-off at f_0 , and a very rapid attenuation immediately above f_0 . However the rate of attenuation gradually falls as the frequency is increased, and approaches 12 db/octave for the single section at frequencies much greater than f_0 .

Both image impedance characteristics are purely resistive below f_0 and purely reactive at higher frequencies.

The **phase shift** varies from zero at zero frequency to 180° at f_0 , but is constant at 180° for all frequencies higher than f_0 .

Fig. 4.50. Three varieties of high-pass constant k filters (A) T section (B) Half section (C) Π section.

High-pass filter—constant k type

Fig. 4.50 shows three forms of simple high-pass filters of the constant k type. In each case

$$Z_1 = 1/j\omega C$$

$$Z_2 = j\omega L$$

Now $Z_1 Z_2 = R^2$, therefore $L/C = R^2$, where R may have any convenient value. The mid-series image impedance is

$$Z_I = R\sqrt{1 - (1/2R\omega C)^2} = R\sqrt{1 - (f_0/f)^2} \quad (28)$$

where $f_0 = 1/(4\pi\sqrt{LC})$, f_0 = cut-off frequency.

The mid-shunt image impedance is

$$Z_I' = \frac{R}{\sqrt{1 - (1/2R\omega C)^2}} = \frac{R}{\sqrt{1 - (f_0/f)^2}} \quad (29)$$

With both T and Π arrangements, the ideal filter has zero attenuation for frequencies greater than f_0 , a sharp cut-off at f_0 , and a very rapid attenuation immediately below f_0 . However, the rate of attenuation gradually falls as the frequency is decreased, and approaches 12 db/octave for the single section for frequencies much less than f_0 .

The phase shift varies from nearly zero at very high frequencies to 180° at f_0 , but is constant at 180° for all frequencies lower than f_0 .

Both image impedance characteristics are purely resistive above f_0 , and purely reactive at lower frequencies.

Fig. 4.51. (A) T section
(B) Π section, series m -derived filters.

(viii) M-derived filters

This is a modified form of the constant k filter. Fig. 4.51A shows a T section series m -derived filter, which has the same value of Z_I as its prototype (Fig. 4.46 and eqn. 21). In fact, when $m = 1$, it becomes the prototype. In general, m may have any value between 0 and 1. It may be joined, at either end, to a constant k or m -derived section, or half-section, having an image impedance equal to Z_I . This derived filter has the same pass band and cut-off frequency f_0 as the prototype, but different attenuation characteristics with sharper cut-off and infinite attenuation at the resonant frequency of the shunt arm, provided that the elements have zero loss.

Fig. 4.51. (C) Low pass (D) High pass T section m -derived filters (E) m -derived half-section for matching purposes.

Values of Z_1 and Z_2 are as for the prototype (constant k) filter. A low-pass T section series m -derived filter is shown in Fig. 4.51C, and an equivalent high-pass section in Fig. 4.51D. In both cases the shunt arm becomes resonant at a frequency f_∞ given by

$$\text{Low pass } f_\infty = \frac{1}{\pi\sqrt{(1-m^2)LC}} \quad (30)$$

$$\text{High pass } f_\infty = \frac{\sqrt{1-m^2}}{4\pi\sqrt{LC}} \quad (31)$$

In the theoretical case when the reactances have zero loss, the shunt arm will have zero impedance and therefore infinite attenuation at frequency f_∞ .

The cut-off frequency f_0 is given by

$$f_0 = 1/(4\pi\sqrt{LC}) \quad (32)$$

and the following relationships hold.

Low pass

$$f_{\infty} = f_0 / (\sqrt{1 - m^2})$$

$$m = \sqrt{1 - (f_0/f_{\infty})^2}$$

High pass

$$f_{\infty} = f_0 \sqrt{1 - m^2} \quad (33)$$

$$m = \sqrt{1 - (f_{\infty}/f_0)^2} \quad (34)$$

The frequency of "infinite" attenuation (sometimes called the peak attenuation frequency) may be controlled by varying the value of m , which variation does not affect the image impedances.

It is generally desirable, for good attenuation characteristics, that the ratio of the cut-off frequency to the frequency of peak attenuation in a high-pass filter should be as high as possible, and not less than 1.25, and in a low pass filter it should be as low as possible and not greater than 0.8. The value of m as given by eqn. (34) is 0.6 when the ratio is 1.25 or 0.8 respectively.

The equivalent Π section series m -derived filter is shown in Fig. 4.51B but here the mid-shunt image impedance is different, and this section cannot be connected at either end to a constant k or m -derived T section except through a half-section to match the respective image impedances.

$$Z_{Im'} = Z_I' [1 + (1 - m^2)(Z_1/2R)^2] \quad (35)$$

In other respects (B) has the same characteristics as (A). An m -type half-section for matching sections having different image impedances is Fig. 4.51E, the values shown being for matching a constant k section on the left and a series m -derived Π section on the right. The value of m should be approximately 0.6 to provide the most nearly constant value of image impedance in the pass band.

Fig. 4.52. (A) T section (B) Π section shunt m -derived filters.

Two forms of shunt m -derived filters are shown in Fig. 4.52. The Π section (B) may be joined at either end to a constant k section or half-section of mid-shunt image impedance Z_I' . The T section requires the medium of a half-section to match the impedances before being so connected.

$$(A) Z_{Im} = \frac{Z_I}{1 + (1 - m^2)(Z_1/4Z_2)} \quad (36)$$

$$(B) Z_I' \text{ is as for Fig. 4.47 (Eqn. 22)}$$

$$\text{Therefore } Z_{Im}Z_{Im'} = Z_I Z_I' = R^2 \quad (37)$$

The design of multiple-section filters

A multiple-section filter is made up from any desired number of intermediate sections (either T or Π), and usually of the m -derived type, together with a terminal half-section at each end. All sections in the filter are matched at each junction on an image-impedance basis. The intermediate sections usually have different values of m such that frequencies which are only slightly attenuated by one section are strongly attenuated by another. The image impedances of these sections are far from constant over the pass band of the filter; hence the necessity for using suitable terminal half-sections.

The terminal half-sections should be designed with a value of m approximately equal to 0.6 to provide the most nearly constant image impedance characteristics in the pass band; with this value of m the image impedance is held constant within 4% over 90% of the pass band. Each of the terminal end sections should, however, be so designed that its frequency of peak attenuation is staggered with respect to the other, and the intermediate sections should then be staggered for the best overall attenuation characteristic.

The total attenuation or phase shift of the combined multi-section filter would be given by the sum of the attenuations or phase shifts respectively of the individual sections or half-sections.

When the design has been completed for all the sections in the filter, the practical form will be obtained by neglecting the junction points between sections and by adding together the values of the inductors in series in each arm, and those of the capacitors in parallel in each arm. If capacitors are in series, or inductors in parallel, the total effective value should be calculated and used in the practical form of the filter.

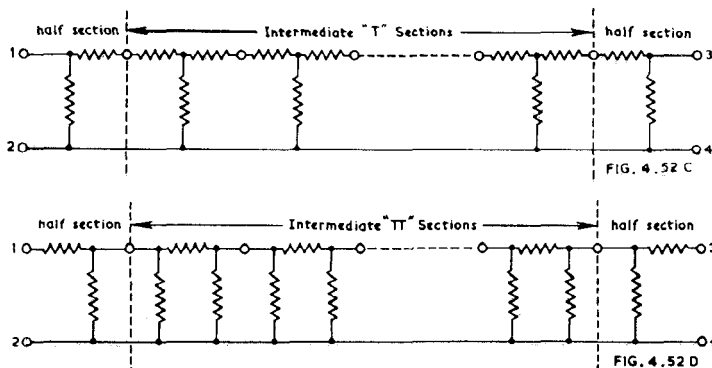

Fig. 4.52. (C and D) Method of building up a multi-section filter using T or Π intermediate sections.

References are listed in Sect. 8(xi).

(ix) Practical filters

In practice a filter network is usually terminated, not by its image impedance which is a function of frequency, but by a resistance of fixed value R where

$$R = \sqrt{Z_1 Z_2} \quad (38)$$

As a result, the impedance mismatching causes some attenuation in the pass-band, which is increased further by the unavoidable losses in the inductors. Moreover, the attenuation in the attenuation-band is less than for the ideal case, and of course never reaches infinity except in the case of a null network.

(x) Frequency dividing networks

Frequency dividing networks are of two types, the filter type (which has only approximately constant input impedance) and the constant-resistance type.

With either type, the **cross-over frequency** (f_c) is the frequency at which the power delivered to the two loads is equal. This occurs with an attenuation of 3 db for each load, with an ideal dividing network having no loss.

The nominal **attenuation per octave** beyond the crossover frequency may be: 6db: available with constant-resistance, but attenuation not sufficiently rapid for general use with loudspeaker dividing networks (Fig. 4.53A)

$$L_0 = R_0 / (2\pi f_c)$$

$$C_0 = 1 / (2\pi f_c R_0)$$

12db: available with either type, and very suitable for general use with loudspeaker dividing networks. Fig. 4.53B shows the constant-resistance type. This is a very popular arrangement.

$$L_1 = R_0 / (2\sqrt{2}\pi f_c)$$

$$L_2 = R_0 / (\sqrt{2}\pi f_c)$$

$$C_1 = 1 / (\sqrt{2}\pi f_c R_0)$$

$$C_2 = 1 / (2\sqrt{2}\pi f_c R_0)$$

The filter type has identical circuit connections but the condensers and inductors are unequal (see Chapter 21 Sect. 3).

18db : available with filter type. This is the maximum rate of attenuation normally used with loudspeaker dividing networks (Fig. 4.53C).

$$L_4 = R_0/(2\pi f_c)$$

$$L_5 = 2R_0/(2\pi f_c)$$

$$L_7 = R_0/(1+m)(2\pi f_c)$$

$$C_5 = 1/(2\pi f_c R_0)$$

$$C_6 = 1/(4\pi f_c R_0)$$

$$C_7 = (1+m)/(2\pi f_c R_0)$$

(L in henrys ; C in farads)

$$L_3 = (1+m)R_0/(2\pi f_c)$$

$$L_4 = R_0/(2\pi f_c)$$

$$L_5 = R_0/(4\pi f_c)$$

$$C_3 = 1/(\pi f_c R_0)$$

$$C_4 = 1/(1+m)(2\pi f_c R_0)$$

$$C_5 = 1/(2\pi f_c R_0)$$

See also Chapter 21 Sect. 4.

SECTION 9 : PRACTICAL RESISTORS, CONDENSERS AND INDUCTORS

(i) *Practical resistors* (ii) *Practical condensers* (iii) *Combination units* (iv) *Practical inductors* (v) *References to practical resistors and condensers.*

(i) Practical resistors

Resistors are in two main groups, wire-wound and carbon, although each group is subdivided. Wire-wound resistors are available with ordinary and non-inductive windings. Nichrome wire is suitable for operation at high temperatures but has a large temperature coefficient; it is suitable for use with $\pm 5\%$ or 10% tolerances. Advance (or constantan, or eureka) is limited in its operating temperature, but is used for tolerances of about $\pm 1\%$. Wire-wound resistors are also graded by the type of coating material.

Carbon resistors are divided into insulated and non-insulated types, while the resistance material may be composition or cracked carbon (high stability). The resistance material may be either solid (e.g. rod) or in the form of a film.

For American and English standard specifications on resistors see Chapter 38 Sect. 3(i) and (ii), including standard resistance values. For Colour Codes see Chapter 38 Sect. 2.

(a) Tolerances

Every resistor has tolerances in resistance, and the price increases as the percentage tolerance is made smaller. Composition resistors are usually obtainable with the following tolerances:

$\pm 5\%$ For critical positions only

$\pm 10\%$ Desirable for semi-critical use in radio receivers and amplifiers (e.g., plate, screen and bias resistors)

$\pm 20\%$ For non-critical positions only (e.g. grid resistors).

"High stability" carbon resistors are available with resistance tolerances of $\pm 5\%$, $\pm 2\%$ and $\pm 1\%$ (Ref. A26).

Wire-wound resistors are available with almost any desired tolerances in resistance ($\pm 5\%$, 10% are usual values in radio receivers).

Comment on tolerances in components

When a manufacturer of resistors or capacitors selects simultaneously for large quantities of each of three tolerances, $\pm 5\%$, $\pm 10\%$ and $\pm 20\%$, there is a distinct possibility that the $\pm 10\%$ tolerance group may be nearly all outside the $\pm 5\%$ tolerances, and therefore in two "channels" differing by more than 10% . Similarly with $\pm 10\%$ and $\pm 20\%$ tolerances. It is therefore good engineering practice to design on the expectation of a large percentage of components lying close to the two limits.

(b) Stability

The resistance of carbon resistors tends to drift with time. Ordinary composition resistors may drift as much as $\pm 2\%$ during storage for 3 months at 70°C and normal humidity (Ref. A27). See also Ref. A35.

Some high stability carbon resistors are limited to a maximum change in resistance of $\pm 0.5\%$ after 3 months' storage at 70°C (Ref. A26).

(c) Dissipation

Composition resistors are usually available with nominal dissipation ratings of $\frac{1}{8}$, $\frac{1}{4}$, 1, 2, 4 and 5 watts (JAN-R-11). The English RIC/113 standard (Ref. A27) includes ratings of $1/10$, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{3}{4}$, 1 and 2.5 watts. Other manufacturers produce $\frac{1}{8}$, $\frac{1}{4}$, $1\frac{1}{2}$ and 3 watt ratings.

English **high stability resistors** are available with $1/10$, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{3}{4}$, 1, $1\frac{1}{2}$ and 2 watt ratings (Ref. A26).

In accordance with the American R.M.A. Standard and JAN-R-11 characteristics *A*, *B*, *C* and *D* [see Chapter 38 Sect. 3(i)], composition resistors may be used at their maximum ratings with **ambient temperatures** up to 40°C.

The JAN-R-11 characteristic *G* and some English resistors (Refs. A3, A26, A27) may be used with maximum ratings up to an ambient temperature of 70°C. In one case (Ref. A27) higher ratings than the nominal value are permitted below 70°C ambient temperature (see below).

At ambient temperatures greater than the maximum rating, resistors may only be used with reduced dissipation and maximum voltage, in accordance with **derating curves**.

The following is a typical power dissipation derating curve for the temperature limits 40°C and 110°C (JAN-R-11 types, *A*, *B*, *C*, *D*):

Temperature	40°	50°	60°	70°	80°	90°	100°	110°
Dissipation	100%	83%	66%	50%	33%	17%	5%	0

The following is the English derating curve for high stability Grade 1, RIC/112 (Ref. A26):

Temperature	70°	80°	90°	100°	110°	120°	130°	140°	150°
Dissipation	100%	87.5%	75%	62.5%	50%	37.5%	25%	12.5%	0

The following is the English rating and derating curve for Grade 2, RIC/113 (Ref. A27):

Temperature	40°	50°	60°	70°	80°	90°	100°	110°
Dissipation	175%	150%	125%	100%	75%	50%	25%	0

A typical **voltage de-rating curve** is the American R.M.A., see Chapter 38 Sect. 3(i).

It is good engineering practice to select a composition resistor, for any particular application, such that the actual dissipation is about 60% of the resistor rated dissipation, after making allowance for any de-rating due to high ambient temperature.

Wirewound resistors are usually available with nominal dissipation ratings of $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, 3, 5, 8, 10, 12, 16, 20 watts and upwards. These are also normally available with tappings.

Wirewound resistors, vitreous enamelled, are usually available in dissipation ratings of 5 or 10 watts and upwards. These are also normally available with tappings.

Adjustable voltage dividers are manufactured in 8 or 10 watt dissipation ratings, together with larger sizes.

"Radio" voltage dividers usually have resistances of 25,000 and 15,000 ohms suitable for connection across 250 volts. The maximum dissipation is something like 5 watts.

(d) Voltage ratings

With low resistances, the applied voltage is always limited by the permissible dissipation. With high resistances there is an additional condition to be met in the maximum voltage rating. In general the maximum voltage is between 250 and 500 volts for $\frac{1}{4}$ to 1 watt ratings, although there are a few below 250 volts, some ($\frac{1}{2}$ watt and over) with maximum voltages of 700 volts or more, and some ($\frac{3}{4}$ watt and over) with maximum voltages of 1000 volts or more.

(e) Temperature rise

A temperature rise of from 40°C to 62°C (with 40°C ambient temperature) is to be expected with ordinary composition resistors at **maximum ratings**. English resistors which are rated at an ambient temperature of 70°C have a maximum surface temperature not greater than 120°C (Grade 2) or 150°C (Grade 1, high stability) (Refs. A26, A27).

A typical small wire-wound resistor may have a maximum temperature of 110°C for 1 watt or 135°C for 2 watts dissipation.

A typical large bare or organic-coating wire-wound resistor has a maximum surface temperature from 170°C to 220°C.

A typical lacquered wire-wound resistor has a **maximum surface temperature** of about 130°C.

A typical vitreous-enamelled resistor normally has a maximum surface temperature from 200°C to 270°C, but even higher temperatures are sometimes used.

High dissipation resistors should be mounted vertically to allow good air circulation, and should be spaced well away from other resistors or components. When mounted in a confined space they should be used at about half the rated maximum dissipation.

(f) Effect of temperature on resistance

The resistance of composition resistors always tends to rise as the temperature is reduced below 20° or 25°C, but at higher temperatures the resistance may either rise or fall, or may fall and then rise (for curves see Ref. A14).

For a temperature rise from 25° to 80°C, the change of resistance is usually under $\pm 7\%$ for low values of resistance.

For the same rise of temperature, high stability resistors have a change of resistance not greater than $+0 - 2.2\%$ for resistances up to 2 megohms (1 and 2 watts, Ref. A26). See also Ref. A36.

The resistance of composition resistors is also affected by a temporary severe change in ambient temperature, followed by return to normal (Ref. A35).

The resistance of a wire-wound resistor generally increases as the temperature is increased, the change being usually not more than 0.025% per °C in the case of low temperature units.

See also Chapter 38 Sect. 3(i) and (ii) for standard specifications.

The effect of soldering

Small ($\frac{1}{4}$ watt) composition resistors are subject to as much as 3% change in resistance, approximately half of which may be permanent, due to soldering; larger dissipation resistors are usually not affected more than 1% (Ref. A24). The maximum permissible change in resistance due to soldering is $\pm 2\%$ (Class 2) or $\pm 0.3\%$ (Class 1, high stability) for resistors coming under the English RIC Specifications (Refs. A26, A27).

(g) Effect of voltage on resistance

The resistance of a composition resistor decreases when the voltage applied across it increases. The percentage change increases as the resistance increases. For a 1 megohm resistor, a typical percentage fall in resistance is given by (Erie Resistor Co.):

Size	$\frac{1}{4}$	$\frac{1}{2}$	1	2	watts
Voltage from zero to	200	350	500	500	volts
Fall in resistance	2.1	2.5	1.3	1.5	%

The voltage coefficient is defined as (Ref. A27):

$$\text{Voltage coefficient} = \frac{100 (R_1 - R_2)}{R_2 (E_1 - E_2)}$$

where R_1 and E_1 are the resistance and voltage respectively at the normal maximum rating, and R_2 and E_2 are the values at one-tenth of E_1 . Limiting values of the voltage coefficient are (Ref. A27):

0.025% per volt for values below 1 megohm

0.05% per volt for values above 1 megohm.

This effect is much reduced by the use of "high stability" resistors, a typical value being 0.4% fall in resistance for 1 megohm, with voltage change from zero to 500 volts (Dubilier). The limiting value of the voltage coefficient for Specification RIC/112 (Ref. A26) is 0.002% per volt.

Some applications require a resistor whose resistance falls as the applied voltage is increased; a wide range of characteristics is available (e.g. Carborundum "Globar" ceramic resistors).

See Chapter 38 Sect. 3(i) for standard specifications.

(h) Effect of humidity on resistance

The effect of humidity is to increase the resistance by up to about 3% under normal conditions. Extreme tropical humidity may cause an increase in resistance generally less than 10%. Some insulated resistors have less than 1% change in humidity due

to humidity tests (e.g., I.R.C. type BTA). See Chapter 38 Sect. 3(i) for humidity tests and limits.

(i) Capacitance of resistors

Every resistor has a capacitance which, at the lower radio frequencies, may be considered as a capacitance between the two ends of the resistor (usually between 0.1 and 1.0 $\mu\mu\text{F}$ for composition resistors). This capacitance may usually be neglected in normal applications in radio receivers. At higher frequencies it is necessary to consider the capacitance as being distributed along the resistance element. This leads to a reduction in resistance which, unlike the end-to-end capacitance, is not removable by tuning [see (k) below]. References A5, A6, A7, A8, A9, A14.

(j) Inductance of resistors

Every resistor has an inductance, partly due to the inductance of the resistor itself and partly due to the leads. However, experience shows that at high frequencies the effect of the inductance is negligible compared with the effects of capacitance.

Typical values of inductance of composition resistors (Dubilier) are given below :

Resistance		100 ohms	1 megohm	
Inductance	$\frac{1}{4}$ watt	0.0007	0.06	μH
	1 watt	0.017	2.0	μH

Wire-wound resistors have much greater inductance than composition types, but where they must be used it is possible to adopt a "non-inductive" winding which reduces the inductance to a low value.

(k) Effect of frequency on resistance

Largely as a result of the distributed capacitance effects, the effective resistance of a rod type carbon or composition resistor falls as the frequency is increased. With resistances up to approximately 1 megohm, the theoretical curve of effective resistance plotted against frequency is given in Ref. A29 (Fig. 5). The effective resistance drops to 90% of the d.c. value

when $f = \frac{0.3}{C_d R_{dc}}$ cycles per second where C_d = total distributed capacitance of rod ;

or as an approximation, assuming $C' \approx C_d/3$, when $f \approx 1/10 C' R_{dc}$ cycles per second where C' = equivalent shunt capacitance at low frequencies (this is usually the published capacitance of the resistor).

If C' is measured with the resistor in its operating position in relation to other components and metal parts, the proximity effects will be included.

C' is constant below 4 Mc/s (Ref. A29).

References A4, A5, A6, A7, A8, A9, A14, A29.

We give below some experimental values :

Ratio of effective resistance to d.c. resistance

R (megohms d.c.) $\times f$ (Mc/s) =	0.1	0.5	1.0	5	10	20
I.R.C. type BTR ($\frac{1}{2}\text{W}$)	0.98	0.93	0.89	0.62	0.46	0.30
I.R.C. type BTA (1W)	0.95	.80	.71	.48	.37	.24
I.R.C. type BT-2 (2W)	0.80	.53	.40	.19	.14	.11
I.R.C. type BTS	1.00	.89	.79	.61	.57	—
I.R.C. type F (lower limit)	—	—	—	.84	.80	.75
Allen Bradley GB-1	0.85	.60	.48	.24	.17	.12
Allen Bradley EB $\frac{1}{2}$	0.90	.68	.57	.46	.23	.15
Speer SCT $\frac{1}{2}$	0.92	.70	.60	.35	.27	.20
Reference A14.						

(l) Noise of resistors

All resistors have an inherent minimum noise voltage due to thermal agitation ("Johnson noise") which is given at 30°C (80°F) by

$$e = 1.29 \times 10^{-10} \sqrt{\Delta f \times R}$$

where e = r.m.s. noise voltage

Δf = bandwidth in c/s of the noise measuring instrument

and R = resistance in ohms.

The thermal agitation noise of ideal resistors at 30°C is tabulated below for a bandwidth of 5 000 c/s.

Resistance	1000	10 000	100 000	1 Meg	8 Meg	ohms
Noise	0.29	0.91	2.9	9.1	25.7	μV

When a current flows through the resistor, there is a small increase in the magnitude of the thermal agitation noise.

In addition to the thermal agitation noise, carbon and metallized resistors also have a noise voltage which is approximately proportional to the direct voltage applied across the resistance. This has been called **current noise** or **resistance fluctuation noise** (Ref. A25). The frequency distribution of this additional noise component, unlike thermal agitation noise, is not uniform but its value decreases with increasing frequency from 30 c/s upwards. The amount of noise varies according to the material and construction of the resistor, and even varies considerably from one resistor to another equivalent type. The "current noise" voltages of some typical English composition resistors (Ref. A3) are given below:

Resistance	1000	10 000	100 000	1 Meg	8 Meg	ohms
Average noise	0.03	0.18	0.35	0.5	0.6	$\mu V/V$
Max. noise	0.13	0.62	1.3	1.8	2.2	$\mu V/V$

Noise values up to 20 $\mu V/V$ have been measured in commercial radio resistors (Ref. A25). The English Specification RIC/113 (Grade 2) issued June 1950, gives the limit of noise as $\log_{10} R \mu V/V$; this is equivalent to 6 $\mu V/V$ for 1 megohm.

Lower "current noise" voltages are produced by high stability cracked carbon resistors (see below) and also by palladium film resistors (Ref. A21).

In addition to the steady "current noise" fluctuations, all carbon composition resistors show abnormal **fluctuations** which do not appear to bear any simple relationship to the steady "current noise" (Ref. A21).

References A2, A3, A4, A13, A14, A15, A16, A17, A18, A19, A20, A21, A25, A32.

(m) High stability cracked carbon resistors (Refs. A10, A26, A28)

These not only have high short and long period stability and close tolerances (up to $\pm 1\%$) but also have low noise, low voltage coefficient and low temperature coefficient. They have practically no non-linearity of resistance and the inductance is very low except for the higher resistance values. They are manufactured in England with resistances from 10 ohms to 10 megohms and dissipations from $\frac{1}{8}$ to 2 watts. The extremely high resistance values are only obtainable in the higher wattage ratings. See also (b), (e), (f) and (g) above, and Chapter 38 Sect. 3(i) for standards.

The historical development, constructions and special features of cracked carbon resistors, with a very extensive bibliography, are given in Ref. A28.

These resistors are particularly suited for use in low-level high-gain a-f amplifiers, and in r-f applications up to 100 Mc/s. The inductance varies from 0.001 μH for a small 100 ohm resistor to 2 μH for a large (spiral element) 1 megohm resistor.

The I.R.C. deposited carbon resistors have tolerances of $\pm 1\%$, $\pm 2\%$ and $\pm 5\%$. The voltage coefficient is approx. 10 parts per million per volt. The temperature coefficient varies linearly from -0.025 to -0.05 (10 M Ω type DCH) or -0.065 (10 M Ω type DCF). Maximum dissipations for high stability are $\frac{1}{4}$ and $\frac{1}{2}$ watt; when high stability is not essential the values are $\frac{1}{2}$ and 1 watt.

(n) Negative temperature coefficient resistors (Thermistors)

Negative temperature coefficient resistors are sometimes used in a.c./d.c. receivers to safeguard the dial lamps when the set is first switched on. For example, one such NTC resistor has a resistance of 3 000 ohms cold and only 200 ohms when the heater current of 0.1 ampere is passing through it. By its use the initial surge on a 230 volt supply may be limited to 0.12 ampere. See also page 1267.

They are also known as "Varistors." Refs. A22, A28, A31, A34.

(o) Variable composition resistors ("potentiometers")

Standard variable composition resistors are described in Chapter 38 Sect. 3(viii). In radio receivers and amplifiers these are commonly used as diode load resistances and as volume controls (attenuators). In general it is desirable to reduce to a minimum or eliminate entirely any direct voltage across them, and any current drawn by the moving contact. Whether or not a current is passed through the terminations, noise voltages appear across any two of the three terminations and, so long as the rotor is stationary, the noise does not differ from that of a fixed resistor of equal resistance. However, when the rotor is turned, additional noise is produced which is of the order of 1 or 2 millivolts per volt applied across the extreme terminations for a speed of rotation of one full rotation per second. The noise produced at any point of the track is approximately proportional to the voltage gradient at this point; consequently the rotation-noise is greater over that portion of a logarithmic resistance characteristic where the most rapid change in resistance occurs, than for the other end of the same characteristic or for a linear characteristic. When a logarithmic characteristic is used for volume control, the rotation noise will therefore be much lower at settings for low volume where noise would be most noticeable (Ref. A30).

Some receiver manufacturers avoid the increased rotation noise caused by direct diode current in a volume control by using a fixed diode load resistor with capacitance coupling to a separate volume control having at least four times the resistance of the diode load resistor.

Variable composition resistors are available with a choice of up to 6 tapers; tapings may be provided at 38% and 62% effective rotation (Mallory). They are also available, if desired, with a switch.

(ii) Practical condensers**(a) Summary of characteristics**

A condenser has tolerances in the value of its capacitance. For most radio receiver applications, tolerances of $\pm 20\%$ or even higher may be used. The closest tolerances available with paper dielectric condensers are $\pm 10\%$ [see Chapter 38 Sect. 3(iii)]. Where closer tolerances are required it is necessary to adopt mica dielectric condensers in which the tolerance may be any standard value between $\pm 20\%$ and $\pm 2\%$ [Chapter 38 Sect. 3(v)].

The capacitance changes with frequency, with temperature, and with age.

A condenser has inductance, so that at some high frequency it becomes series-resonant.

A condenser has a.c. resistance, and dissipates energy in the form of heat; the loss is approximately proportional to the square of the frequency and is also affected by the temperature. This energy loss is partly dielectric loss (which predominates at low frequencies) and partly electrode and lead losses (which predominate at higher frequencies). It may be replaced for the purpose of calculation by the "equivalent series resistance."

A condenser thus has a complex impedance, with resistive, capacitive and inductive components. The impedance may be capacitive over one range of frequencies, inductive over another, and resistive at one or more frequencies.

A condenser with a solid or liquid dielectric takes a longer time to charge than an ideal condenser having the same capacitance; this effect is due to "dielectric absorption." When such a condenser is short-circuited it fails to discharge instantaneously—a second discharge may be obtained a few seconds later. As a consequence the capacitance of such a condenser is a function of the duration of the applied direct voltage; when it is used in an a.c. circuit, the capacitance decreases as the frequency rises. This effect is pronounced with paper dielectric, but is very small with mica dielectric condensers.

A condenser has d.c. leakage, and behaves as though it were an ideal condenser with a high resistance shunted across it.

A condenser with a solid dielectric tends to deteriorate during service, and may break down even when it is being operated within its maximum limits.

(b) The service life of a condenser

Condensers under voltage may be subject to gradual deterioration and possible breakdown, due to the solid dielectric (if any) and other insulation. This deterioration is much more rapid with some dielectrics than with others, and also varies considerably between different batches from the same factory.

Except for electrolytic condensers, there should be no deterioration with age except while under voltage; the service life may therefore be taken as the time of operation under voltage.

The maximum temperature of a condenser has a pronounced effect on the service life. In some types, every 10°C rise in temperature causes 50% decrease in life; other types are less sensitive to temperature.

The safe working voltage of a condenser at a given temperature is much less than the "ultimate dielectric strength"—as low as one tenth of this value in some cases. The "factory test" voltage is intermediate between these two values, but it is no guide to the safe working voltage. The only satisfactory procedure, if long life is essential, is to obtain from the manufacturer the safe working voltage at the proposed temperature of operation.

Condensers for operation on a.c. should have maximum a.c. ratings for safe working voltage, frequency and temperature. The peak operating voltage, whether a.c. or pulse, should be within the maximum voltage rating. The maximum surge voltage (usually during "warming up") should be within the surge rating, if quoted, or alternatively should not exceed the maximum working voltage by more than 15%.

(c) Electrolytic condensers*

An electrolytic condenser provides more capacitance in a given space and at a lower cost per microfarad than any other. It is usually manufactured with a capacitance of $4\mu\text{F}$ or more. The capacitance **tolerances** may be -20% , $+100\%$, or -20% , $+50\%$, while JAN-C-62 permits $+250\%$. Unlike other types, electrolytic condensers may only be used on substantially direct voltage, and they must be correctly connected with regard to polarity. Electrolytic condensers are generally used in radio receivers and amplifiers with a steady direct voltage plus an a.c. ripple. The highest rated voltage rarely exceeds 500 V peak, even for use under the most favourable conditions.

The capacitance increases somewhat with **increase of temperature**, and decreases rapidly with temperatures below -5°C . The capacitance also decreases with **age**—one dry type shows a 5% decrease in capacitance after 7000 hours operation at 20°C ambient temperature, and a 20% decrease at 40°C .

The **capacitance** at 10 000 c/s is usually less than that at low frequencies. Typical wet types at 10 000 c/s have only from 30% to 50% of the capacitance at 50 c/s. Typical dry types are better in this regard, having capacitances at 10 000 c/s from 42% to 85% of that at 50 c/s, at 20°C . However, the **temperature** has a marked effect on the capacitance versus frequency characteristic. One etched-foil type (Ref. B13) has 42% of its nominal capacitance at 20°C , 95% at 33°C , and 107% at 50°C .

The **series-resistance** of a new condenser at ordinary working temperature is fairly low (not more than 25 ohms for $8\mu\text{F}$ at 20°C , 450 V working) but it rises rapidly at higher temperatures and temperatures below 10°C . The series resistance rises considerably during life and eventually may be the cause of unsatisfactory operation of a receiver.

Among dry electrolytics, those with etched foil anodes are much inferior to those with plain foil electrodes when used for a-f by-passing, owing to their high impedance particularly at the higher frequencies. For example, at 10 000 c/s an ideal $8\mu\text{F}$ capacitor has an impedance of approximately 2 ohms, whereas typical plain-foil electrolytics have impedances from 3.5 to 6.5 ohms and those with etched-foil electrodes have impedances from 8 to 22 ohms (Ref. B13).

*The following remarks apply to aluminium electrodes. However tantalum electrodes are also used (Ref. B17).

The **dissipation factor** is a function of both frequency and temperature. One $10\text{ }\mu\text{F}$ etched-foil capacitor has a dissipation factor of 10% at 100 c/s, 68% at 1000 c/s and 92% at 10 000 c/s, at 20°C . The dissipation factor decreases rapidly with increase of temperature, and at 1000 c/s is 30% at 33°C and 13% at 50°C for the same capacitor (Ref. B13).

When electrolytic condensers are required to be operated across **voltages of more than 450 volts**, two or more condensers may be connected in series but the **effective total capacitance** will then be half (or less) that of the single unit. In such a case it is advisable to connect a resistor, say 0.25 megohm, across each capacitor.

Electrolytic condensers have **self-healing properties**—after a momentary surge of over-voltage, resulting in break-down of the dielectric, the electrolytic condenser is more likely to recover than a non-electrolytic type. Wet electrolytic condensers are very good in this respect.

Electrolytic condensers have an appreciable **leakage current**; this may be from 0.002 to 0.25 mA per microfarad and varies considerably with the type of condenser and the “working voltage,” being higher for higher values of working voltage. The maximum leakage current in milliamperes permitted by JAN-C-62 is $(0.04 \times \text{capacitance in microfarads}) + 0.3$. This is equivalent to a shunt resistor of 0.7 megohm for an $8\text{ }\mu\text{F}$ condenser, 450 V rating. At voltages lower than the working voltage, the leakage current falls, but at higher voltages it increases very rapidly. The leakage current also increases rapidly at higher temperatures.

If an electrolytic condenser is **left idle** for some days, the initial leakage may be quite substantial, but it tends to become normal after a few minutes. If the condenser has been left idle for several months, the time of recovery is longer.

The **power factor** of an electrolytic condenser may be between 2% and 3% for the best condensers and is usually between 5% and 10%. Some of the older wet types had power factors of 25% or greater.

Electrolytic condensers should not be used in positions where the **ambient temperature** is high or the alternating current component is excessive, otherwise the service life will be short. Ambient temperatures up to 50°C are always satisfactory while 60° , 65°C or 70°C is permissible for many types and some may be used at higher temperatures (e.g. 85°C).

Special types are available for very low temperatures (Ref. B18).

Electrolytic condensers are in two major groups.

Wet electrolytic condensers have vents, and must be mounted vertically with the vent unobstructed. They are valuable as first filter condensers in a rectifier system. Some wet types are used as voltage regulating devices, to limit the peak voltage during the warming-up period. All wet types have rather greater leakage currents than dry types. **Dry electrolytic condensers** are very widely used as filter and by-pass condensers. They are inferior to the wet type as regards frequent and severe voltage surges and short period overloads, when they are liable to fail permanently, but are preferable to the wet type in most other respects. They are manufactured in several forms—plain foil, etched, sprayed or fabricated foil. Most modern compact units have etched or fabricated foil, but the plain foil type has a lower impedance at radio frequencies. “Surgeproof” types are available with a safe operating voltage of 450 volts but which have heavy leakage current when the voltage exceeds 500 volts. This type is able to handle very heavy ripple currents without deterioration.

Reversible dry electrolytic condensers are manufactured, but they have higher leakage currents than standard types.

Electrolytic condensers when used as **first filter condensers** in condenser-input filters require careful consideration. The d.c. voltage plus the peak value of the ripple voltage must not exceed the rated voltage of the capacitor while the ripple current must not exceed the ripple current rating. The ripple current may be measured by a low-resistance moving iron, or thermal, meter; a moving-coil rectifier type of instrument is not suitable. Alternatively the ripple current may be calculated—see Chapter 30 Sect. 2.

Some typical **ripple current ratings** are given below (T.C.C.). Plain foil types have a higher ripple current rating than equivalent etched foil types.

Ambient temperature	20°C	40°C	60°C	70°C
8 μ F 350 V "micropack" plain foil	148	125	85	32 mA
16 μ F 350 V "micropack" plain foil	250	200	110	50 mA
8 μ F 450 V etched foil	88	67	33	10 mA
16 μ F 450 V etched foil	162	122	62	20 mA
16 μ F 450 V plain foil	300	260	160	85 mA
32 μ F 450 V plain foil	500	405	230	100 mA

With multiple capacitor units, only one of the units is normally intended for use as the first filter condenser; see catalogues for identification.

See Chapter 38 Sect. 3(x) for standard ratings.

(d) Paper dielectric condensers

Impregnated paper forms a very useful dielectric, being intermediate between electrolytic and mica condensers as regards cost, size and leakage for a given capacitance. It is usually manufactured in units from 0.001 to 0.5 μ F, larger values being built up from several smaller units in parallel in one container. The impregnating material may be resin, wax, oil or a synthetic compound. Some impregnating materials enable condensers to withstand extremely wide temperature ranges (e.g. -50° to $+125^{\circ}\text{C}$ —Sprague "Prokar" with plastic impregnant). Waxes may be used for moderate voltages and temperatures, as in radio receivers (from -30°C to $+65^{\circ}\text{C}$ for R.M.A. Class W). Other impregnants are used for higher temperatures (e.g., 85°C , as R.M.A. Class M; 100°C as T.C.C. "metalpack" and "metalmite"). The permissible insulation resistance at 25°C is not less than 5000 megohms for capacitances up to 0.15 μ F, falling to 1000 megohms for 1 μ F, but this falls rapidly at higher temperatures, being 35% of these values at 40°C .

A typical 1 microfarad wax paper condenser designed for audio frequency applications has the following characteristics:

Frequency	1000 c/s	10 000 c/s	100	360	Kc/s
Inductance	0.2	0.2	0.2	0.2	μ H
Resistance (effective)	1.1	0.43	0.3	0.25	ohms
Reactance	-159^*	-15.9^*	-1.50	0^{**}	ohms
Q	145	37	5	0	
Power factor	0.007	0.027	0.19	1	
Percentage power factor	0.7	2.7	19	100	%

* equal to ideal

** resonance

Some paper dielectric capacitors are impregnated with a high permittivity wax to reduce the dimensions of the capacitor (Ref. B13). These capacitors have less desirable electrical characteristics than those with normal waxes. At 10 000 c/s the capacitance falls to 89% of its value at 100 c/s; the capacitance varies from -19% to $+6\%$ as the temperature is varied from -30° to $+70^{\circ}\text{C}$.

Wax-impregnated paper dielectric condensers are sometimes used for grid coupling purposes from a preceding plate at high potential, but plastic-impregnated or mica dielectric is to be preferred on account of leakage. As an example, take a paper condenser with capacitance = 0.01 μ F at 40°C . The minimum insulation resistance will be $5000 \times 0.35 = 1750$ megohms. If the grid resistor has a resistance of 1 megohm and the preceding plate voltage is 175 volts, there will be a voltage of 0.1 volt on the grid as the direct result of leakage.

In most other applications the leakage may be neglected entirely.

Plastic (polystyrene) impregnated paper dielectric condensers have a very high insulation resistance, of the order of 500 000 megohms per microfarad, and are much more suitable for use as grid coupling condensers (e.g. T.C.C. Plastapacks, 50 to 5 000 μ F). A test after 9 months' handling under bad climatic conditions showed insulation resistances of 24 000 to 100 000 megohms (Aerovox Duranite, 0.01 to 0.22 μ F). These condensers have power factors as low as those of mica condensers, while the temperature coefficient of capacitance is from -100 to -160 parts in a million per $^{\circ}\text{C}$. For maximum stability they should not be operated above 60°C , but the insulation resistance remains very high even up to 75°C . These are available

in capacitances from 100 to 10 000 μF in tubular form and from 0.02 to 4 μF in rectangular metal boxes (Ref. B11).

Mineral oil is used as an impregnant for working voltages from 1000 to 25 000 volts and operating temperatures from -30° to $+71^{\circ}\text{C}$ (T.C.C. "Cathodray"). The insulation resistance of a mineral oil impregnated capacitor is greater than that with petroleum jelly impregnation, in the ratio of 2.5 to 1 at 0°C , rising to 12.5 to 1 at 70°C (Ref. B13).

Paper dielectric condensers are made in two forms—inductive, and non-inductive. The former is limited to a-f applications, while the latter may be used at radio frequencies.

Ordinary paper dielectric capacitors should not be subjected to high a.c. potentials. Special types are produced by some manufacturers for use under these conditions, for example with vibrator power packs and line filters.

For Standard Specifications see Chapter 38 Sect. 3(iii) and (iv).

Metallized paper dielectric condensers

This type utilizes a metal-sprayed or metal-evaporated paper dielectric instead of the more conventional metal foil and paper construction. This construction results in considerable reduction in size, while it also has a partial self-healing property in the case of breakdown. The insulation resistance of unlacquered condensers is quite low—of the order of 100 megohm microfarads—but some of those with a lacquered film have an average insulation resistance as high as 8000 megohm microfarads at 25°C (Refs. B14, B15).

There is a gradual reduction in the insulation resistance due to the self-healing property, the degree depending on the number of punctures. It is desirable for the total circuit resistance to be not less than 500 or 1000 ohms, to reduce the carbonising effect of the arc. However if the circuit resistance is high, there may be insufficient current to clear completely any breakdown, and the insulation resistance may fall. Consequently, this type of condenser should not be used in high impedance circuits without seeking the advice of the manufacturer.

A metallized paper dielectric unit should be used with discretion as the first filter condenser following a thermionic rectifier, since the high peak breakdown current may damage the rectifier unless the circuit resistance is sufficiently high.

The ratio of reactance to resistance (Q) of one lacquered unit with a capacitance of 2 μF is 200 at 0.5 Kc/s, 140 at 2 Kc/s and 60 at 10 Mc/s; a 0.1 μF unit has $Q = 98$ at 10 Mc/s (Ref. B15).

The inductance may be made very low, and these condensers are very useful for a-f and r-f by-passing. The usual (English) temperature limit is 71°C for d.c. operation, 60°C for a.c. In tubular form (wax-coated) these are available from 0.0001 to 2 μF with voltage ratings 150, 250, 350 and 500 V d.c. (RIC/136). Larger sizes are available with capacitances up to 20 μF (400 V d.c. or 250 V a.c.) and voltages up to 550 V d.c. (4 μF).

Voltage-temperature derating curves for Astron (U.S.A.) are 100% up to 86°C , linearly down to 38% at 120°C for units up to 1 μF ; larger units are 100% up to 76°C , down to 22% at 120°C (Ref. B16).

The effect of 5000 hours' operating life on capacitance is negligible up to 65°C and 8% at 100°C . The effect of the same operation is to increase the power factor from an initial value of 0.5% to 0.6% at 65°C , or 0.8% at 100°C (Ref. B16).

The paper is usually impregnated with wax, although mineral oil has also been used. Mineral wax impregnated units are generally preferred because of their higher breakdown voltage, although their capacitance falls about 10% as the temperature is increased from 50°C to 85°C . Mineral oil impregnated units have more constant capacitance with temperature change.

These condensers are damaged by moisture and the unit is therefore well dried initially and hermetically sealed to prevent the ingress of moisture.

Standard Specifications—Chapter 38 Sect. 3(ix).

(e) Mica dielectric condensers

Mica has very high electrical stability and very low a.c. loss. It also permits the manufacture of condensers with close tolerances in capacitance, and low leakage. It is used in the manufacture of condensers with capacitances from $5 \mu\mu\text{F}$ to $0.047 \mu\text{F}$ for radio receiver applications, with voltage ratings from 300 to 2500 V. The insulation resistance is in excess of 3000 for the cheaper grade (Class A) and 6000 megohms for other classes (American R.M.A. REC-115). The value of Q is over 1000 for a typical capacitance of $200 \mu\mu\text{F}$ at a frequency of 1 Mc/s; the maximum value of Q occurs at frequencies about 100 Kc/s.

Mica condensers are available in metal, moulded and ceramic casings [see Chapter 38 Sect. 3(v)].

"**Silvered mica**" condensers are used when very high precision is required. Such a condenser with a capacitance of $1000 \mu\mu\text{F}$ exhibits a capacitance change of less than 0.1% over a frequency range from low frequencies to 2 Mc/s. The effect of temperature on capacitance is a change of less than 60 parts in a million for 1°C temperature change (RIC/137).

A typical 0.001 microfarad silvered mica condenser has the following characteristics:

Frequency	1000 c/s	10 000 c/s	100	500	Kc/s
Resistance (effective)	0.024	0.024	0.024	0.024	ohm
Q	3400	5500	7000	5800	
Power factor	0.00029	0.00018	0.00014	0.00017	
Percentage power factor	0.029	0.018	0.014	0.017	%

Silvered mica condensers are normally available with capacitances from 5 to 20 000 $\mu\mu\text{F}$ with tolerances $\pm 1\%$, $\pm 2\%$, $\pm 5\%$, $\pm 10\%$ and $\pm 20\%$ (subject to minimum tolerance $\pm 1 \mu\mu\text{F}$) (RIC/137). The average temperature coefficient is $+25 \times 10^{-8}$ per $^\circ\text{C}$, with limits from $+5 \times 10^{-8}$ to $+50 \times 10^{-8}$ per $^\circ\text{C}$ (U.I.C.).

Standard Specifications—Chapter 38 Sect. 3(v).

(f) Ceramic dielectric condensers

Ceramic dielectric condensers may be grouped under five heads:

1. Types intended primarily for temperature compensation, having a series of negative and positive temperature coefficients with close tolerances on the coefficients.
2. Types having temperature coefficients nearly zero.
3. General purpose types with a broad spread of temperature coefficients. This may be further divided into two groups, those having positive and negative temperature coefficients.
4. Types with temperature coefficients not specified. These are available with capacitances from $0.5 \mu\mu\text{F}$ upwards.
5. High- K types having relatively poor power factors and indeterminate temperature coefficients.

The first group is intended for use in the tuned circuits of radio receivers, in which their special temperature versus capacitance characteristics are used to reduce frequency drift during warming-up and running. A condenser having a negative temperature coefficient may be used to compensate the positive temperature coefficient of the tuned circuit alone. For standard specifications see Chapter 38 Sect. 3(vi).

The second group is intended for use in tuned circuits requiring nearly constant capacitance, such as in i-f transformers.

All except High- K types have high stability and values of Q from 335 to 1000, except for capacitances less than $30 \mu\mu\text{F}$. The insulation resistance is not less than 7 500 megohms (R.M.A.).

The High- K types are not suitable for compensation purposes, but are used for by-passing and other non-critical applications. They are manufactured with capacitances up to 15 000 $\mu\mu\text{F}$, with capacitance tolerances of $\pm 20\%$. The value of Q is from 30 to 100.

(g) Gang condensers

Gang condensers usually have air dielectric, and are available in 1, 2 and 3 (occasionally 4) gang units. Some are fitted with trimmer condensers—see (h) below—while others are not. The shape of the plates may be designed to provide any desired capacitance characteristic (Refs. B5a, B5b) among which are :

(1) **Straight line capacitance** : Each degree of rotation should contribute an equal increment in capacitance.

(2) **Straight line frequency** : Each degree of rotation should contribute an equal increment in frequency.

(3) **Logarithmic Law** : Each degree of rotation should contribute a constant percentage change of frequency.

(4) **Square Law** : The variation in capacitance should be proportional to the square of the angle of rotation.

Some gang condensers have all sections identical, while others have the oscillator section with specially shaped plates to give correct tracking without the use of a padder condenser. For standard specifications, see Chapter 38 Sect. 3(vii).

The normal construction incorporates an earthed rotor, but condensers with insulated rotors are also available. Condensers with split stators and either earthed or insulated rotors are available for special applications.

(h) Trimmer condensers (“compensators”)

These are available in innumerable forms, and can only be briefly mentioned.

The compression mica type is the least satisfactory of all since it tends to suffer from drift in capacitance, and is far from being linear in its characteristic. It is used in receivers for the medium frequency broadcast band and in the less expensive dual-wave receivers.

The concentric or vane air-dielectric types are more expensive but have greater stability, are easier to adjust, and the better types are more satisfactory under tropical conditions. Ceramic trimmers are also obtainable.

Trimmers are available in a wide range of capacitances, but for ordinary use with gang condensers should preferably have a minimum capacitance not greater than $2\ \mu\mu\text{F}$, and a capacitance change not less than $15\ \mu\mu\text{F}$ (R.M.A. REC-101, REC-106-A).

See also Chapter 38 Sect. 3(vii and xi) for standard specifications.

(iii) Combination units

Combinations of one or more capacitors with one or more resistors are becoming common, and are very convenient. Some popular combinations are

(a) Diode filters incorporating one resistor and two capacitors with a common earth return.

(b) Cathode bias units incorporating one resistor shunted by a capacitor.

(c) Plate and grid decoupling units incorporating one capacitor and one resistor.

(d) Audio frequency coupling unit incorporating a plate load resistor, coupling capacitor and grid resistor with also (in one example) a grid stopper resistor and capacitor.

(iv) Practical inductors

Iron-cored inductors are covered in Chapter 5. Radio frequency inductors, both air-cored and iron-dust cored, are covered in Chapter 11. The calculation of inductance of air-cored inductors at all frequencies is covered in Chapter 10.

SECTION 1 : IDEAL TRANSFORMERS

(i) *Definitions* (ii) *Impedance calculations—single load* (iii) *Impedance calculations—multiple loads.*

(i) Definitions

An **ideal transformer** is a transformer in which the winding reactances are infinite, and in which winding resistances, core loss, leakage inductances and winding capacitances are all zero. In such a transformer the voltage ratio between any two windings is equal to the turns ratio of the windings, under all conditions of loading, as illustrated in Fig. 5.1. Also, in such a transformer the currents in any two windings are inversely proportional to the ratio of turns in the windings under all load conditions.

$$\frac{E_2}{E_1} = \frac{N_2}{N_1}$$

$$\frac{I_2}{I_1} = \frac{N_1}{N_2}$$

Fig. 5.1. Ideal two-winding transformer. E_1 and E_2 are alternating voltages (r.m.s.). I_1 and I_2 are alternating currents (r.m.s.) but the indicated directions of current flow are at a chosen instant and correspond to the direction of voltage at that instant. Similar remarks apply to Fig. 5.2.

Modern iron-cored transformers often approach so closely to perfection for their particular purposes that their analysis on the basis of ideal transformer theory may give useful practical approximations for design purposes.

A **double-wound transformer** is one in which, as illustrated in Fig. 5.1, separate primary and secondary windings are used to permit isolation of the primary and secondary circuits except through mutual inductive coupling.

Auto-transformers may be used with economy in some cases : a single winding is tapped to give the required turns ratio, which may be greater or less than unity, between primary and secondary. An ideal step-up auto-transformer is shown in Fig. 5.2.

FIG. 5.2

$$\frac{E_2}{E_1} = \frac{N_2}{N_1}$$

$$\frac{I_2}{I_1} = \frac{N_1}{N_2}$$

Fig. 5.2. Ideal step-up auto-transformer.

An auto-transformer is always more economical to construct than a two winding transformer as indicated in the following tabulation :

Type of Winding	Ratios	Total Volt-ampere rating of windings	Transformer Output V.A.
Auto	10 : 9 or 9 : 10	20	100
Auto	2 : 1 or 1 : 2	100	100
Auto	3 : 1 or 1 : 3	133	100
Auto	5 : 1 or 1 : 5	160	100
Auto	10 : 1 or 1 : 10	180	100
Double	any ratio	200	100

The currents in the primary and secondary sections are exactly 180° out of phase, and the resultant current flowing through the common portion of the winding is the difference between the two. When the ratio is 1 : 2 or 2 : 1, the currents in the two sections of the winding are equal.

In ideal transformer theory there is no distinction between auto- and two-winding transformers and they need not therefore be considered separately in this section.

(ii) Impedance calculations—single load

When the secondary of a simple two-winding ideal transformer is loaded with a resistance R_2 as shown in figure 5.3, the equivalent or **transformed load** R_1 as measured between the primary terminals is

$$R_1 = (N_1/N_2)^2 R_2 \quad (1)$$

and since the voltage ratio between primary and secondary is equal to the turns ratio, this may be written as

$$R_1 = (E_1/E_2)^2 R_2 \quad (2)$$

A transformer therefore merely transforms a load imposed on its secondary. Its primary does not in the ideal case impose any load unless a load is applied to the secondary. It is the turns ratio between primary and secondary, and not the number of turns in the primary, that governs the transformed or reflected load impedance.

FIG. 5.3

Fig. 5.3. Ideal two-winding transformer with loaded secondary.

If however a transformer is to approximate to the ideal, the number of turns in the primary must be sufficient to make the reactance of the primary high compared with the transformed value of the load impedance as measured across the primary terminals.

For an ideal transformer with a centre-tapped primary as shown in Fig. 5.4, the transformed load measured across the whole primary (between terminals, P, P) is equal to the transformed value R_1 . If however only one half of the primary is used (between either of terminals P and terminal C.T.) the transformed load presented is $\frac{1}{4} R_1$.

Fig. 5.4. Ideal transformer with primary centre-tap and loaded secondary.

As a practical example of the primary centre tap, consider the use of the transformer of Fig. 5.4 to feed a 500 ohm line ($R_2 = 500$ ohms). If the transformer has an impedance ratio $(N_1/N_2)^2$ equal to 10 : 1, the transformed load across the whole of the primary, e.g., when the primary is fed by a push-pull amplifier, is $10 \times 500 = 5000$ ohms. If, however, only one half of the primary were used for connection to a single-ended amplifier, the load presented to the amplifier would be 1250 ohms.

For an ideal transformer with a winding tapped for load matching, as shown in Fig. 5.5, the calculation of the tap to be selected for any particular load follows from the application of eqn. (1).

Fig. 5.5. Ideal transformer with secondary tapped for load matching.

In these equations a load connected across terminals A and B is denoted by R_{AB} and the number of turns in the secondary between these two terminals is given by N_{AB} , and corresponding designations apply for any pair of terminals across which the load is connected.

If, for example, the terminals A, B provide a match with a 10 ohm secondary load with a total of N_{AB} secondary turns, the number of turns N_{AD} required between terminals A and D to provide a similar match to a 500 ohm line is given simply by

$$(N_{AD}/N_{AB})^2 = 500/10 = 50, \text{ so that}$$

$$N_{AD}/N_{AB} = \sqrt{50} = 7.07.$$

The number of turns in the 10 ohm winding is approximately one-seventh of the number of turns for matching to 500 ohms. It is, of course, permissible to use any pair of secondary terminals such as B, C or C, D and so on, so that a wide range of transformation ratios is available from a transformer arrangement such as that shown in Fig. 5.5.

(iii) Impedance calculations—multiple loads

Where two or more loads are connected simultaneously to the windings of a transformer, the conditions for matching may be determined readily by the following methods.

Consider an ideal transformer having two secondaries of N_2 and N_3 turns connected to loads R_2 and R_3 respectively as shown in Fig. 5.6. It follows immediately from eqn. (2) that

$$E_2/E_1 = N_2/N_1; E_3/E_1 = N_3/N_1; E_3/E_2 = N_3/N_2 \quad (3)$$

and, since the transformer is an ideal one, these relations hold irrespective of the relative values of the loads.

Fig. 5.6. Ideal transformer with multiple loads.

It is sometimes convenient to draw the diagram as in Fig. 5.7, which is equivalent in every way to Fig. 5.6. If, as a special case, $N_2/N_3 = R_2/R_3$, then the voltages of the two points A and B will be the same, and the link AB may be omitted without any effect. The currents in both sections of the transformer and in R_2 and R_3 will then be the same.

The value of the reflected or transformed load R_1 measured across the primary terminals can be obtained by considering the power in relation to the voltages specified in eqn. (3).

Fig. 5.7 Ideal transformer with multiple loads as in Fig. 5.6, but with the secondaries connected at points A, B.

Let W_1 = total input watts to the primary = E_1^2/R_1

W_2 = watts in the load R_2 = E_2^2/R_2

W_3 = watts in the load R_3 = E_3^2/R_3

Then $W_1 = W_2 + W_3$ (since there are no transformer losses)

$$\begin{aligned} \text{so that } \frac{E_1^2}{R_1} &= \frac{E_2^2}{R_2} + \frac{E_3^2}{R_3} \\ &= \frac{E_1^2}{R_2} \left(\frac{N_2}{N_1} \right)^2 + \frac{E_1^2}{R_3} \left(\frac{N_3}{N_1} \right)^2. \end{aligned}$$

We therefore have

$$\frac{1}{R_1} = \frac{1}{R_2(N_1/N_2)^2} + \frac{1}{R_3(N_1/N_3)^2} \quad (4)$$

so that the total load R_1 presented by the primary is equal to the parallel combination of the two transformed loads $R_2(N_1/N_2)^2$ and $R_3(N_1/N_3)^2$.

If an additional winding of N_4 turns is connected to a load R_4 we obviously have in the same way

$$\frac{1}{R_1} = \frac{1}{R_2(N_1/N_2)^2} + \frac{1}{R_3(N_1/N_3)^2} + \frac{1}{R_4(N_1/N_4)^2} \quad (5)$$

and so on, for any number of loads. Such expressions are equally applicable whether the secondary windings used are separate windings or whether they form part of a single tapped secondary. For example if, in the transformer shown in Fig. 5.5, we have loads R_{AB} , R_{AC} and R_{BD} connected to terminals AB, AC, and BD respectively, we will have

$$\frac{1}{R_1} = \frac{1}{R_{AB}(N_1/N_{AB})^2} + \frac{1}{R_{AC}(N_1/N_{AC})^2} + \frac{1}{R_{BD}(N_1/N_{BD})^2}$$

and so on.

A typical practical case is one in which a known power output W_1 from an amplifier is fed into a known reflected impedance R_1 with two secondaries feeding loads R_2

and R_3 (such as two loudspeakers) which are required to operate with power inputs of W_2 and W_3 respectively, so that $W_1 = W_2 + W_3$. The required transformer turns ratios are then given by

$$R_1 W_1 = E_1^2; R_2 W_2 = E_2^2; R_3 W_3 = E_3^2 \quad (6a)$$

$$\text{so that } R_2 W_2 / R_1 W_1 = E_2^2 / E_1^2 = N_2^2 / N_1^2 \quad (6b)$$

$$\text{and } R_3 W_3 / R_1 W_1 = E_3^2 / E_1^2 = N_3^2 / N_1^2 \quad (6c)$$

For example if $W_2 = 3$ watts $R_2 = 500$ ohms

$W_3 = 4$ watts $R_3 = 600$ ohms

and $W_1 = 7$ watts $R_1 = 7,000$ ohms

we have

$$\frac{N_2^2}{N_1^2} = \frac{500 \times 3}{7000 \times 7} = \frac{1}{32.7} \quad \text{Therefore } \frac{N_2}{N_1} = \frac{1}{5.7}$$

and similarly $N_3/N_1 = 1/4.5$.

Expressions such as (6) may be written in the more general form

$$N_n/N_1 = \sqrt{(R_n/R_1)(W_n/W_1)} \quad (7)$$

where N_n = number of turns on secondary n ,

N_1 = number of turns on primary,

R_n = load applied to secondary n ,

R_1 = transformed total primary load,

W_n = watts in load R_n ,

and W_1 = total watts input to primary,

but it must be noted that these relations hold only when all loads are connected so that the specified input conditions to the primary do exist. Eqn. (7) is also applicable to determine the turns ratios of two or more separate transformers feeding two or more loads from a common amplifier which delivers W_1 watts into a total load of R_1 ohms.

Fig. 5.8. Ideal transformer with multiple loads and tapped secondary, which is effectively identical with Fig. 5.6.

If a transformer is supplying power to two or more loads, such as loudspeakers, and one of these is switched out of circuit, the impedance reflected on to the primary will change due to the reduction of loading on the secondary. In order to avoid the resultant mismatching it is advisable to switch in a resistive load, having a resistance equal to the nominal (400 c/s) impedance of the loudspeaker, so as to take the place of the loudspeaker which has been cut out of circuit. In this case the resistance should be capable of dissipating the full maximum power input to the loudspeaker. Such an arrangement will also have the result that the volume from the remaining speakers will be unchanged.

Alternatively if it is desired to switch off one loudspeaker and to apply the whole power output to a single speaker, it will be necessary to change the number of secondary turns so as to give correct matching. This change may generally be arranged quite satisfactorily by the use of a tapped secondary winding. In this case the loudspeaker would be used on the intermediate tap when both speakers are in use, and on the whole winding for single speaker operation.

It does not matter whether two or more secondary windings or a single tapped winding is employed. The arrangement shown in Fig. 5.8 is effectively identical with that of Fig. 5.6.

SECTION 2 : PRACTICAL TRANSFORMERS

(i) *General considerations* (ii) *Effects of losses.*

(i) General considerations

The treatment in section 1 based on ideal transformer theory is an extremely useful first approximation in design problems, particularly if the transformers to be used are so liberally designed that their general characteristics approximate to the ideal.

In practice it is usually necessary to take into account :

- (a) The resistance of each winding
- (b) The core loss
- (c) The inductances of the windings
- (d) The leakage inductances
- (e) The capacitances between windings and between each winding and ground, and the self capacitance of each winding.

A useful equivalent circuit of a practical transformer is shown in Fig. 5.9.

FIG. 5.9

Fig. 5.9. Equivalent circuit of a practical transformer.

In this equivalent circuit we have an ideal transformer with a turns ratio N_2/N_1 (equal to the turns ratio of the actual transformer), with the incidental characteristics of the actual transformer represented by separate reactances and resistances.

r_1 = the resistance of the primary winding

L_1 = the equivalent primary leakage inductance

r_2 = the resistance of the secondary winding

L_2 = the equivalent secondary leakage inductance

R_0 = the equivalent core-loss resistance (including both hysteresis and eddy current losses)

L_0 = the inductance of the primary winding

C_1, C_2 = the primary and secondary equivalent lumped capacitances

C_w = the equivalent lumped capacitance between windings

R_1 = input resistance of transformer on load

and R_2 = the load resistance across the secondary.

Such an equivalent circuit is capable of representing a practical design with considerable accuracy, but actual calculations would be tedious and in some cases very difficult.

The reactances and resistances shown therein have varying effects on the input-output voltage ratio according to the frequency of the signal which the transformer is handling (Ref. A10). In general, the equivalent circuit can be presented in three distinct simplified forms for use when considering the transformer operating at low, medium and high frequencies respectively (Figs. 5.10B,C,D).

Audio transformers can be conveniently dealt with in this manner, whereas power transformers operating over a very limited frequency range can be more simply designed on the basis of Fig. 5.10A.

The whole of the equivalent circuit of Fig. 5.10A can be referred to the primary, as in Fig. 5.11 where the ideal transformer has been omitted and r_2 and R_2 multiplied

by the square of the turns ratio. This is often a convenient way of making calculations.

Fig. 5.10A. Simplified equivalent circuit for calculating the effect of losses.

Fig. 5.10B. Low frequency equivalent circuit.

Fig. 5.10C. Medium frequency equivalent circuit.

Fig. 5.10D. High frequency equivalent circuit.

R_w = Total winding resistance referred to primary

L_s = Total leakage inductance referred to primary

C = Total winding capacitance referred to primary

R_L = Secondary load resistance referred to primary

Fig. 5.11. Simplified equivalent circuit referred to the primary.

(ii) The effects of losses

If a transformer is designed to deliver power into a resistance load, such as valve heaters, the primary and secondary copper losses are usually designed to be of the same order.

A particular transformer reaches its maximum efficiency when the copper losses have become equal to the iron losses (proof given in Ref. A10), although this does not necessarily occur at full load unless the transformer is so designed.

The **efficiency** is the ratio of the output power to the output power plus the losses. For audio and power transformers for radio purposes typical efficiencies range from 70 to 95 per cent, with the majority of power transformers falling between 80 and 90 per cent.

The **regulation** of a transformer is defined differently in American and British practice, the primary voltage being held constant throughout.

American definition. The percentage voltage regulation is the difference between the full-load and the no-load secondary voltages, divided by the **full-load** voltage and multiplied by 100.

British definition. The percentage voltage regulation is the difference between the full-load and the no-load secondary voltages, divided by the **no-load** secondary voltage and multiplied by 100 (B.S.205 : 1943).

However, the difference between the two definitions is quite small for small percentages of voltage regulation.

The regulation of audio transformers when operating over a limited frequency range (say 200-2000 c/s), that is the ratio of E_2/E_1 , is affected mainly by the copper losses.

Thus $E_2/E_1 \approx \eta T$ and $I_2/I_1 \approx 1/T$,
 where η = efficiency
 and T = turns ratio. (1)

As a further consequence the impedance ratio is changed, and, making the same assumptions as above,

$$R_1 \approx r_1 + r_2/T^2 + R_2/T^2 \quad (2)$$

At low frequencies, the reflected impedance is altered by the shunt effect of the primary inductance, while at high frequencies, a similar change is caused by the leakage inductance and winding capacitances. This is covered in Sect. 3(iii).

The damping of a loudspeaker, connected as a load to the secondary of an output transformer, is also affected to some degree by the losses. Where an accurate indication of the damping factor is required, these losses should be taken into account. Refer to Chapter 21 Sect. 3.

SECTION 3 : AUDIO-FREQUENCY TRANSFORMERS

(i) *General considerations* (ii) *Core materials* (iii) *Frequency response and distortion*—(a) *Interstage transformers* (b) *Low level transformers* (c) *Output transformers* (iv) *Designing for low leakage inductance* (v) *Winding capacitance* (vi) *Tests on output transformers* (vii) *Specifications for a-f transformers.*

(i) General considerations (References A6 and A10)

Audio frequency transformers can be divided into three major categories,

- (a) Low level input
- (b) Medium level interstage
- (c) Output.

For design purposes it is necessary to know

- (1) Operating level, usually expressed in db above or below a reference level of 1 milliwatt (i.e. dbm),
- (2) Frequency response, with permitted deviation, quoting reference level at which measurements are made,
- (3) Permissible distortion, at specified operating levels and frequencies,
- (4) Impedance, phase angle, and nature of source and load between which transformer is to be connected,
- (5) Value of d.c. (if any) flowing through any winding,
- (6) Hum reduction requirements,
- (7) Phase shift permitted.

Operating level.

This restricts the choice of core materials and determines the physical size. Suitable core alloys include *MUMETAL* and *RADIOMETAL* together with silicon

steels in various grades. As *MUMETAL* saturates at a comparatively low flux density, it is only suitable for low level transformers. Economic factors will probably dictate which material is finally used.

Frequency response

At low frequencies the response falls off due to the finite value of primary inductance. At high frequencies, the winding capacitance and leakage inductance are responsible for the response limitations.

Distortion (a) Low frequency

This is mainly dependent on the maximum operating flux density at the lowest frequency of interest. Distortion due to this cause falls off rapidly with increase in frequency. Other sources of distortion are observed when transformers operate in valve plate circuits. The drop in valve load impedance due to the shunting effect of the primary inductance may cause the valve to distort. Further, the load impedance will also change to a partially reactive one at low frequencies. The valve will therefore operate with an elliptical loadline and will introduce additional distortion unless care is taken.

A simple method of measuring the harmonic distortion in the cores of a-f transformers is described in Ref. C33.

Distortion (b) High frequency

At this end of the audio spectrum the load impedance changes again in magnitude and sign, thus causing an associated valve to generate distortion.

Source and load

Before the design of a transformer can be proceeded with, something must be known about the impedances between which the transformer is required to operate. Assuming that it is a low level unit, for example, it may be intended to operate from a ribbon microphone, a low impedance line, a gramophone pickup or the plate of a valve. It may have to feed the grid of a pentode or triode, a line or a mixer circuit. The secondary may be shunted by a resistance or a frequency correcting network. Unless these factors concerning the external circuits are known it is not possible to predict with any degree of accuracy, the ultimate performance of the transformer.

D.C. polarization

If an unbalanced d.c. component is present in one of the windings, this will cause a reduction in inductance over that attainable without d.c. This would require a larger transformer to meet the same performance specifications. In some cases where the d.c. magnetizing force is high, the use of high permeability alloys is not feasible. As far as practicable, unbalanced d.c. should be avoided in transformers, either by using a push-pull connection or shunt feed. For calculation of primary inductance with a d.c. component present, refer to Section 6.

Hum reduction

When the operating level is very low, it may be found desirable to shield the transformer to decrease the hum level to a suitable magnitude. This can be achieved in several ways, *MUMETAL* shields up to three in number being particularly effective. An outer case of sheet metal or cast iron is normally employed. The use of a balanced structure such as a core type instead of a shell type lamination will assist in reducing the effects of extraneous a.c. fields.

Phase shift

In certain applications it is desirable to apply negative feedback over an amplifier incorporating one or two transformers. To achieve stability with the desired amount of gain reduction, it is necessary to exercise careful control of phase shift over a frequency range very much wider than the nominal frequency range of the transformer (see Chapter 7 Sect. 3).

(ii) Core materials

High permeability alloys are now produced by several manufacturers under a variety of trade names. These are listed below, with silicon steel shown for comparison.

See also Ref. C34.

NICKEL IRON AND OTHER ALLOYS

Material	ρ	μ_0 d.c.	μ_{max} d.c.	(B-H) Sat.	
				Gauss	Lines/sq.in.
Mumetal	62	30 000	130 000	8 500	55 000
Permalloy C	60	16 000	75 000	8 000	52 000
Radiometal	55	2 200	22 000	16 000	103 000
Permalloy B	45	2 000	15 000	16 000	103 000
Permalloy A	20	12 000	90 000	11 000	71 000
Cr-Permalloy	65	12 000	60 000	8 000	52 000
Mo-Permalloy	55	20 000	75 000	8 500	55 000
1040	56	40 000	100 000	6 000	39 000
Megaperm	97	3 300	68 000	9 300	60 000
Hipernick	46	3 000	70 000	15 500	100 000
45 Permalloy	45	2 700	23 000	16 000	103 000
Rhometal*	95	250—2 000	1 200—8 500	12 000	78 000
4% Silicon Steel	55	450	8 000	19 500	125 000

ρ = resistivity in microhm cm ; μ_0 = initial permeability

μ_{max} = maximum permeability obtainable.

For audio transformer work the first four are frequently used. *RHOMETAL* has a special field of application, namely for transformers handling ultrasonic and radio frequencies up to several megacycles.

Flux densities of the order of 22 000 lines per square inch can be used with *MUMETAL* and approximately double this value with *RADIOMETAL*, the upper limit being set by the permissible distortion. For further information on this point see Sect. 3(iii).

For higher power **output transformers**, high silicon content (up to 4½%) sheet steel is in general use. To retain high permeability at low flux densities, the strips or laminations should be annealed after shearing and punching. Spiral cores of grain-oriented silicon steel are of considerable use in this application.

As a general rule, the output transformer should have the largest core which is practicable or permissible having regard to cost or other factors. A large core of ordinary silicon steel laminations is usually better than a small core of special low-loss steel.

The weight of steel in the core is a function of the minimum frequency, the permissible distortion, the core material, and the maximum power output. As a rough guide, subject to considerable variation in practice, the core may be taken as having

Weight in lbs. = $0.17 \times$ watts output

Volume in cu. ins. = $0.7 \times$ watts output.

These are for normal typical conditions, and may be decreased for less extended low frequency response or for a higher permissible distortion. For good fidelity, an increase in core size to double these values is desirable.

Several new **core materials** are now available including *CASLAM* and *FERROX-CUBE*.

CASLAM is a soft magnetic core material with finely laminated structure for use at frequencies from 50 c/s up to at least 10 Kc/s. It is composed of flake iron particles pressed into a compact mass of the desired shape in such a way as to produce innumerable thin magnetic layers aligned in the plane of the flux. By virtue of its dense compacted structure many of the assembly and fixing problems associated with the older stacking method are eliminated. Grade 1 is a low density material with a maximum permeability of 860. Grade 2 is a denser material with a higher maximum permeability of 1000. Grade 3 is similar to grade 1 in magnetic characteristics but has better strength and machining qualities.

For choke cores a pair of E's can be butted together but where minimum gap is required the block can be broken and then rejoined after the coil is positioned. Because of the fibrous laminated structure exposed by breaking, microscopic inter-leaving occurs when the join is remade in the correct manner.

*Properties depend upon different heat treatment deliberately given.

Rigid clamping is less important since there are no free laminations to vibrate under load. For this reason also, combined with the somewhat discontinuous nature of the material, the acoustic noise emitted by the block is considerably reduced, especially at higher frequencies.

PHYSICAL PROPERTIES OF CASLAM

Property	Caslam 1	Caslam 2	Caslam 3
Maximum permeability	860 at 4 Kg	1000 at 4 Kg	
Effec. permeability	500 at 10 Kg	830 at 10 Kg	Similar
Hys. loss for $B_{max} = 10$ Kg. at 50~	7000	7000 ergs/cc/cycle	to
Coercive force $B_{max} = 10$ Kg. at 50~	2.4	2.4 oersteds	grade 1
Sat. flux density	18 Kg	18 Kg	
Total a.c. loss, $B_{max} = 10$ Kg. at 50~	2.5	2.75 watts/lb.	
Density	7.0	7.4 gms/cc	
Max. oper. temperature	110°C	110°C	150°C
Resistivity (ohm-centimetre)			
(a) Normal to plane of laminae	0.04		0.03
(b) In plane of laminae	0.003		0.002

The a.c. loss is almost entirely hysteresis, the eddy current loss being less than 10% of the total. For this reason, the a.c. permeability at 50~ is approximately equal to the d.c. figure and at higher acoustic frequencies, blocks of *CASLAM* compare favourably in magnetic properties with stacks built up from normal silicon iron sheet.

Dust cores generally suffer from low permeability and, to reduce eddy currents, particle size has to be reduced; this causes further reduction in permeability.

Other new ferromagnetic materials such as the ferromagnetic spinels and *FERROX-CUBE* are described in Chapter 11 Sect. 3(v)E, and find their applications principally at frequencies above the audio range.

(iii) Frequency response and distortion

(a) Interstage transformers—Class A and B

At the mid-frequency* the amplification is very nearly equal to the amplification factor of the valve multiplied by the turns ratio of the transformer, where the secondary is unloaded.

At low frequencies the gain falls off due to the decrease in primary reactance. The ratio of the amplification at a low frequency A_{lf} compared with that at the mid-frequency A_{mf} can be expressed thus—

$$\frac{A_{lf}}{A_{mf}} = \frac{1}{\sqrt{1 + \left(\frac{R}{\omega L_0}\right)^2}} \quad (1)$$

where L_0 = primary inductance

and R = plate resistance plus primary resistance.

The response will fall off 3 db at a frequency such that $\omega L_0 = R$. At a frequency such that

$$\omega L_0 = 2R \quad (2)$$

the response will be down approximately 1 db from the mid-frequency level.

At high frequencies the leakage reactance and shunt capacitance, in conjunction with the plate and winding resistances, form a low Q series resonant circuit. Above this resonant frequency the gain will fall off rapidly. In the neighbourhood of resonance the change in gain will depend on Q_0 , the Q of the resonant circuit. This factor can be varied by adding external resistance or by winding the secondary partly with resistance wire (Ref. C3). The resonant frequency can be varied by changing the value of the total leakage inductance, L , or the interwinding capacitances. These are both functions of the transformer structure. See also page 518.

By careful choice of core material, lamination dimensions and method of sectionalizing the winding, it is possible to achieve a frequency response extending beyond the normal audio range (Refs. C2, C4, C5, C6 and Figs. 5.12 and 5.13A).

*The mid-frequency is the frequency at which maximum gain is obtained.

As the leakage inductance L_s is proportional to the square of the turns, N , it is possible to extend the high frequency response by reducing N . This, of course, reduces L_o in the same proportion as L_s , but this effect can be overcome by the use of a high permeability alloy.

For low level working it is usual to assume an initial a.c. permeability of 350 for silicon steel. If a *RADIOMETAL* core with an initial a.c. permeability of say, 1600, and of similar dimensions is substituted, N could be reduced in the ratio of $\sqrt{1600/350}$ or 2.14/1 and L_s approximately 4.6/1 over that for the silicon steel transformer. Similarly if a *MUMETAL* core having an initial a.c. permeability of 10 000 and of similar dimensions is substituted, N could be reduced in the ratio of $\sqrt{(10\ 000/350)}$ or 5.34/1 and L_s approximately 28.5/1.

Fig. 5.12. Transformer wound with balanced secondaries.

In those examples, the primary inductance has remained constant, but the leakage inductance has decreased over 4 times and 28 times respectively without any sectionalizing of the winding or interleaving. This indicates the improvement possible with the use of high permeability alloys.

Care must be taken, with the reduction in turns, that the flux density in the core does not exceed safe limits from the point of view of distortion (see Refs. C7, C8, C9, C10).

In the case of transformers working at low levels and hence, generally, a low flux density, the distortion may not be a consideration. It is possible to achieve an improved high frequency response, while keeping the distortion at the same level at low frequencies, by increasing the core cross section and proportionately reducing the turns. This however, increases the mean length of turn and also L_s , so the nett reduction of L_s is not as great as would be anticipated. In addition, the cost of the transformer increases, particularly if a high permeability alloy is used. Class B input (driver) transformers are usually called upon to handle appreciable amounts of power during part of the audio frequency cycle, but are designed on the basis of open circuit working when considering primary inductance. Winding resistance and leakage inductance must be kept low to avoid distortion (Refs. C21, C22).

Fig. 5.13A. Typical coil arrangements in audio transformers.

(iii) (b) Low level transformers

Transformers working about or below a zero level of 1 milliwatt (0 dbm) usually employ a *MUMETAL* core. In most instances hum shielding is necessary to attain the desired signal to hum ratio. This is generally required to be in excess of 60 db. Satisfactory shielding can be obtained by using around the transformer one or more shields made of high permeability alloy. Where a.c. fields are strong, the outer shield is normally designed to be made of an alloy which has a high saturation flux density. Thus the inner shields of, say, *MUMETAL*, are working at maximum efficiency in a low a.c. field where their permeability is a maximum. Sometimes

sheet steel or thick cast iron outer cases are used. More often a special alloy, such as Telcon 2129, is used. This material has magnetic properties similar to *RADIO-METAL*, but is suitable for deep drawing. Inner shields are often of copper to give shielding from electric fields (Refs. C11, C12). Some improvement is possible if a core type structure is used in place of a shell type, owing to the cancellation of stray voltages induced in the winding by external fields.

As an example of the use of high permeability alloys, the following design problem is presented. Calculate the primary turns for a 50 ohm to 50 000 ohm transformer working at zero level (0 dbm). The frequency response must not fall more than 1db below mid-frequency response, at 50 c/s. Distortion must not exceed 1% at zero level at 50 c/s. The source impedance is 50 ohms resistive and the secondary is unloaded. Core material to be used is *MUMETAL*.

1st Step. Calculate primary inductance.

For 1 db attenuation, $\omega L_0 = 2R$ (Eqn. 2).

$$L_0 = 2R/\omega = 2 \times 50/2 \times \pi \times 50 = 0.32 \text{ henry.}$$

2nd Step. Calculate primary turns.

Assume square stack of Magnetic and Elec. Alloys No. 35 lamination. Length of magnetic path, $l = 4.5$ inches

Cross sectional area = 0.56 square inches.

$$L_0 = \frac{3.2A \mu N^2}{10^8 \times l} \quad \text{Therefore } N^2 = \frac{L_0 \times 10^8 \times l}{3.2 \times A \times \mu}$$

$$N^2 = \frac{0.32 \times 10^8 \times 4.5}{3.2 \times 0.56 \times 10^4} \quad \text{Therefore } N = 90 \text{ turns.}$$

3rd Step. Calculate working flux density.

$$\text{Primary voltage } E = \sqrt{W \cdot R}$$

where W = input power

$$\text{Therefore } E = \sqrt{1 \times 10^{-3} \times 50} = 0.224 \text{ V}$$

$$0.224 \times 10^8$$

and

$$B = \frac{4.44 \times 50 \times 90 \times 0.56}{2000 \text{ lines per square inch}}$$

$$= 310 \text{ Gauss.}$$

4th Step. Determine percentage distortion.

Referring to Fig. 5.13B and using curve for $\omega L_0 = 2R$, it will be noted that the percentage distortion is approximately 0.75%. This assumes that the permeability value, μ , is still 10 000 at the operating flux density. In practice μ may exceed this figure and thus the distortion as calculated above may be larger than would be measured in a finished transformer. In this problem, for simplification, no account has been taken of the stacking factor, which would modify the result slightly.

When the secondary of the transformer is loaded, R in eqn. 1 then becomes R_1 as in eqn. 3 and R in Fig. 5.13B is read as R_1 . The calculation for distortion then follows in a similar manner to the unloaded secondary example worked earlier.

(iii) (c) Output transformers

The factors affecting the frequency response of output transformers (Ref. C13) are similar to those affecting interstage transformers. Refer to Figs. 5.10B, C and D.

Fig. 5.13B. Total harmonic distortion plotted against flux density for different ratios of primary reactance to R where R = plate resistance + primary resistance (Ref. C9).

The response falls off from the mid-frequency gain by 3 db at a low frequency such that

$$\omega L_0 = R_A \quad (3)$$

Attenuation is 1 db when

$$\omega L_0 = 2R_A \quad (4)$$

$$\text{where } R_A = \frac{(r_p + R_w)R_L}{r_p + R_w + R_L}$$

r_p = plate resistance of valve

R_L = load resistance referred to the primary

and R_w = total winding resistance referred to the primary.

The response falls off from the mid-frequency gain by 3 db at a high frequency such that

$$\omega L_S = R_B \quad (5)$$

Attenuation is 1 db when

$$\omega L_S = 0.5 R_B \quad (6)$$

where $R_B = r_p + R_w + R_L$

and L_S = total leakage inductance referred to primary.

$$\text{The gain at the mid-frequency} = \frac{E_0}{E_i} = \frac{\mu R_L}{R_B} \quad (7)$$

where E_i = voltage input to grid of output valve

E_0 = voltage output across R_L

and μ = amplification factor of output valve.

It is thus possible to specify the primary and leakage inductances permissible when the frequency response requirements are known. An example will illustrate this.

Determine the minimum primary inductance and maximum leakage inductance permitted in an output transformer designed to match a pair of Class A 2A3 triode valves with a 5 000 ohm load. The response is to be within 1 db from 50 to 10 000 c/s. The plate resistance of each valve is 800 ohms. Neglect R_w .

Make all calculations from plate to plate.

For a fall of 1 db at 50 cycles per second,

$$\omega L_0 = 2R_A$$

$$\text{Now } R_A = \frac{5000 \times 1600}{5000 + 1600} = 1200 \text{ ohms approx.}$$

$$\omega L_0 = 1200 \times 2 = 2400$$

$$L_0 = 2400/2 \times \pi \times 50$$

$$= 7.6 \text{ henrys approx.}$$

This is the value that would be measured on a bridge at low induction.

For a fall of 1 db at 10 000 cycles per second,

$$\omega L_S = 0.5 R_B$$

$$\text{Now } R_B = 5000 + 1600 = 6600 \text{ ohms.}$$

$$\omega L_S = 0.5 \times 6600 = 3300$$

$$L_S = 3300/2 \times \pi \times 10\,000$$

$$= .052 \text{ henry approx.} = 52 \text{ millihenrys.}$$

Note particularly that distortion requirements may necessitate an increase in L_0 and a decrease in L_S .

The following table indicates the relationship between the low frequency attenuation and the ratio of $\omega L_0/R_A$:

TABLE 1

Loss	Relative amplification	$\omega L_0/R_A$
0.5 db	0.94	2.76
1.0 db	0.89	1.94
2.0 db	0.79	1.30
3.0 db	0.71	1.00
6.0 db	0.50	0.58

The inductances required for various values of R_A , for a bass response loss of 1 decibel are as follows, correct to two significant figures :

TABLE 2

Value of R_A ohms	Bass response down 1 db at			
	150 c/s	100 c/s	50 c/s	30 c/s
800	1.7 H	2.6 H	5.1 H	8.5 H
1200	2.6 H	3.8 H	7.6 H	13 H
1500	3.2 H	4.8 H	9.5 H	16 H
2000	4.3 H	6.4 H	13 H	21 H
3000	6.4 H	9.5 H	19 H	32 H
4000	8.5 H	13 H	26 H	42 H
5000	11 H	16 H	32 H	53 H
7500	16 H	24 H	48 H	80 H
10 000	21 H	32 H	64 H	110 H
15 000	32 H	48 H	95 H	160 H
20 000	43 H	64 H	130 H	210 H
50 000	110 H	160 H	320 H	530 H

where R_A is approximately equal to the load resistance R_L in parallel with the effective plate resistance of the valve ; however see comments below. When the plate resistance is very high, as for a pentode without feedback, R_A may be taken as being approximately equal to R_L .

For loss in bass response to be reduced to 0.5 decibel these inductance values should be increased by a factor of 1.9 times. For a reduction of 2 db the factor becomes 0.67.

Since the permeability of the core material varies with induction, the frequency response will vary with signal level—the limiting low frequency will usually extend lower as the signal level is increased. It is therefore desirable that the inductance values tabulated above be calculated or measured at low signal levels. In the case of feedback from the secondary, this effect should be taken into account.

Table 2 gives the value of inductance to provide a nearly constant output voltage, but this is only one of several requirements to be satisfied. The **core distortion** is a function of the ratio $\omega L_o/R_A$ (this may be derived from equations 9 and 10) and for low distortion a high ratio of inductive reactance to R_A is required, and this is equivalent to having a low value of bass attenuation (see Table 1). The bass attenuation in Table 2 (1 db at specified minimum frequencies) is based on $\omega L_o/R_A = 1.94$, resulting in fairly low core distortion. Still lower core distortion would be achieved by increasing the inductance and hence, incidentally, decreasing the bass attenuation.

The other important secondary effect resulting from a finite value of inductance is the **phase angle of the load** presented to the output valve(s). If the value of inductance from Table 2 is used for bass response down 1 db at a specified frequency, the phase angle of the load presented to the output valves will be between 45° and 90° for a triode either without feedback or with negative voltage feedback. This will cause a pronounced elliptical load-line, normally resulting in severe valve distortion at this frequency, at full power output.

If R_A in Table 2 is taken as being equal to R_L , the maximum phase angle of the load will be less than 28° for bass response 1 db down at the specified frequencies. If the factor 0.67, for bass response down 2 db, is applied to Table 2, the maximum phase angle of the load will be less than 38° . If the factor 2.0, for bass response down about 0.5 db, is applied to Table 2, the maximum phase angle of the load will be about 15° . This appears to be a reasonable value for good fidelity.

Table 2 may therefore be used as a general guide to the choice of inductance values where more exact calculations are not required—see below.

Summary of general application of Table 2

To give low core distortion, nearly constant output voltage and a total load impedance effective on the valve which is not too reactive :—

1. Take $R_A = R_L$.
2. Apply Table 2 as printed for ordinary use.
3. Multiply inductance values by a factor of 2 for good fidelity.
4. The specified frequencies in Table 2 are to be interpreted as the minimum frequencies of operation for the transformer.

Where the source impedance is high, the high frequency fall off is determined largely by L_s and the winding capacitances as in the case of interstage transformers.

Similar devices to that employed in the construction of interstage transformers can be used to extend the range of output transformers. The use of *RADIOMETAL*, specially annealed high silicon content steel (such as *SUPERSILCOR*), and grain oriented steels, are all common in better quality output transformers (Refs. C14, 15).

It is feasible to "build-out" a transformer into a half section filter and thus maintain the impedance, viewed either by the source or the load, constant over a wide frequency range. In addition the phase angle variation is reduced towards the extremes of the range. This reduces distortion and maintains full power output to a greater degree than otherwise possible.

This idea can be applied to interstage transformers and output transformers quite successfully (Refs. C19, C20). Even large modulation transformers and class B driver transformers for broadcast equipment have provided improved performance when treated in this way (Refs. C16, 17, 18).

In radio receivers and record players advantage can be taken of this "building-out" procedure, to limit the high frequency response to any given point, say 6000 c/s, with rapid attenuation thereafter. This usually involves only one extra component; a condenser across the secondary winding of the output transformer. This is quite an effective "top" limit, more so than the normal tone control. The output transformer is designed to have the necessary amount of leakage inductance for the network to function as intended.

The **winding resistances** are not of major importance in interstage transformers, but assume greater significance in output transformers. An appreciable amount of power may be lost unless the resistances of both primary and secondary are kept to reasonable proportions. In the normal good quality transformer the total resistance reflected into the primary side is approximately double the measured d.c. resistance of the primary. The total winding resistance (referred to the primary) will vary between 10 and 20 per cent of the load resistance, which means an insertion copper loss of 0.5 to 1 db. This extra resistance must be considered when choosing the turns ratio to reflect the correct load (see Eqn. 2, Sect. 2), otherwise an impedance error of 10 to 20 percent will occur. Core losses will not materially affect the calculation as these losses do not reach their maximum except at full power at the lowest audio frequency of interest.

Distortion in output transformers

When a transformer has its primary connected to an audio frequency source of zero impedance, the waveform of the voltage on the secondary will be the same as that of the source—in other words there is no distortion.

When a transformer is connected in the plate circuit of a valve, the latter is equivalent to a resistance r_p in series with the source and the transformer primary. If the secondary of the transformer is also loaded by a resistance R_2 , this is equivalent (as regards its effect on distortion) to a total primary series resistance R ,

$$\text{where } \frac{1}{R} = \frac{1}{r_p} + \frac{1}{R_2(N_1/N_2)^2}$$

N_1 = primary turns

and N_2 = secondary turns.

In the following treatment the symbol R is used to indicate the total effective primary series resistance, whether it is caused by r_p alone or by a combination of this and secondary loading.

The resistance R in series with the primary causes a voltage drop proportional to the current flowing through it, which is the magnetizing current. Now the form of the magnetizing current is far from being sine-wave, since it is distorted by the non-linear B - H characteristic of the core material.

This distorted current waveform has no bad effect when R is zero, but results in distortion of the voltage waveform which becomes progressively greater as R is increased, for any one fixed value of B_{max} .

The resulting harmonic distortion with silicon steel has been calculated by Dr. N. Partridge, and his results are embodied in the formula which follows (Refs. C24, C25, C26, C27).

$$\frac{V_h}{V_f} = S_H \cdot \frac{10^9}{8\pi^2} \cdot \frac{l}{N^2 A} \cdot \frac{R_A}{f} \left(1 - \frac{R_A}{4Z_f}\right) \quad (8)$$

This formula can be modified to include the core stacking factor, 90%, and to use inch units instead of centimetres. It then becomes

$$\frac{V_h}{V_f} = \frac{5.54 S_H l R_A}{N^2 A f} \left(1 - \frac{R_A}{4Z_f}\right) \quad (9)$$

where V_h = the harmonic voltage appearing across the primary,

V_f = the fundamental voltage across the primary,

S_H = the distortion coefficient of the magnetic material,

l = the length of the magnetic path,

N = number of primary turns,

R_A = resistance (or equivalent resistance) in series with the primary, (refer under eqn. 4, Sect. 3),

A = cross-sectional area of core,

f = frequency of fundamental in cycles per second,

Z_f = impedance of primary at fundamental frequency $\approx 2\pi fL$

and L = inductance of primary in henrys at chosen flux density.

In most cases the final term $(1 - R_A/4Z_f)$ can be omitted with a further simplification.

The right hand side of this equation gives the value of the fractional harmonic distortion; the percentage harmonic distortion may be obtained by multiplying this value by 100. The formula holds only for values of R/Z_f between 0 and 1; this limits its application to output circuits having a maximum attenuation of 3 db.

Fig. 5.13C. The distortion coefficient of Silcor 2 as a function of B (Ref. C25).

Values of S_H for Silcor 2 can be obtained from Fig. 5.13C. Similarly Fig. 5.13D can be used to determine the permeability of Silcor 2 and hence the inductance of the primary from the formula

$$L = \frac{2.88 N^2 A \mu}{10^9 l} \text{ henrys} \quad (10)$$

where μ = permeability at operating flux density
and core stacking factor is 90%.

Fig. 5.13D. Variation of permeability with B at 50 c/s of Silcor 2 laminations, 0.014 in. thick (Ref. C25).

Both of these figures have been adapted from those published by Partridge (Ref. C25).

An example is quoted to demonstrate the use of these formulae.

Determine the transformer distortion produced when a pair of KT66 valves (very similar to type 6L6-G) connected as triodes are operated in conjunction with a transformer having the following characteristics.

Lowest frequency of operation

50 c/s.

Maximum flux density

40 000 lines/sq. in.

Core stack of M.E.A. 78 Pattern lams. Silcor 2

2 ins.

(Refer to Sect. 5 and also Fig. 5.18C for lamination data).

Operating conditions of KT66 valves

Plate voltage

400 volts

Plate resistance (per valve)

1450 ohms

Load resistance (total)

10 000 ohms

Power output

14 watts

1st step. Calculate primary voltage

$$E = \sqrt{WR} = \sqrt{14 \times 10\,000} = 374 \text{ V.}$$

2nd step. Calculate primary turns

$$N = \frac{E \times 10^8}{4 \times fBA} \quad (\text{allowing } 90\% \text{ core stacking factor})$$

$$= \frac{374 \times 10^8}{4 \times 50 \times 4 \times 10^4 \times 1.25 \times 2} = 1870 \text{ turns.}$$

3rd step. Determine μ from Fig. 5.13D

$$\mu = 4300.$$

4th step. Calculate Z_f ($\approx 2\pi fL$)

$$Z_f = \frac{2\pi f 2.88 N^2 A \mu}{10^8 l}$$

$$= \frac{2 \times \pi \times 50 \times 2.88 \times 1.87 \times 1.87 \times 10^8 \times 1.25 \times 2 \times 4300}{10^8 \times 7.5}$$

$$= 45\,300 \text{ ohms.}$$

5th step. Calculate R_A (parallel resistance of plate and load resistance).

$$R_A = \frac{(r_p + R_W) R_L}{r_p + R_W + R_L} \quad (\text{see eqn. 4, Sect. 3})$$

assuming $R_W = 400$ ohms

then $R_A = \frac{(2900 + 400) 10\,000}{13\,300} = 2480 \text{ ohms.}$

6th step. Calculate $1 - (R_A/4Z_f)$

$$1 - (R_A/4Z_f) = 1 - (2480/4 \times 45\,300) = 0.986.$$

Thus this factor can be neglected without serious error.

7th step. Determine S_H from Fig. 5.13C

$$S_H = 60.$$

8th step. Calculate fractional distortion

$$\frac{V_h}{V_f} = \frac{5.54 S_H I R_A}{N^2 A f} = \frac{5.54 \times 60 \times 7.5 \times 2480}{1.87 \times 1.87 \times 10^6 \times 2.5 \times 50} = .014.$$

Thus percentage distortion is $.014 \times 100$ or 1.4%.

Note : High fidelity output transformers may be designed with distortion less than 0.05% at maximum power output at 50 c/s.

The value of the distortion coefficient S_H is constant for any given material operating at any one value of B_{max} . The value of S_H will be different for each harmonic, but its value for the third harmonic (S_3) is very close to the r.m.s. sum of all harmonics (S_{rms}) when there is no direct current component.

It will be noticed that the curve in Fig. 5.13C reaches a minimum at about $B_{max} = 10\,000$ lines/sq. in., and that the distortion coefficient rises at both lower and higher values of B_{max} , although the lower rise is only slight. Actually the lower part of the curve (below the knee) drops away rapidly and eventually reaches zero at $B_{max} = 0$. Some alloy core materials have appreciable values of the distortion coefficient even when approaching $B_{max} = 0$ (Ref. C9).

When there is a direct polarizing field, even as well as odd harmonic distortion are both evident. Under these conditions, below 65 000 lines/sq. in., the r.m.s. sum of the second and third harmonic currents S_{2+3} approximates to the r.m.s. sum of all the harmonic currents.

It will be seen from this analysis that it is desirable to use a low impedance source, (e.g., triodes), and a high inductance primary for best results at low frequencies.

Distortion at high frequencies

At high frequencies distortion is produced, apart from normal valve distortion due to non-linearity of characteristics, by the leakage inductance and winding capacitances which change the magnitude and phase angle of the load impedance.

The load on the secondary, if a loudspeaker, also complicates this trouble. Here again, a low impedance source is desirable; a high impedance source will accentuate the distortion due to this effect. With Class B amplifiers, it is essential that the leakage inductance between each half of the primary be as small as possible, otherwise there will not be proper cancellation of even order harmonics, and higher order harmonics will be generated (Ref. C23). A static shield between primary and secondary will prevent any stray even harmonics being fed into the secondary by capacitive coupling. This shield will alter the winding capacitances and increase the leakage inductance, hence it must be employed judiciously.

In Class B output transformers, high leakage inductance and winding capacitances cause distortion and decrease in power output. To a considerable degree, these remarks on distortion at high frequencies also apply to Class AB transformers.

(iv) Designing for low leakage inductance*

Assuming that the turns and winding dimensions are kept constant, leakage inductance can be progressively reduced by interleaving the winding structure until the limit is reached when

$$a/3N^2 < c \quad (11)$$

where a = total thickness of all winding sections

N = number of leakage flux areas

and c = thickness of each insulation section.

*This treatment follows Crowhurst, N. H. (Ref. C28).

FIG. 5.13H

Fig. 5.13H. Leakage inductance chart (Ref. C28).

Intercepts with the mean length of turn, 9.5 inches and winding width, b , of 1.875 inches gives a vertical of 0.012.

Assuming 270 turns, leakage inductance = 0.14 millihenry, or 14 millihenrys for 2700 turns.

(v) Winding capacitance*

This information assists in computing the various winding capacitances of multi-layer windings used in the construction of audio-frequency transformers, chokes and other equipment. They apply to windings in which turns are wound on layer by layer, either interleaved or random wound, so that the P.D. between adjacent turns belonging to consecutive layers will be much greater than that between adjacent turns

*Reprint of an article by Crowhurst, N. H., in *Electronic Eng.* (Ref. C29).

in the same layer. The capacitance effect between adjacent turns in the same layer is neglected, only that between layers being considered. Capacitance between winding and core, and electrostatic screens, if used, must also receive attention.

Fig. 5.13J illustrates a cross section of a piece of winding in which layer interleaving is used. It is seen that the dielectric between adjacent conductors in consecutive layers is complex both in shape and material. The turns on the top layer shown fall so that each turn drops in the space between two turns on the second layer, corrugating the interleaving material with a slight resulting increase in capacitance compared with that between the middle and bottom layers shown. Due to the spiral form of each layer, the position of turns in consecutive layers to one another will change at different points round the direction of winding, thus the capacitance between any pair of layers will automatically take up the average value. The composite dielectric is made up of conductor insulation, most commonly enamel, interleaving material and the triangular shaped spaces left between adjacent turns and the interleaving material. These spaces will be filled with dry air if the windings are dried out and hermetically sealed, or with impregnating compound if the windings are vacuum impregnated. The latter procedure will give rise to a somewhat higher capacitance.

Fig. 5.13J. Section through layer interleaved winding (Ref. G29).

Fig. 5.13K. Effective capacitance of a pair of layers (Ref. G29).

In practice the major controlling factor determining the total capacitance between two adjacent layers of winding is the thickness of the interleaving material, thus distributed capacitance may conveniently be estimated in terms of the thickness of interleaving material, giving this material a value of dielectric constant empirically obtained, allowing for the average effect of the other dielectrics in the composite arrangement.

Effective layer to layer capacitance

Take a winding having only two adjacent layers, its turns distributed uniformly throughout the two layers as shown in section at Fig. 5.13K. Consider an element dx at a distance x from the end of the winding where the conductor steps up from one layer to the other. In the complete winding the elemental capacitance due to the section dx will be transformed so that it can be represented as an equivalent value across the whole winding. If the length of the whole layer is l and the capacitance per unit layer length C , then the effective capacitance of the element referred to the whole winding will be $(x/l)^2 C dx$. The capacitance due to the whole winding will be

$$\int_0^l (x/l)^2 C dx = \frac{1}{3} l C.$$

Thus the effective capacitance of such a two-layer winding is one-third of the capacitance between two layers measured when their far ends are unconnected.

Take now a winding consisting of n whole layers: there will be $(n - 1)$ adjacent pairs of layers throughout the winding and the effective capacitance of each pair of layers, referred to the whole winding, will be a capacitance of $(2/n)^2$ times their capacitance.

ance referred to the high potential end and considered as a pair. Thus the capacitance of n whole layers referred to the whole winding becomes

$$\frac{4}{3} \cdot \frac{(n-1)}{n^2} \cdot Cl$$

For large values of n the capacitance becomes inversely proportional to the number of layers. Fig. 5.13Q illustrates a typical winding shape together with the dimensions as used in the related diagrams. The capacitance per layer, given in the foregoing formula as Cl , is proportional to the product of the length per mean turn L_{mt} and the length of layer L_w .

Vertical sectionalizing

It is sometimes of advantage to sectionalize the winding as shown at Fig. 5.13L, each vertical space being filled completely before proceeding to fill the next one.

FIG. 5.13 L

Fig. 5.13L: Sectionalizing to reduce capacitance (Ref. C29).

Although physically the winding will have the same overall cross-sectional dimensions its self-capacitance will be equivalent to that of a winding having $1/N \times$ layer length and $N \times n$ layers, where N is the number of vertical sections. The distributed capacitance of the winding due to such sectionalizing thus is reduced by the factor $1/N^2$. Note that this rule applies only to referred interlayer capacitance and does not apply to capacitance between the top and bottom of the winding and adjacent windings or screens. The various reduction factors for vertical sectionalizing are given in Table 4.

TABLE 4

Number of vertical sections	Distributed capacitance component	Winding to screen capacitance arrangement as Figure 5.13M		
		(a) One side earthy	(a) Centre point earthy	(b) One side earthy
1	1	1	0.5	0
2	0.25	0.75	0.25	0.125
3	0.111	0.704	0.185	0.185
4	0.0625	0.6875	0.1875	0.219
5	0.04	0.68	0.168	0.24
6	0.0278	0.676	0.176	0.255
∞	0*	0.667	0.167	0.333

*The method of winding is here changed so that for the purposes of this column, the dimensions L_w and T_w will change places.

Effect of mixing windings

In the design of a transformer it is often necessary to mix the primary and secondary windings in order to reduce leakage inductance. This arrangement will generally be a disadvantage as regards minimizing winding capacitance, since it exposes greater surface area of winding in proximity to either the other winding or an earthed screen. If the ratio of the transformer is fairly high, then from the high impedance winding the whole of the low impedance winding appears at common audio potential, usually earthy. But if the ratio of the transformer is not very high, capacitance between

points at differing audio potentials in the two windings may have serious effects, and it is generally best to arrange the windings so as to avoid such capacitance.

Fig. 5.13N shows a cross-section suitable for an inter-valve transformer designed to operate two valves in push-pull from a single valve on the primary side. The H.T. end of the primary is earthy and is therefore diagrammatically earthed. The high potential end of the primary is adjacent to the earthy end of one of the half secondaries so that the capacitance between windings at this point is effectively from anode to earth. The two high potential ends of the secondary are remote from the primary and so minimize the possibility of unbalanced capacitance transfer from primary to one half secondary.

FIG. 5.13M

FIG. 5.13N

Fig. 5.13M. Arrangements using vertical sectionalizing. See Table 1 (Ref. C29).

Fig. 5.13N. Push-pull secondary inter-valve transformer secondary arrangements (Ref. C29).

Another problem which often arises is in the design of push-pull output transformers, particularly for Class AB or Class B circuits, where it is essential that each half of the primary be well coupled to the whole secondary. From the viewpoint of leakage inductance and winding resistance, it is unimportant whether the secondary sections are connected in series or parallel. Fig. 5.13P illustrates three arrangements for a transformer of this type, each of which may be best suited under different circumstances. At (a) is an arrangement which gives minimum primary capacitance, but suffers from the defect that leakage inductance and winding resistance are unequal for the two primary halves. For Class A operation using valves requiring an optimum load of high impedance this arrangement is sometimes the best. At (b) is an arrangement intended to equalize winding resistance and leakage inductance from each half-primary to the whole secondary as well as primary self-capacitance. This arrangement is particularly suited to circuits employing low loading Class AB or Class B operation. The alternative arrangement shown at (c) results in a slightly lower referred capacitance across one half only of the primary. In general this unbalance is not desirable, but if leakage inductance is adequately low, the coupling between all the windings may be so good that the reduction in capacitance may be apparent across the whole primary.

FIG. 5.13P

Fig. 5.13P. Arrangements for push-pull output transformer (Ref. C29).

TABLE 5.

WINDING & SCREEN ARRANGEMENT & CONNECTION	CAPACITANCE FACTOR		WINDING & SCREEN ARRANGEMENT & CONNECTION	CAPACITANCE FACTOR	
	One side earthly	Centre point earthly		One side earthly	Centre point earthly
	—	·25		1·25	·25
	1	·5		1·11	·11
	·22	·055		2·11	·611
	·5	—		*	1
	1·5	·5		3	1·5
	*	·5		1·94	·44
	2	1		1·75	·25

Table 5 gives a pictorial representation of various ways in which high impedance windings may be arranged in relation to earthy points shown as screens. The table is equally applicable if these points are earthy low impedance windings. The capacitance factors for alternative connexions of the windings, with either one side or the centre point at earth potential, are given relative to the average capacitance between one end layer of the winding and one screen.

The two arrangements marked with an asterisk indicate that it is necessary to reverse the direction of winding in order to achieve the capacitance factor shown.

Random winding

In what is known as random winding, no interleaving material is used. For ideal

FIG. 5.13Q

Fig. 5.13Q. Dimensions used in figures 5.13R, 5.13S, 5.13T, 5.13U (Ref. C29).

FIG. 5.13R

Fig. 5.13R and 5.13S. For distributed capacitance due to layer winding (Ref. C29). Refer length of winding L_{w1} on their respective scales, to intercept at A then along the horizontal reference lines to intercept with the thickness of dielectric material T_d , at B. From this point refer along the slanting reference lines to intercept with the empirically determined value of dielectric constant k , at C, then along the horizontal reference lines to the unity reference vertical at D. From this point refer down the slanting reference lines to intercept with the number of layers n , at E, whence the referred capacitance is read off on the scale at the right.

For interwinding, or winding to screen capacitance: As above, for the winding dimensions and dielectric thickness to a point corresponding to D, whence, for winding

to screen capacitance, or interwinding capacitance when the other winding is all at low potential, refer down the slanting reference lines to intercept with the section capacitance factor obtained from Table 4. For interwinding capacitance where there is appreciable potential in the adjacent portions of both windings, individual attention will be necessary for each interwinding space, and the turns factor scale will assist here.

FIG. 5.13S

random winding the layers should be built up so that at all times during winding the top surface is level. Failure to do this will not greatly affect the self-capacitance, but will result in increased danger of breakdown due to electrical or mechanical stresses. As the number of layers is always large, it is convenient to reduce the calculation to simple terms of the winding dimensions.

The essential variables are: length of winding L_w , length of mean turn L_{mt} , winding thickness T_w (see Fig. 5.13Q), and number of turns, T . Considering variation of each of these quantities in turn, the others being taken as constant: variation of L_w will vary the referred capacitance per layer as before, and additionally the effective number of layers will vary inversely as $L_w^{\frac{1}{2}}$; variation of L_{mt} simply varies the

FIG. 5.13T

FIG. 5.13U

Fig. 5.13T and 5.13U (Ref. C29). For distributed capacitance due to random winding. Refer length of winding L_w and length of mean turn L_{mt} on their respective scales, to intercept at A then along the horizontal reference lines to intercept with the vertical line for thickness of winding T_w at B. From here refer up the slanting reference lines to the right-hand edge of the data sheet, and then back along the horizontal lines to intercept with the vertical lines for the number of turns at C from which referred capacitance is read off along the slanting lines at C_p .

layer size, as before ; variation of both T_w and T varies the number of layers in direct proportion to $T_w^{\frac{1}{2}}$ or T . Thus the whole expression for variation of capacitance can be written,

$$C_p \propto \frac{L_{mt} L_w^{3/2}}{T_w^{\frac{1}{2}} T^{\frac{1}{2}}}$$

Figures 5.13T and 5.13U are based on this relation and empirical values obtained from average results with random windings.

Example 1

A push-pull output transformer is arranged as at Fig. 5.13N : primary winding has a total of 12 layers, $T_d = 3$, $k = 2$: insulation between primary and screen, $T_d = 15$, $k = 5$; main dimensions, $L_w = 2$ in., $L_{mt} = 8$ in.

Distributed capacitance, using Figs. 5.13R and 5.13S, $L_w = 2$ in., $L_{mt} = 8$ in., $T_d = 3$, $k=2$ and $n = 12$, is $C_p = 240 \mu\mu\text{F}$.

Capacitance from each primary to screen, substituting $T_d = 15$, $k = 5$, is $C_p = 1200 \mu\mu\text{F}$. The capacitance factors for the arrangement of Fig. 5.13N are : (a) 0.25 ; (b) 0.5 ; (c) 0.375. Thus the total capacitance referred to the whole primary for each method of connexion is,

(a) $300 \mu\mu\text{F} + 240 \mu\mu\text{F} = 540 \mu\mu\text{F}$.

(b) $600 \mu\mu\text{F} + 240 \mu\mu\text{F} = 840 \mu\mu\text{F}$.

(c) $450 \mu\mu\text{F} + 240 \mu\mu\text{F} = 690 \mu\mu\text{F}$.

Example 2

An intervalve transformer, to operate from push-pull to push-pull, uses a simple arrangement having both windings all in one section : $L_w = 0.6$ in., $L_{mt} = 2.5$ in., T_w (each winding) = 0.1 in. ; insulation between windings, T_d , $k = 3$; Turns, 4 000 c.t./12 000 c.t.

Distributed capacitance, using Figs. 5.13T and 13U $L_w = 0.6$ in., $L_{mt} = 2.5$ in., $T_w = 0.1$ in., T (primary) = 4 000, is $C_p = 58 \mu\mu\text{F}$. For secondary, $T = 12 000$, $C_p = 34 \mu\mu\text{F}$.

Capacitance coupling between one-half primary and one-half secondary, using Figs. 5.13R and 13S, actual capacitance, $L_w = 0.6$ in., $L_{mt} = 2.5$ in., $T_d = 10$, $k = 3$, is $C_p = 100 \mu\mu\text{F}$. Both windings wound in same direction, turns factor across this capacitance referred to whole primary is $\frac{1}{2} + \frac{1}{2} = 2$, so referred capacitance is $400 \mu\mu\text{F}$. Windings wound opposite directions, turns factor referred to primary is $\frac{1}{2} - \frac{1}{2} = 1$, so referred capacitance is reduced to $100 \mu\mu\text{F}$. Referring these two values to secondary, turns factors are $1/2 + 1/6 = 2/3$ or $1/2 - 1/6 = 1/3$, giving capacitance values referred to whole secondary of $45 \mu\mu\text{F}$ or $11 \mu\mu\text{F}$ respectively.

A complete analysis would need to consider leakage inductance between each primary and each half secondary, and separate source and load impedances applied to each half. For this purpose, the primary and secondary shunt capacitances across each half would be $116 \mu\mu\text{F}$ and $68 \mu\mu\text{F}$ respectively, while the capacitance coupling would be $1,600 \mu\mu\text{F}$ or $400 \mu\mu\text{F}$ referred to half primary. The secondary shunt capacitances referred to the half primaries would be $610 \mu\mu\text{F}$.

Example 3

A direct coupled inter-valve transformer is arranged as at Fig. 5.13M : $L_w = 1.5$ in., $L_{mt} = 6$ in., $T_d = 20$, $k = 1$ (air spaced) ; T_w (each whole winding) = 0.2 in. ; Turns 4 000/12 000 c.t.

Distributed capacitance, using Figures 5.13T and 5.13U, $L_w = 1.5$ in., $L_{mt} = 6$ in., $T_w = 0.2$ in., T (primary) = 4 000, gives $C_p = 400 \mu\mu\text{F}$. Secondary, $T = 12 000$ gives $C_p = 225 \mu\mu\text{F}$ (or $450 \mu\mu\text{F}$ per half secondary).

Interwinding capacitance, using Figs. 5.13R and 5.13S, actual capacitance, $L_w = 1.5$ in., $L_{mt} = 6$ in., $T_d = 20$, $k = 1$, give RC_p just over $90 \mu\mu\text{F}$ say $100 \mu\mu\text{F}$.

Vertical sectionalizing will reduce the distributed component in each case, but will also vary the interwinding capacitance. Using the information in Table 4 the results may be presented as in Table 6.

In practice three sections for the primary and four or five sections for each half-secondary will be best, remembering capacitance reduction is more important in the

secondary. By making the earthy end of primary and secondary at opposite ends of the vertical groups, interwinding capacitance coupling effects are minimized.

TABLE 6

Number of vertical sections	Primary capacitance			Half secondary capacitance		
	Dis-tributed	Inter-winding	Total	Dis-tributed	Inter-winding	Total
1	400	100	500	450	—	450
2	100	75	175	112.5	12.5	125
3	44.4	70.4	115	50	18.5	68.5

5	16	68	84	18	24	42
6	—	—	—	12.5	25.5	38

(vi) Tests on output transformers

Summary of R.M.A. Standard SE-106A (Sound systems)

The distortion shall be measured with a zero-impedance source of voltage in series with a pure resistance R_{TG} of value $0.4 (\pm 5\%)$ times the square of the standard distribution voltage, V_{TR} , from which the tap is designed to work, divided by the manufacturer's rating, W_{TR} , for the power drawn by that tap at that distribution voltage :

$$R_{TG} = (0.4 V_{TR}^2 / W_{TR})(1 \pm 0.05).$$

Measurements shall be made at the lowest frequency of the rated frequency response or 100 c/s, whichever is the higher ; at 400 c/s and at 5000 c/s if within the rated frequency response.

The power-handling capacity of a speaker matching transformer is the maximum r.m.s. power drawn by the transformer at which the specified distortion (which shall be not more than 2%) is not exceeded. The power drawn by the transformer, W_T , shall be determined by dividing the square of the actual voltage measured across the primary terminals, V_{TP} , by the square of the standard distribution line voltage, V_{TR} , from which the primary tap is designed to work, and multiplying this quotient by the manufacturer's rating for the power, W_{TR} , drawn by that tap at that distribution voltage :

$$W_T = W_{TR} (V_{TP} / V_{TR})^2$$

The rating shall be determined as follows : The power at the stated distortion at 100 c/s shall be multiplied by 2. This figure shall be compared with the other measurements made at the other test frequencies, and the lowest power figure shall be taken as the power-handling capacity. In case the transformer is provided with more than one primary tap, the rating shall be given for the tap drawing the highest power at the rated distribution voltage. If there is more than one secondary tap, the power rating shall be given for the tap with the lowest measured power rating when properly terminated.

If the transformer is to be used in a system employing emphasized bass, a transformer must be chosen which has a rating higher than the nominal power to be handled in proportion to the bass emphasis employed. Likewise, transformers to handle organ music must have a rating at least four times the nominal power to be handled.

The frequency response of a speaker matching transformer is the variation of output voltage as a function of frequency, with a constant source voltage in series with a known impedance connected to the primary, expressed as a variation in db relative to the output voltage at 400 c/s.

For measurement, the transformer shall be connected as for distortion measurement (see above). The frequency response shall be measured using a constant source voltage, which will deliver one-half rated input power, W_{TR} , to the transformer at 400 c/s

The loss of a speaker matching transformer is the inverse ratio of the power delivered by the secondary of the transformer to a pure resistance equivalent to the rated load impedance, to the power delivered by the same source if the transformer is replaced by an ideal transformer of the same impedance ratio, expressed in db. For measurement, the transformer shall be connected as for distortion measurement (see above).

The impedance presented by the ideal transformer to the source shall be taken as

$$R_{T1} = V_{TS}^2 / W_{TR}.$$

The power delivered to the secondary load is (V_{TS}^2 / R_{TL}) where V_{TS} is the voltage across the load resistance R_{TL} .

The power delivered to the ideal transformer is (V_{T1}^2 / R_{T1}) where V_{T1} is the voltage across the load resistance R_{T1} .

The loss is given then by

$$\text{Loss} = 10 \log_{10} \frac{V_{T1}^2 / R_{T1}}{V_{TS}^2 / R_{TL}}.$$

The loss shall be measured at 400 c/s and at a value of source voltage at which rated power is delivered to the ideal transformer. The loss shall not exceed 2 db (equivalent to 63% minimum efficiency).

(vii) Specifications for a-f transformers

The following details are suggested for forming part of a specification for a transformer. See also Ref. C32.

In all cases, it is desirable to submit a circuit showing the transformer application when writing a specification.

(1) Input transformers

- (a) Operating level ; this should be quoted in db above or below specified reference level, usually 1 milliwatt.
- (b) Frequency response with permissible variation in db from a reference frequency, generally 1000 c/s.

Conditions of measurement must be specified—usually normal operating conditions.

- (c) Impedance ratio or turns ratio.
- (d) Positions of any taps should be stated.
- (e) Source and source impedance.
- (f) Load and load impedance. This may be the grid of a following amplifier valve. The secondary winding may also be shunted by a frequency-correcting network ; if so, full details should be given.
- (g) Total r.m.s. harmonic distortion ; this should be measured at max. output at the lowest frequency of interest.
- (h) Minimum resonant frequency.
- (i) Insertion loss in db—frequently quoted at 400 c/s.
- (j) Permissible phase characteristics at lowest and highest frequencies of interest.
- (k) Direct currents in windings.
- (l) Magnetic and electrostatic shielding.

(2) Interstage transformers

In general, as for input transformers, with the addition that the type of valves used in the preceding stage, together with their operating conditions, should be specified. Where push-pull input is intended, the maximum out-of-balance current should be stated.

(3) Output transformers

As (2) above. Where multiple secondary windings are employed the power to be delivered to each should be stated.

SECTION 4 : MAGNETIC CIRCUIT THEORY

(i) *Fundamental magnetic relationships* (ii) *The magnetic circuit* (iii) *Magnetic units and conversion factors.*

(i) Fundamental magnetic relationships

Just as we have an electrical circuit, so the core of a transformer can be regarded as a magnetic circuit through which a flux passes, its value depending on the magnetomotive force producing it and on the nature of the magnetic circuit. These are related by an equation resembling Ohm's Law for electrical circuits :

$$F = \phi R \text{ or } \phi = F/R \text{ or } R = F/\phi \quad (1)$$

where F = magnetomotive force (m.m.f.) in **gilberts** (c.g.s. electromagnetic units) analogous to electromotive force (e.m.f.) in electrical circuits,

ϕ = total flux = the total number of lines of flux (or maxwells ; 1 maxwell = 1 line of flux),

R = reluctance (equivalent to resistance in electrical circuits). The c.g.s. electromagnetic unit of reluctance is the reluctance of 1 cubic centimetre of vacuum, which is very closely that of 1 cubic centimetre of air. Reluctances are combined in series or parallel like resistances ; when in series they are added.

Fig. 5.14. Typical magnetic circuit with iron core and air-gap.

A typical magnetic circuit is shown in Fig. 5.14 where we have the greater part of the magnetic circuit through iron, and a short length (the air gap) through air. In this case the total reluctance is the sum of the reluctances of the iron-circuit and the air gap. The flux ϕ is caused by N turns of wire carrying a current I amperes and producing a magnetomotive force given by

$$F = (4\pi/10) NI \approx 1.257 NI \quad (2)$$

where F = magnetomotive force in gilberts,

N = number of turns,

and I = current in amperes.

Thus 1 ampere turn ≈ 1.257 gilberts.

Instead of considering the total flux, it is often more convenient to speak of the **flux density**, that is the number of lines (maxwells), per square inch or per square centimetre (c.g.s. electromagnetic unit = 1 gauss = 1 maxwell per square centimetre). The symbol for flux density is B . Thus

$$\phi = BA \quad (4)$$

where ϕ = total flux,

B = flux density, either in lines per square inch or in gauss (maxwells per square centimetre),

and A = cross sectional area of magnetic path (practically equal to the cross sectional area of the core in the iron section), in square inches or square centimetres respectively.

The **magnetizing force** (also known as the magnetic potential gradient or the magnetic field intensity) is defined as the magnetomotive force per unit length of path :

$$H = F/l$$

where H = magnetizing force in oersteds (or gilberts/centimetre),

F = magnetomotive force in gilberts,

and l = length of path in centimetres.

Alternatively, if F is expressed in ampere-turns, H may be expressed in ampere-turns per inch or per centimetre.

The **permeability** (μ) is defined by the relationship ;

$$\mu = B/H$$

where B = flux density in gauss (maxwells per square centimetre),

μ = permeability*,

and H = magnetizing force in oersteds.

In air, H is numerically equal to the flux density (B).

Permeability is the equivalent of conductivity in electrical circuits. Permeability in iron cores is not constant, but varies when the flux is varied. The relationship between B , H and μ is shown by the " BH characteristics" of the iron, as shown for example in Fig. 5.15. The value of μ at any point is the value of B divided by the value of H at that point.

For example, the permeability at point C is equal to OE/OD, where OE represents the flux density at point C, and OD represents the magnetizing force at point C. The permeability is therefore the slope of the line OC. A curve may be drawn indicating the value of μ for any value of H , and this curve may be plotted on the same graph with, of course, the addition of a μ scale (dashed curve in Fig. 5.15).

The **incremental permeability** is the permeability when an alternating magnetizing force is superimposed on a direct magnetizing force.

FIG. 5.16

Fig. 5.16. Hysteresis loop of a typical magnetic material.

The **initial permeability** is the permeability at values of H approaching zero.

The **hysteresis loop** of a typical magnetic material is shown in Fig. 5.16. When the magnetizing force increases from zero (demagnetized condition) to the positive peak, the B - H characteristic is followed from O to A, where A represents the maximum (peak) values of H and B . As the value of H decreases to zero and then increases in the opposite direction, the path followed is along the curve ACDE, where E is the negative equivalent to A, occurring half a cycle later than A. From E, the path followed is along the curve EFGA†. The area of the curve ACDEFGA represents power loss, known as hysteresis loss, in the magnetic material.

Point C is the value of B for zero magnetizing force (i.e., $H = 0$) and it represents the residual magnetism; this value of B is called the **remanence**, or **remanent flux density**†.

*Strictly speaking, μ is measured in gauss per oersted, but it is common practice in engineering work to speak of the permeability as a pure number which is the ratio between μ and μ_0 where μ_0 is the permeability of vacuum, and has a value of unity.

†Actually this "cyclic condition" is not reached until after a number of cycles have occurred. In the early cycles the position of A falls slightly each cycle.

‡This strictly applies only to the initial cycle; the term residual flux density is used for symmetrical cyclically magnetized conditions. The latter term is also sometimes used when it is not desired to distinguish between the initial and cyclic conditions.

FIG. 5.15

Fig. 5.15. BH characteristics of a typical transformer steel. The dashed curve is the permeability μ where $\mu = B/H$.

Point D is that at which the applied negative magnetizing force brings the value of the residual magnetism to zero.

The length OC is called the **coercive force** (strictly this applies only for symmetrical cyclically magnetized conditions).

The **average permeability** is the slope of the straight line EOA (shown dashed in Fig. 5.16).

The locus of the extremities (A or E) of the normal hysteresis loops of a material is called its **normal magnetization curve**; this is the same as the B - H curve of Fig. 5.15.

When alternating current is passed through the winding, the iron will pass through the hysteresis curve ACDEFGA (Fig. 5.16) each cycle. The maximum value of H is called H_{max} , and the corresponding value of B is called B_{max} , the curve being normally symmetrical in the positive and negative directions in the absence of a direct current component.

When dealing with alternating currents, it is usual to quote ampere-turns per inch in r.m.s. values; the corresponding values of flux density may be quoted either in terms of B or B_{max} . It is obvious that $H_{max} = \sqrt{2}H$, but B_{max} is normally greater than $\sqrt{2}B$.

(ii) The magnetic circuit

A typical magnetic circuit is shown in Fig. 5.14. Certain assumptions are generally made for simple theoretical treatment, including—

1. That the flux confines itself entirely to the iron over the whole length of the iron path (in practice there is always some leakage flux, which is more serious when there is an air gap).
2. That the flux is uniformly distributed over the cross-sectional area of the iron.

In Fig. 5.14 we therefore have :

$$\text{Total magnetomotive force} \quad F \approx 1.26 NI \text{ from (2)}$$

$$\text{Total reluctance} \quad R = R_{iron} + R_{air}$$

where R_{iron} = reluctance of iron path

and R_{air} = reluctance of air path.

$$\text{Total flux } \phi = F/R = F/(R_{iron} + R_{air}) \text{ from (1).}$$

The reluctance of the air gap is given by

$$R_{air} = F/\phi = Hl/BA = kl/A \quad (7)$$

where l = length of air gap,

A = equivalent area of air gap, allowing for "fringing"

$$\approx (a + l)(b + l)$$

and a, b = actual dimensions of pole faces.

Values of k are given by the table below :

H	oersteds	ampere turns/cm	ampere turns/inch
B	gauss	gauss	lines/sq. inch
l	centimetres	centimetres	inches
A	sq. centimetres	sq. centimetres	square inches
k	1	0.796	0.313

The reluctance of the iron path is not constant, so that the best approach is graphical.

The magnetic **potential difference** (U) is the equivalent of potential difference in electrical circuits. The sum of the potential differences around any magnetic circuit is equal to the applied magnetomotive force.

Applying this to Fig. 5.14,

$$F = U_{iron} + U_{air} \quad (8)$$

where F = total magnetomotive force,

U_{iron} = magnetic potential difference along the whole length of iron,

and U_{air} = magnetic potential difference across the air gap.

Fig. 5.17. Total flux versus magnetic potential difference, with air loadline.

This is applied in Fig. 5.17 where OM represents the applied magnetomotive force ($F \approx 1.26 \text{ NI}$), and the curve shows the total flux (ϕ) plotted against F for iron only. The shape of the curve is the same as that of the B - H characteristic of Fig. 5.15, but the vertical scale $\phi = Ba$, and the horizontal scale $F = IH$.

The "loadline" through M represents the effect of the air-gap; it follows the equation

$$U = F - \phi R_{air} \quad (9)$$

and its slope is $-(1/R_{air})$. The intersection of the "loadline" and the curve at point P gives the operating point. Therefore ON represents the magnetic potential difference along the iron path, while NM represents the magnetic potential difference across the air gap.

It will thus be seen that variation of the air gap merely changes the slope of the "loadline" PM and moves point P, without changing the base line OM.

In order to be more generally applicable, the scales of Fig. 5.17 may be changed—

vertical scale : from ϕ to B (Note $\phi = Ba$)

horizontal scale : from F to H (Note $F = IH$)

from U to U/l (i.e., magnetic potential difference per inch)
as in Fig. 5.18A.

(iii) Magnetic units and conversion factors

The basic units generally adopted are the c.g.s. electromagnetic units such as the gauss, the oersted and the gilbert, with the centimetre as the unit of length. Practical units such as the lines per square inch and ampere-turns per inch are widely used in engineering design. More recently, the Giorgi M.K.S. system, with its webers and webers per square metre, has achieved considerable popularity. The full range of these various systems of units is given in Chapter 38 Sect. 1.

The following table of conversion factors will be helpful in converting from one system to another.

H = MAGNETIZING FORCE,
(GILBERTS PER INCH, OR AMPERE-TURNS PER INCH).

FIG. 5.18A

Fig. 5.18A. Flux density versus magnetizing force, with air loadline.

Magnetic Units—Conversion Factors

Multiply	by	to obtain
F in ampere-turns	$0.4\pi = 1.257$	F in gilberts
F in gilberts	$1/0.4\pi = 0.796$	F in ampere-turns
F in pragilberts*	0.1	F in gilberts
F in gilberts	10	F in pragilberts*
F in ampere-turns	$4\pi = 12.57$	F in pragilberts*
F in pragilberts*	$1/4\pi = 0.0796$	F in ampere-turns
H in ampere-turns/in.	$0.4\pi/2.54 = 0.495$	H in oersteds
H in oersteds	$2.54/0.4\pi = 2.02$	H in ampere-turns/in.
H in praoersteds*	10^{-3}	H in oersteds

ϕ in lines of flux		
ϕ in webers*		ϕ in maxwells

SECTION 5 : POWER TRANSFORMERS

(i) *General* (ii) *Core material and laminations* (iii) *Primary and secondary turns*
 (iv) *Currents in windings* (v) *Temperature rise* (vi) *Typical design* (vii) *Specifications for power transformers.*

(i) General

The general design principles of power transformers have been dealt with in detail elsewhere (Refs. D1, D2, D3, D4) but an outline is given below of the design procedure for small power transformers for use in radio and electronic equipment. For transformers of this kind, efficiencies ranging from 80 to 90 per cent are common. The ratio of copper to iron losses is usually about 2 to 1. Winding capacitances have little effect on circuit operation and are usually neglected. For radio receivers it is common practice to provide some form of electrostatic screening between the primary and the other windings. This can be achieved in one of several ways (Ref. D5) :

(a) By using a turn of shim copper or brass of full winding width between primary and secondary, taking care to insulate the ends to avoid a shorted turn. This shield is then earthed.

(b) By winding the earthed low voltage filament between primary and secondary.

(c) By winding the high voltage secondary in two separate halves, one on top of the other, over the primary. The innermost and outermost leads are joined and become the centre tap which is then earthed. The two leads from the middle of the winding then become the high tension outers, and are connected to the rectifier plates. In this way the capacitance from primary to secondary is made very small. It is important in this method of construction to ensure that adequate insulation is used between the two plate leads within the winding, as the whole of the potential difference of the high tension winding appears between them.

With the normal method of construction the leakage inductance between either half of the secondary and the primary is unequal. In large transformers this becomes

*M.K.S. unit : See Chapter 38 Sect. 1.

important and, to maintain balance, the primary is wound between the halves of the secondary or the latter are wound side by side over the primary.

(ii) Core material and size

Various grades of core material are available all differing in silicon content from 0.25 to 4.5 per cent (Refs. D6, 7). They feature lower loss, increasing cost and brittleness with increase in silicon. Several manufacturers make somewhat similar grades and these are listed hereunder (Ref. D8).

TRANSFORMER STEELS

Silicon Content*	M. and E.A.	Baldwin	Sankey	Allegheny	Armco
4%	Silcor 1	Quality 5	Super Stalloy	Transf. C	Trancor 2
3½%	Silcor 2	Quality 4	Stalloy	Transf. D	Trancor 1
2¾%	Silcor 3	Quality 3B	42 Quality	Electrical	Spec. Elec.
1%	Silcor 4	Quality 1	Lohys	Armature	Armature

*This applies exactly to Silcor (Magnetic and Elec. Alloys Ltd.).

The core losses for the various Silcor grades measured at 50 c/s. with 0.014 inch sheet, at two different values of flux density are shown below.

B_{max}	Watts lost per pound			
	Silcor 1	Silcor 2	Silcor 3	Silcor 4
10 Kilogauss	0.59	0.63	0.89	1.32
13 Kilogauss	1.04	1.07	1.51	2.24

It will be observed that for small changes in flux density the core loss varies as the square of the flux density. For radio power transformer work, core materials similar to Silcor 2 are commonly used. Measurements of losses can be made with a low power factor wattmeter, or by the three ammeter method. A system suitable for mass production testing has been described recently (Ref. D9).

Cold rolled, grain oriented 2.7 per cent silicon steels are becoming of increasing importance. Typical trade names for this material are "Hipersil" and "Crystalloy" (Ref. 10). Flux densities in excess of 110 000 lines per square inch (17 kilogauss), can be employed without high core loss. Owing to low core losses at such high flux densities, the application of this material to small transformers for electronic equipment is increasing. It can be used in strip form, being wound around the winding in one method of assembly. In another method, the strip core is sawn in half and the two halves clamped together around the winding. Either method results in a considerable saving in material and labour over the present method of punching laminations and hand stacking the winding with them.

The most popular laminations in current use are the *E* and *I* "scrapless" variety (Refs. D11, 12, 13, 14). These are so dimensioned that the *I* is punched from the window of the *E* thus avoiding wastage. The usual ratio of dimensions of these laminations are as follows: Window height 1, tongue 2, window width 3, *I*-length 6, magnetic path 12.

Similar laminations are stamped by several different firms:

Standard Lamination Sizes					
Pattern Number					
Tongue	M.E.A.	Baldwins	Sankey	Allegheny	Chicago
9/16 in.	18	—	—	EI-56	—
$\frac{5}{8}$	145	392	—	EI-625	F000
$\frac{3}{4}$	35	217	70	EI-75	D000
$\frac{7}{8}$	147	—	—	EI-11	B000
1	29	430	111	EI-12	1000
$1\frac{1}{8}$	—	—	158	EI-112	13000
$1\frac{1}{4}$	78	420	133	EI-125	14000
$1\frac{3}{8}$	152	362	—	EI-138	—
$1\frac{1}{2}$	120	—	149	EI-13	—

Laminations for small power transformers are generally 0.014 inch thick ; thicker laminations up to 0.025 inch are occasionally used, but result in increased losses and shortened lamination die life.

To determine the core size, it is first necessary to estimate the power requirements. Then we may apply the empirical relation

$$A = \frac{\sqrt{VA}}{5.58} \quad (1)$$

where A = cross-sectional area in square inches
and VA = voltamps output.

For case of production an approximately square stack is desirable. Thus having determined A , the tongue size can be estimated from \sqrt{A} . Where high voltage windings, or windings operating above ground, or at a high potential between other windings, are used, it becomes necessary to employ a lamination which has a different ratio of dimensions from those quoted earlier, the window height being increased to allow room for extra insulation. The input current taken by a transformer on no-load is commonly called the magnetizing current. In fact, it consists of two components in phase quadrature. The in-phase component, usually small, is the iron loss plus a very small copper loss. The quadrature portion is the true magnetizing current. Their vector sum does not normally exceed about a third of the full load current.

(iii) Primary and secondary turns

The primary turns required can be determined from the fundamental transformer equation.

$$N = \frac{E \times 10^8}{4.44 fBA} \quad (2)$$

where N = primary turns, f = frequency in c/s

B = max. flux density

and A = cross-sectional area of core in sq. ins.

Assuming an average stacking factor of 90 per cent, the factor 4.44 becomes 4 in the denominator. The stacking factor reduces the apparent height of the stack, the reduction being caused by insulation, scale and burr due to die wear. With very thin laminations, the stacking factor decreases to 80 per cent approximately. For a flux density of 64 500 lines per square inch (10 kilogauss) eqn. (2) becomes :

$$\begin{array}{lll} \text{For 240 volts 50 c/s} & 230 \text{ volts 50 c/s} & 117 \text{ volts 60 c/s} \\ N = \frac{1860}{A} & N = \frac{1780}{A} & N = \frac{755}{A} \end{array}$$

where A = gross cross-sectional area of core in sq. ins.

The flux density employed depends on the application, the power rating, the core material and the frequency. For oscilloscopes and pre-amplifiers, densities of 40 000 to 50 000 lines per square inch (about 7 000 gauss) are used. For small transformers below about 50 watts, densities up to 90 000 lines per square inch (14 000 gauss) are used, gradually decreasing to about 65 000 lines (10 000 gauss) as the transformer size increases to several hundred watts.

Having chosen a suitable flux density, the turns required for each secondary winding may be calculated.

It can be shown that, approximately,

$$N_2 = \frac{E_2 \cdot N_1}{E_1 \cdot \sqrt{\eta}} \quad \text{where } \eta = \text{transformer efficiency.}$$

As a first approximation it may be assumed that $\eta = 0.85$ and $\sqrt{\eta} = 0.92$.

The values thus obtained for the secondary turns may be checked by more detailed calculations once wire gauges have been chosen and winding resistances calculated. For this purpose the equivalent circuit of Figure 5.11 may be used.

If a secondary is to feed a rectifier and the d.c. output of the valve is specified, reference should be made to Chapter 30 or a valve data book to determine the required

secondary voltage. Allowance must be made for any voltage drops due to the d.c. resistance of the rectifier filter.

(iv) Currents in windings

To enable the wire gauges to be chosen and to assess the copper losses in the windings, it is necessary to estimate the current in each winding. Where windings are used to supply valve heaters and resistance loads, the winding current is the same as the load current. In a secondary winding feeding a rectifier the winding current must be estimated from a knowledge of the type of rectifier and its associated filter and their characteristics. For normally-loaded full wave rectifiers the following values of secondary current may be used as a fairly close guide for design purposes.

Condenser input filter : The r.m.s. current in each half of the transformer secondary may be taken approximately as 1.1 times the direct current to the load. For further details see Chapter 30 Sect. 2.

Choke input filter : The r.m.s. current in each half of the transformer secondary may be taken approximately as 0.75 times the direct current to the load. For further information, see Chapter 30, Sect. 4 (also Sect. 3). With half-wave rectification there will be a d.c. component of the current which will affect the transformer design if the total d.c. ampere turns are considerable. For half-wave battery chargers using bulb rectifiers, this must be taken into consideration when selecting core size and wire gauges (Ref. D15).

In the case of transformers supplying full-wave rectifiers, the full load primary current can be estimated by calculating the total secondary loading in voltamps, allowing an efficiency of 85% as a first approximation. This is then the primary input in voltamps which, when divided by the primary voltage, will give the desired current. Where secondaries feed a resistive load, the loading is the product of the voltage and current. Where a secondary feeds a full-wave rectifier the load is the product of the direct current and the direct voltage output from the rectifier plus the power lost in the rectifier. This latter can be calculated, for a condenser input filter, from data presented in Chapter 30, Sect. 2. It should be noted that indirectly heated, close-spaced rectifiers such as the 6X4, are more efficient than types such as the 5Y3-GT, with its heavier filament power and lower plate efficiency. This is one reason why the former are almost exclusively used in the majority of small a.c. radio receivers.

The primary input current as calculated above should be accurate to within 10% for small transformers.

Wire gauges and copper losses

For the usual type of radio receiver power transformer it will be safe to choose wire gauges on the basis of 450-800 circular mils* per ampere (i.e. 2830-1590 amperes per square inch), but values up to 1000 circular mils per ampere (i.e. 1270 amperes per square inch) may be desirable in larger units, or if a high flux density is used with high loss lamination steel. The latter figure is easy to remember as 1 circular mil per milliamp.

In practice, wire gauges may be chosen arbitrarily on a basis of (say) 700 circular mils per ampere (i.e. approximately 1800 amperes per square inch) and check calculations should then be made to see that

- (a) the build of the winding (i.e. winding height) is satisfactory for the window space available,
- (b) the copper loss is not so high as to cause excessive temperature rise,
- (c) the voltage regulation is satisfactory.

Wire tables in this Handbook will simplify these calculations (Chapter 38 Sect. 19).

(v) Temperature rise

This is dependent upon the cooling area, the total loss and the ratio of iron to copper loss. To avoid deterioration of the insulating materials, it is necessary to limit the working temperature to 105°C for Class A insulation which includes paper, cotton,

*A circular mil is the area of a circle 1 mil (1/1000 inch) in diameter.

silk, varnish and wire enamel (Refs. D16, 17). The temperature rise in the winding, as measured by the change of resistance method, will be about 10°C lower than the maximum (hot spot) temperature. Thus with an ambient temperature of 40°C (104°F) plus a margin of 10°C for the difference between measured and hot spot temperature, it will be seen that the maximum permissible rise is 55°C, as measured by the change of resistance.

It is common practice to allow 10°C margin for change in line voltage, frequency, or operation in situations with restricted ventilation. Thus 45°C is generally accepted as the maximum permitted rise above ambient when measured by resistance change.

The temperature difference between winding and core varies between 10° and 20°C according to the distribution of losses. This means that even with an ambient temperature of 25°C (77°F), the core temperature may be 60° (140°F). This will feel quite hot to the touch, although the internal temperature may be well under the permitted maximum. Measurement of the core temperature may be made with a spirit thermometer if good thermal contact is maintained between the core and the thermometer bulb.

The winding temperature rise can be calculated by measuring the cold resistance, R_0 at an observed temperature T_1 . After a heat run at full load the hot resistance R is measured and the ambient temperature T_2 is again measured.

Taking the temperature coefficient of resistivity (α) of copper as 0.003 93, the temperature rise T is found from the formula

$$T = \frac{R - R_0}{R_0 \alpha}$$

To correct for any changes in ambient temperature during the heat run it is necessary to subtract the difference $T_2 - T_1$ from T to find the actual rise. An example will illustrate this.

The primary resistance of a transformer measured when cold was 30 ohms at an ambient temperature of 20°C. After an 8 hour full load run, the resistance was 36 ohms, while the ambient temperature was then 18°C. It is required to find the winding temperature rise.

$$T = \frac{36 - 30}{30 \times 0.00393} = \frac{6}{30 \times 0.00393} = 51^\circ\text{C}.$$

Now $T_2 - T_1 = (18 - 20)^\circ\text{C} = -2^\circ\text{C}$.

Winding temperature rise = $[51^\circ - (-2)]^\circ\text{C} = 53^\circ\text{C}$.

Standard methods of testing small radio receiver power transformers have been published (Refs. D18, D22). The cooling area of a transformer for the "scrapless" type laminations with standard ratio of dimensions is

$$A = T(7.71T + 11S)$$

where A = cooling area

T = width of tongue

and S = height of stack.

For a square stack $S = T$ and $A = 18.71T^2$ (Ref. 11).

Having calculated the iron and copper losses and the total cooling area, it is possible to estimate the temperature rise before a sample transformer is wound. The watts lost per square inch of cooling area is first calculated. Reference to Fig. 5.18B will then show the temperature rise to be expected with an accuracy of approximately $\pm 10\%$.

(vi) Typical design

(Refs. D19, D20, D21, D23).

Specifications :

Primary 240 V 50 c/s

Secondary (i) 6.3 V 2.6 A

Secondary (ii) 300 V + 300 V r.m.s. for full wave 6X4 rectifier with condenser input filter to deliver 60 mA d.c.

Secondary loading

Secondary (i) 6.3 V 2.6 A or 16.5 watts

D.C. output 343 V 0.06 A or 20.5 watts

Rectifier loss (see Chap. 30) $\overline{2.0}$ watts approx.

Total loading $\overline{39.0}$ watts

Primary input (assuming an efficiency of 85%) 46.0 watts.

Thus the input current is $46/240$ or 0.19 A. Core cross-section : $A = \sqrt{39/5.58} = 1.12$ square inches. Choosing pattern EI-112 lamination of Silcor 2 material, a suitable stack for calculated cross section is 1.125 inches, that is, a square stack.

Primary turns :

With a flux density of 13 kilogauss (84 000 lines per square inch) and a stacking factor of 0.9,

$$N_p = 240 \times 10^8 / 4 \times 50 \times 84\,000 \times 1.125 \times 1.125 = 1130.$$

Secondary (ii) turns :

$$N_1 = E_1 N_p / E_p \sqrt{\eta} = 300 \times 1130 / 240 \sqrt{0.85} = 1530 + 1530.$$

$$\text{Turns per volt} = N_1 / E_1 = 1530 / 300 = 5.1.$$

$$\text{Secondary (i) turns} = (6.3 \times 5.1) = 32.$$

Wire gauges :

Assume a current density of 600-700 circular mils per ampere. Referring to wire tables, a suitable primary gauge is 29 A.W.G. enam.

Turns per layer = 95. Refer Figs. 5.18C and wire tables in Chapter 38 Sect. 19.

$$\text{No. of layers} = 1130 / 95 = 12.$$

$$\text{R.M.S. current in secondary (ii) is } (0.06 \times 1.1) = 0.066 \text{ A.}$$

Fig. 5.18B. Temperature rise versus loss per square inch of cooling surface for ambient temperature 25°C (Ref. D.1.)

Suitable wire gauge is 34 A.W.G. enam.

Turns per layer = 167.

No. of layers = $3060/167 = 19$.

Suitable secondary (i) gauge is twin 20 A.W.G. enam.

Turns per layer of twin wire = 16.

No. of layers = $32/16 = 2$.

A twin wire is used in preference to a single wire of 17 or 18 A.W.G. in order to save winding height.

Winding Build :

Primary build = No. of layers \times (enam. wire diam. + interlayer insulation)
 $= 12 \times (12.2 + 2) \times 10^{-3}$ inches
 $= 0.170$ inch.

Secondary (ii) build = $19 \times (6.9 + 1) \times 10^{-3}$ inch
 $= 0.150$ inch.

Secondary (i) build = $2 \times (32.4 + 5) \times 10^{-3}$ inch
 $= 0.075$ inch.

Allowing 50 mil former thickness and 10 mil insulation between windings and over outer winding, total build is $(0.170 + 0.150 + 0.075 + 0.050 + 0.040)$ inch
 $= 0.485$ inch.

Winding height = 0.562 inch.

Build expressed as a percentage of window height
 $= 0.485/0.562 \times 100 = 86.5\%$.

In this particular design, the heater winding is wound between primary and high tension windings to serve as a static shield.

Mean length of turn calculations—see Fig. 5.18D.

A = Former build plus insulation = $0.050 + 0.010 = 0.060$ inch

B = Primary build plus insulation = $0.170 + 0.010 = 0.180$ inch

C = Secondary (i) build plus insulation = $0.075 + 0.010 = 0.085$ inch

D = Secondary (ii) build plus insulation = $0.150 + 0.010 = 0.160$ inch

4S = $2 \times (\text{stack} + \text{tongue}) = 4.5$ inches

Primary mean length of turn = 5.44 inches

Secondary (i) mean length of turn = 6.27 inches

Secondary (ii) mean length of turn = 7.04 inches.

Winding resistance :

If each value for the mean length of turn is multiplied by the number of turns in its own winding and then divided by twelve, the resulting quantity will be the number of feet of wire in each winding. By referring to the wire tables, the resistance in ohms per thousand feet for any particular gauge can be found. Dividing the wire length by a thousand and multiplying by the resistance per thousand feet, will determine the winding resistance.

Primary resistance = $5.44 \times 1130 \times 81.8/12 \times 1000 = 42$ ohms

Secondary (i) resistance = $6.27 \times 32 \times 12/2 \times 12 \times 1000 = 0.09$ ohms

Secondary (ii) resistance = $7.04 \times 3060 \times 261/12 \times 1000 = 470$ ohms

Copper loss :

Primary copper loss = $(0.19)^2 \times 42 = 1.52$ watts

Secondary (i) copper loss = $(2.6)^2 \times 0.09 = 0.61$ watts

Secondary (ii) copper loss = $(0.066)^2 \times 470 = 2.05$ watts

Total copper loss = 4.18 watts

Iron loss :

Loss per pound of Silcor 2 at flux density of 13 kilogauss = 1.07 watts.

Weight of core = 2.17 lbs.

Therefore total iron loss = $(1.07 \times 2.17) = 2.32$ watts.

Temperature rise :

Total of iron and copper loss = $(2.32 + 4.18) = 6.5$ watts.

Cooling area of square stack = $18.71 \times (1.125)^2 = 23.6$ sq. inches.

Therefore watts lost per sq. inch = $6.5/23.6 = 0.275$ watts.

From Fig. 5.18B temperature rise = 35°C .

Efficiency :

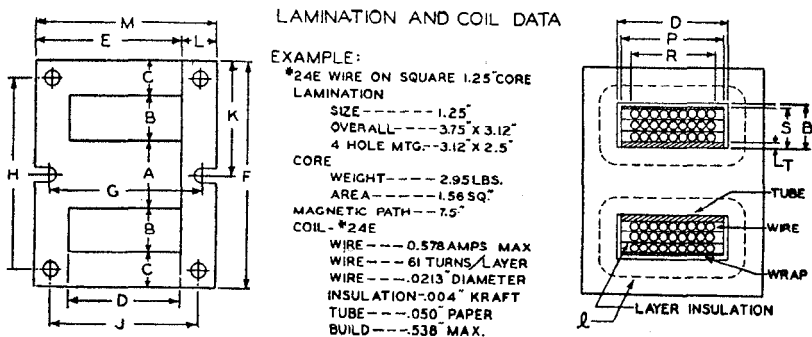

$$\text{Efficiency} = \text{Power output} / (\text{power output plus losses})$$

$$= 39 / (39 + 6.5) \times 100 = 86\%.$$

Regulation, calculated from British definition :

$$\text{Primary voltage drop} = 0.19 \times 42 = 8 \text{ V}$$

$$\text{Regulation due to resistance of primary} = 8 \times 100 / 240 = 3.3\%.$$

Fig. 5.18C. Lamination and coil data (Ref. D20).

FIG. 5.18 D

Fig. 5.18D. Method of computing mean length of turn (Ref. D20).

The percentage regulation of any secondary winding is calculated by dividing the full-load voltage drop of the winding by the open-circuit winding voltage and multiplying by 100. By adding the percentage regulation of the primary winding, the overall regulation for the secondary winding under examination is found.

Secondary (i) voltage drop	$= 2.6 \times 0.09 = 0.234 \text{ V}$
Regulation, overall (i)	$= (0.234 \times 100/6.8) + 3.3 = 6.7\%$
Secondary (ii) voltage drop	$= 0.066 \times 470 = 31 \text{ V}$
Regulation, overall (ii)	$= (31 \times 100/650) + 3.3 = 8.1\%$
Full load secondary (i) voltage	$= 6.35 \text{ V}$
and full load secondary (ii) voltage	$= 300 \text{ V} + 300 \text{ V.}$

This should be a satisfactory design.

As the temperature rise is low, it might be feasible to effect economies by re-design. For example, a higher loss core material could be used. Alternatively the flux density could be increased by decreasing the turns or the size of the stack. A new design could also be tried on the next smaller size lamination.

(vii) Specifications for power transformers

The following may be incorporated into a specification for a power transformer.

- Input voltage and frequency; should these quantities vary, the range of variation must be stated.
- Secondary full load voltages and currents. If tapped windings are required this should be indicated. Tolerances on voltages should be stated.
- Regulation of secondary voltages other than for rectifier plate circuit.
- Power factor of each secondary load.
- Rectifier system, if d.c. output is required; e.g. full wave, half wave, etc.
- Type of rectifier valve to be used.
- Type of filter circuit; e.g. choke or condenser input, etc.
- Capacitance of input condenser, or inductance and resistance of input choke.
- D.C. full load current and voltage at filter input.
- D.C. regulation.
- External voltages between windings, or between windings and ground. Should transformer windings be interconnected externally, this should be indicated.
- Static shields. Number and position of each should be indicated.
- Any limiting dimensions together with mounting and lead terminations.
- Ambient temperature in which the transformer is to operate.

A circuit should be supplied showing intended use of transformer.

In all cases it is desirable for the design of the whole rectifier system, comprising transformer, rectifier and filter system, to be carried out by the one engineer.

SECTION 6 : IRON-CORED INDUCTORS

(i) General (ii) Calculations-general (iii) Effective permeability (iv) Design with no d.c. flux (v) Design of high Q inductors (vi) Design with d.c. flux (vii) Design by Hanna's method (viii) Design of inductors for choke-input filters (ix) Measurements (x) Iron-cored inductors in resonant circuits.

(i) General

Iron cored inductors fall into several different categories depending upon the circuit requirements. In some applications these inductors may have to carry a.c. only, in others, both a.c. and d.c. They may have to work over a wide range of frequencies, or at any single frequency up to the ultrasonic range. Iron-cored inductors are employed as smoothing and swinging chokes in power supplies, as equalizer elements in audio frequency equipment, as modulation chokes and as filter elements in carrier equipment, to mention a few varied applications.

To design such an inductor it is therefore necessary to know some or all of the following specifications—

- (a) inductance, or range of inductance if variable,
- (b) alternating voltage across the coil,
- (c) direct current through the coil,
- (d) frequency of operation,
- (e) maximum shunt capacitance,
- (f) minimum frequency of self-resonance,
- (g) minimum Q over frequency range and/or
- (h) frequency of maximum Q ,
- (i) d.c. resistance,
- (j) shielding,
- (k) temperature rise,
- (l) size and weight limitations,
- (m) insulation requirements.

(ii) Calculations—general

The inductance L of an iron-cored coil may be calculated using the relation

$$L = \frac{3.2 \times N^2 \times \mu \times a}{10^8 \times l} \text{ henrys} \quad (1)$$

where N = number of turns

a = effective cross sectional area of coil in square inches

l = length of magnetic circuit in inches

and μ = effective permeability.*

The effective permeability depends on the type of steel used, on the a.c. and d.c.

FIG. 5.19

PATH OF MAGNETIC CIRCUIT

Fig. 5.19. Magnetic cores, showing method for calculation of length of magnetic path.

*A more precise term is "inductance ratio."

flux densities in the core, and on whether the core laminations are interleaved or whether there is an air gap in the magnetic circuit.

The length of the magnetic circuit is the length measured around the core at the centre of cross section of each magnetic path. Referring to Fig. 5.19, the path taken will be along the centre of each leg except where there are two windows, when each path through the centre leg will be along a line one-quarter of the way across the leg. In this latter case only a single path round the window is considered in calculating the magnetic circuit length.

Eqn. (1) is properly applicable only when the cross-sectional area of the core is uniform throughout the magnetic circuit. Where the cross section is non-uniform, a conservative value of L will usually be obtained by using for a the minimum value of the cross-sectional area. For more accurate calculations in such cases reference should be made to a suitable text-book (e.g. Ref. E1).

(iii) Effective permeability

For any given sample of lamination steel the effective permeability depends primarily on the a.c. and d.c. flux densities in the core.

Irrespective of the presence of air gaps in the magnetic circuit, the maximum a.c. flux density B_{max} in the core is determined by the cross section of the core, the number of turns in the coil, the alternating voltage across the coil and the frequency, and may be calculated directly from the relation derived from eqn. (2) in Sect. 5,

$$B_{max} = \frac{E \times 10^8}{4.44 f N a} \quad (2)$$

The d.c. magnetizing force in the core depends on the total number of d.c. ampere-turns, less the number of ampere-turns absorbed in any air gap, divided by the length of the magnetic circuit in inches (see Sect. 4).

Fig. 5.20 shows the variation of effective permeability with variation of a.c. flux density and d.c. magnetizing force for typical electrical sheet steel. It will be observed that the effective permeability increases up to a maximum as the a.c. flux density increases, and then drops rapidly due to saturation of the core. For any particular value of a.c. flux density the effective permeability decreases as the d.c. magnetizing force is increased.

Where the a.c. flux in the core is much less than the d.c. flux, it is convenient to refer to the effective permeability as the **incremental permeability** since it depends on the characteristics of the core material in relation to small changes in the total flux. This term is therefore generally used in dealing with filter chokes and other inductance coils having a relatively large number of turns and carrying a relatively large direct current.

(iv) Design with no d.c. flux

If there is no d.c. flux in the core the calculation of inductance is straightforward because the effective permeability depends only on the number of turns, the frequency, the core cross section, and the applied voltage. This case arises when the windings of a coil or transformer do not carry direct current or when the windings carrying direct current are so arranged that the d.c. flux in the core is zero as, for example, with transformers used in balanced push pull amplifiers.

Design of a coil to obtain a required value of inductance is therefore also quite straightforward, and the following steps may be followed—

- (1) Choose an available core and calculate from eqn. (1) the number of turns required to give the necessary inductance assuming a value of effective permeability of between 1 000 and 5 000 depending on a very rough estimate of the a.c. flux density in the core.
- (2) Calculate the a.c. flux density for this number of turns in relation to the known frequency and voltage across the coil.
- (3) Correct the estimate of the number of turns using a revised value of permeability for the calculated flux. If the first estimate was far out, repeat steps (2) and (3).

Fig. 5.20. Effective permeability (μ) of silicon steel versus a.c. maximum flux density, for various values of d.c. magnetising force H_0 (by courtesy of Allegheny Ludlum Steel Corporation).

- (4) If the flux density is excessive (i.e. above about 50 000 lines per square inch) increase the number of turns until the flux density is satisfactory.

In case step 4 is necessary, the magnetic circuit must be broken by an air gap and the gap adjusted until the required value of inductance is obtained; but if the larger value of inductance is satisfactory or useful the air gap may be omitted.

- (5) Calculate the wire gauge required, and the copper and iron losses as in the design of a power transformer. Check also that the d.c. resistance of the winding is not excessive for the purpose for which the coil is to be used.

If an air gap of length α inches is used in the core, the value of inductance becomes

$$L = \frac{3.2N^2a}{10^8 l} \times \frac{1}{(1/\mu + \alpha/l)} \quad (3)$$

and this expression may be used for calculations. Alternatively, it will be clear that if the air-gap is large, so that $1/\mu \ll \alpha/l$, eqn. (3) approximates to

$$L = 3.2N^2 \cdot a/10^8 \alpha \quad (4)$$

FIG. 5. 21

Fig. 5.21. Experimentally determined curve showing values of "a" as a function of frequency for several magnetic materials (Ref. E2).

(v) Design of high Q inductors

This sub-section follows S. L. Javna (Ref. E2) and is set out in a step-by-step form for ease of working. The following table defines the symbols used by Javna in the formulae presented here.

- A = Effective cross-sectional area of magnetic-flux path, in sq. in.
- A_g = Gross cross-sectional area of magnetic-flux path, in sq. in.
- a = Empirical constant, see Fig. 5.21.
- B = Maximum flux density in the core, in lines per sq. in.
- F = Fraction of core-window area occupied by copper wire of coil
- f = Frequency, in cycles per second.
- g = Actual gap length, in inches.
- h = Empirical constant, see Fig. 5.22.
- L = Inductance of iron-cored coil, in henrys.
- l = Mean length of magnetic path, in inches.
- m = Mean length of a turn of the coil, in inches.

- μ_{Δ} = Incremental permeability of core with respect to air at operating frequency.
 N = Number of turns in coil.
 n = A.W.G. (B. and S.) wire gauge number of conductor.
 $R_{a.c.}$ = Apparent a.c. coil resistance caused by core loss, in ohms.
 $R_{d.c.}$ = Copper loss resistance, in ohms.
 s = Total lamination window area, in sq. in.
 V = Voltage across coil, in volts.
 w = Weight of core, in pounds.

A typical problem will be solved to illustrate the design procedure.

A 5 henry inductor is to be designed on a one inch square stack of Allegheny pattern EI-12 audio transformer A silicon steel annealed laminations. The voltage across the coil will be 10 V a.c. at 1000 c/s. It is required to determine the turns and gauge of wire, the gap width and Q at the operating frequency. Assume a stacking factor of 0.9.

Tabulation :

$$\left. \begin{aligned}
 l &= 6.0 \text{ ins} \\
 w &= 1.5 \text{ lbs.} \\
 A_g &= 1.0 \text{ sq. in.} \\
 A &= 0.9 \text{ sq. in.} \\
 s &= 0.75 \text{ sq. in.}
 \end{aligned} \right\} \text{ from Fig. 5.18C}$$

$m = 5.5 \text{ ins. from Fig. 5.18D}$
 $F \approx 0.3$, a typical value for this lamination
 $k = 1.3 \times 10^{-8}$ from Fig. 5.22.
 $a = 1.987$ from Fig. 5.21.
 μ_{Δ} is found from Fig. 5.20.

Calculation :

$$\begin{aligned}
 B &= \left(\frac{1.74mV^4 10^7}{akwf^4 L^2 A^2 s F} \right)^{1/(a+2)} &&= 48.6 \text{ lines/sq. in.} \\
 R_{a.c.} &= \frac{39.5kB^{a_{\text{eff}}} L^2 / V^2}{3.44mV^2 10^8} &&= 430 \text{ ohms} \\
 R_{d.c.} &= \frac{sFB^2 A^2 f^2}{2\pi f L} &&= 440 \text{ ohms} \\
 Q &= \frac{R_{a.c.} + R_{d.c.}}{V 10^8} &&= 36 \\
 N &= \frac{4.44 f B A}{V 10^8} &&= 5150 \text{ turns.} \\
 n &= 49.8 + 9.96 \log (1.2R_{d.c.}/mN) &&= 33 \text{ A.W.G.} \\
 g &= \left(\frac{1.59N^2 A_g}{L 10^8} - \frac{LA_g}{2\mu_{\Delta} A} \right) &&= 0.08 \text{ in.}
 \end{aligned}$$

Coil build check :

Turns/layer using 33 A.W.G. enam. = 133 from winding data chart,
 thus number of layers = $5150/133 = 39$.
 Interlayer insulation from winding data chart = 0.0015 in.,
 thus winding build = $39(0.0078 + 0.0015) = 0.363 \text{ in.}$
 Former thickness = 0.05 in.
 Insulation under and over winding = 0.02 in.,
 thus total coil build = $(0.363 + 0.05 + 0.02) = 0.433 \text{ in.}$
 Max. build from Fig. 5.18C = 0.43 in.,
 thus the winding should fit the window satisfactorily.

It should be noted that $R_{a.c.}$ and $R_{d.c.}$ are usually very nearly equal and where a square stack of scrapless laminations is used, m will approximate l . Due to the large air gap the inductance will remain practically independent of voltage and frequency. The basic design equations may be used and applied to almost any magnetic material. The constants a and k for other magnetic materials can be obtained from graphs drawn from measurements made in accordance with the method mentioned in the

FIG. 5.22

Fig. 5.22. Experimentally determined curve showing values of “ k ” as a function of frequency for several magnetic materials (Ref. E2).

original reference. Further information on iron-cored inductor design is contained in Refs. E3, E4, E5, E6, E7, E8, E9.

(vi) Design with d.c. flux

(Ref. E10).

When a d.c. flux is set up in the core by unbalanced direct currents in the windings, the effective permeability is decreased, as is shown in the curves of Fig. 5.20.

The amount of d.c. flux set up in the core depends on the applied d.c. magnetizing force (i.e. the total unbalanced ampere-turns in the windings), on the length of the magnetic circuit, and on the length of any air gap in the magnetic circuit.

The effective permeability depends on

- (i) the d.c. flux density in the core
- (ii) the a.c. flux density in the core

and (iii) the length of air gap in the magnetic circuit.

There is an optimum air gap giving a maximum value of the effective permeability for any particular value of total d.c. magnetizing force and a.c. flux density (Ref. E11).

For very low values of a.c. flux density, the following table gives the variation of incremental permeability with d.c. magnetizing force (A.T./inch of total length of magnetic circuit) and the ratio of the length of air gap to the total length of the magnetic circuit.

Incremental Permeability of High Silicon Steel
Total d.c. magnetizing force

Gap Ratio	1.0 AT/in.	2.0 AT/in.	5 AT/in.	10 AT/in.	20 AT/in.	30 AT/in.
0	1000	820	490	340	250	140
0.0005	720	700	680	560	360	170
0.0010	530	520	510	490	410	250
0.0015	—	425	410	400	370	270

Such data may be obtained using the methods given in "Magnetic Circuits and Transformers" (Ref. A3) Ch. 7, which sets out the general methods suitable for calculation of inductance with d.c. flux in the core.

The method developed by Crowhurst (Ref. E18) makes a considerable saving in time by the use of charts, particularly when a number of inductors are to be designed.

However, when the a.c. flux density is very small, as for example in many filter chokes, the method developed by Hanna may be used.

FIG. 5.23

Fig. 5.23. LI^2/V plotted against NI/l with various gap ratio intercepts (Ref. E13).

(vii) Design by Hanna's Method

(Ref. E12)

Strictly, the method is applicable only when the core to be used is of constant cross section throughout the length of the magnetic path, but it gives a useful first estimate in cases where the cross section is not uniform.

Let N = number of turns in coil

I = direct current through coil

L = Inductance in henrys (at low a.c. flux density)

l = length of magnetic gap (inches)

a = length of air gap (inches)

a/l = air-gap ratio

a = cross-sectional area of core (square inches)

and $V = l.a$ = Volume of core (cubic inches).

Then, assuming in a typical case that L is 12 henrys and I is 80 mA proceed thus—

(a) choose lamination size and stack	e.g. EI-11 $\frac{1}{4}$ in.
(b) find V from Fig. 5.18C	4.03 cub. in.
(c) calculate $L I^2 / V$	190×10^{-4}
(d) find NI/l from Fig. 5.23	58
(e) find l from Fig. 5.18C	5.26 in.
(f) calculate N	3800 turns
(g) assume suitable wire gauge	33 A.W.G.
(h) find turns per layer from winding data chart	118
(i) calculate number of layers	33
(j) calculate coil build using 0.0015 in. insulation	0.31 in.
(k) calculate winding build using 0.05 in. former	0.36 in.
(l) find maximum build from Fig. 5.18C so that winding will fit window satisfactorily	0.367 in.
(m) calculate mean length of turn from Fig. 5.18D	4.8 ins.
(n) calculate coil resistance	315 ohms
(o) calculate power lost in coil	2 watts
(p) calculate cooling area (see Sect. 5)	14.3 sq. ins
(q) calculate dissipation in watts/sq. in.	0.14 watts/sq. in.
(r) find temperature rise from Fig. 5.18B	20°C.
(s) find gap ratio α/l from Fig. 5.23	0.0029
(t) calculate air gap $(\alpha/l) \times l$	0.0075 in.

With any particular core, the highest inductance is obtained with the largest possible number of turns, as limited by the window space available, the permissible value of d.c. resistance, and heating of the winding with the specified current.

(viii) Design of inductors for choke-input filters

(Ref. E13)

(a) The input choke

Chapter 30 Sect. 3 Eqn. 1, 2 or 3 gives the minimum value required for the inductance of the input choke of a choke-input filter for any particular values of load resistance and frequency.

The required inductance for any particular value of load resistance may be achieved by designing the choke by Hanna's method as given above. It is only necessary to check that the value of the a.c. flux density in the core is small, so that Hanna's method will be applicable. For a full-wave rectifier the a.c. voltage applied to the choke is of twice the supply frequency and its peak amplitude is approximately two-thirds of the direct voltage at the input to the filter.

If, however, good regulation is required over a wide range of loads, it is necessary for the inductance of the input choke to be sufficiently high at the highest value of load resistance, that is, at the minimum value of load current. Some minimum load current greater than zero must be provided because the inductance would need to be infinite to maintain regulation down to zero load.

For a wide range of load variation (say 10 : 1) it would be very uneconomical to design a choke to have a constant inductance at all load currents as large as that required at minimum load. The choke is therefore designed so that its inductance will vary with the direct current through it, in such a way that the inductance is sufficiently high at all values of the load current. This method is discussed fully by Dunham (Ref. E14) and Crowhurst (Ref. E19) and reference should be made to their papers for detailed design considerations.

For many purposes, the following simple design procedure is adequate.

(1) From Eqn. (1) (2) or (3) of Chapter 30 Sect. 3, determine the required values of the choke inductance at minimum and maximum d.c. load currents.

(2) Select an interleaved core and, assuming a permeability of (say) 1000, design a choke to give the inductance required at minimum d.c. load current. For this purpose use the procedure of Sect. 6(iv) above but correct the assumed value of permeability using Fig. 5.20 and taking into account the number of d.c. ampere-turns

per inch of core path length. The peak a.c. voltage, of double mains frequency, across the choke, may be taken to be about two thirds of the d.c. voltage at the input to the filter.

(3) Using Fig. 5.20 note the change in permeability μ when maximum d.c. load current flows through the choke and check that the value of inductance under these conditions is sufficient. If it is not sufficient an increase in turns may be satisfactory and this can be checked by repeating the procedure above. If this is not satisfactory a small air gap may be necessary, but calculations then become complex.

A choke so designed is commonly referred to as a **swinging choke** because its inductance varies with the direct current through it.

(b) The second choke

The design of the second choke of a choke input filter is straightforward, and Hanna's method may be used after determining the required value of inductance by the methods set out in Chapter 31 Sect. 1.

(ix) Measurements

Measurements of inductances of iron-cored coils must be made under conditions similar to those under which the coils are to be used, because the value of inductance depends to a marked degree on the a.c. flux density in the core and also on any d.c. flux set up in the core by direct currents in the windings.

Bridge methods are desirable for accurate measurements of inductance but must be arranged to simulate the operating conditions of the coil being measured. Owen and Hay bridges are widely used when there is a large flux due to direct current (Refs. E15, E16).

For many purposes it is satisfactory to determine the effective inductance (or more accurately, the impedance) of a coil by measuring the current through the coil when the rated a.c. voltage is applied to it; but this method is not usually feasible when a d.c. component is also present.

FIG. 5.24

Fig. 5.24. Determination of the impedance of an inductor L carrying direct current.

When a d.c. flux must be produced in the core to simulate operating conditions, the circuit arrangement of Fig. 5.24 may be used to determine the a.c. impedance of the coil. A valve voltmeter is used to adjust the a.c. voltage drop across the known variable resistance R to equality with the a.c. voltage drop across the inductance L . The required value of direct current through the coil is obtained by adjusting the tapping on battery B and the rheostat R_1 (or by adjusting any other variable direct current source), the current being measured by a d.c. ammeter or milliammeter. The required alternating voltage across the choke coil is then adjusted by varying the tapping on transformer T , the voltage across the coil being read on the valve voltmeter; this adjustment is not usually critical. The resistance R is then varied until the same reading is obtained on the valve voltmeter when it is connected across R

by operating the switch S . If the valve voltmeter responds to direct voltages, it must be connected to the circuit through a blocking condenser and grid leak as shown in the diagram.

The value Z obtained for the impedance of the coil will differ from its reactance owing to coil losses, but for most purposes it will be satisfactory to assume that it is equal to the reactance. If the frequency used is f , the value of inductance is given approximately by

$$L \approx Z/2\pi f.$$

or $L \approx Z/314$ Henrys, for $f = 50$ c/s.

$$\approx Z/376 \text{ Henrys for } f = 60 \text{ c/s.}$$

where Z is numerically equal to the value of R for balance.

For choke coils carrying direct current, and operating with a high a.c. flux density, reference should be made to the method of approximate measurement given by F. E. Terman (Ref. E15) Fig. 40 and pp 57-58.

(x) Iron-cored inductors in resonant circuits

The performance of iron-cored inductors in resonant circuits cannot be calculated mathematically owing to the immense complexity. While most work is carried out empirically, it is helpful to have a general grasp of the problem, and this may perhaps best be carried out graphically (see Ref. E17).

Mathematics, to the radio engineer, is merely a tool to be used in his design work. For this reason it is often used in a slovenly manner or with insufficient precision or understanding.

There are normally three stages in the solution of a problem—

1. Transferring the mechanical or electrical conditions into a mathematical form.
2. Solving the mathematics.
3. Interpreting and applying the mathematical solution.

The first stage is dealt with in Chapter 4 ; the second stage is the subject of this chapter, while the third stage requires careful consideration of all the relevant conditions. A solution only applies under the conditions assumed in stage one, which may involve some approximations and limits. In all cases the solution should be checked either experimentally or theoretically to prove that it is a true solution.

This chapter is not a textbook on mathematics, although it is in such an easy form that anyone with the minimum of mathematical knowledge should be able to follow it. It has been written primarily for those who require assistance in "brushing up" their knowledge, and for the clarification of points which may be imperfectly understood. It is "basic" rather than elementary in its introduction, and could therefore be read with advantage by all.

Sufficient ground is covered for all normal usage in radio receiver design, except for that required by specialists in network and filter design.

Reference data have been included for use by all grades

SECTION 1 : ARITHMETIC AND THE SLIDE RULE

(i) *Figures* (ii) *Powers and roots* (iii) *Logarithms* (iv) *The slide rule* (v) *Short cuts in arithmetic*

(i) Figures

A figure (e.g. 5) indicates a certain number of a particular object—e.g. five resistors, or five radio receivers ; or else five units of a particular scale—e.g. five inches, five microfarads or five ohms. No matter what we may do with adding, subtracting, multiplying or dividing, if we begin with ohms we must finish with ohms, and so on with any other unit. We cannot add together dissimilar objects without identifying each type, and similarly with any other mathematical process.

(ii) Powers and roots

As figures are often too large, or too small, to be shown completely in the ordinary form, there is a Scientific Notation commonly used—

Numbers above unity	Numbers below unity
$10^1 = 10$	$10^{-1} = 0.1$
$10^2 = 100$	$10^{-2} = 0.01$
$10^3 = 1\ 000$	$10^{-3} = 0.001$
$10^4 = 10\ 000$	$10^{-4} = 0.000\ 1$
$10^5 = 100\ 000$	$10^{-5} = 0.000\ 01$
$10^6 = 1\ 000\ 000$	$10^{-6} = 0.000\ 001$
	and so on
	$10^0 = 1$

Note that 10^2 means $10 \times 10 = 100$; 10^3 means $10 \times 10 \times 10 = 1000$ and so on. The “2” and the “3” are called exponents, or indices (plural of index).

10^2 is called “10 squared”

10^3 is called “10 cubed”

10^4 is called “10 to the fourth” etc.

10^{-1} is called “10 to the minus 1” etc.

Examples : 2 750 000 is written 2.75×10^6

0.000 025 is written 2.5×10^{-5} .

Multiplying is carried out as in the examples :

$$(1.5 \times 10^6) \times (4 \times 10^{-3}) = 6 \times 10^3$$

$$(4.5 \times 10^3) \times (2 \times 10^2) = 9 \times 10^5$$

Reference should be made to the table of multiples and sub-multiples in Chapter 38 Sect. 17, Table 59.

The same procedure may be applied, not only to 10, but to any figure, e.g. 3 ;

$$3^0 = 1$$

$$3^1 = 3$$

$$3^2 = 3 \times 3 = 9$$

$$3^3 = 3 \times 3 \times 3 = 27$$

$$3^{-2} = 1/3^2 = 1/9$$

$$3^{-3} = 1/3^3 = 1/27$$

Roots : The expression $9^{\frac{1}{2}}$ may be written $\sqrt{9}$, where the sign $\sqrt{}$ is called the square root. Similarly $27^{\frac{1}{3}}$ may be written $\sqrt[3]{27}$ where the sign $\sqrt[3]{}$ is called the cube root.

The whole question is dealt with more fully, and more generally under “Algebra” in Sect. 2.

(iii) Logarithms

We may write $100 = 10^2$

or we may express this in different language as

$$2 = \log_{10} 100$$

which is spoken of as “log 100 to the base 10.” Here 2 is the logarithm of 100 to the base 10.

Tables of logarithms to the base 10 are given in Chapter 38 Sect. 20, Table 71. They are useful in multiplying and dividing numbers which are too large to handle conveniently by the ordinary procedure.

A typical logarithm is 2.4785. Here the figure 2 to the left of the decimal point is called the **index**, and the figures 4785 to the right of the decimal point are called the **mantissa**.

(1) The **index** of the logarithm of a number greater than unity is the number which is less by one than the number of digits (figures) in the integral* part of the given number; for example the index of the logarithm of

57 640	is 4
5 764	is 3
576.4	is 2
57.64	is 1
5.764	is 0

If the number is less than unity, the index is negative, and is a higher number by one than the number of zeros that follow the decimal point of the given number; for example the index of the logarithm of

.576 4	is -1
.005 764	is -3.

To denote that the index only is negative, the minus sign is usually written above it; e.g. $\bar{1}$, $\bar{3}$.

(2) The **mantissa** of the logarithm is found from the tables. Proceed to find the first two figures in the left hand column of the table, then pass along the horizontal line to the vertical column headed by the third figure. To this number add the number in the difference column under the fourth figure of the given number. The mantissa is the result obtained by this process with a decimal point before it.

For example, to find $\log_{10} 5764$.

The index is 3

The mantissa is .7604 + .0003 = .7607

Therefore $\log_{10} 5764 = 3.7607$.

Similarly, $\log_{10} 0.5764 = \bar{1}.7607$ (note that the index is negative, but the mantissa positive).

To find the number whose logarithm is given, it is possible to use either antilog. tables (if these are available) or to use the log. tables in the reverse manner. In either case, only the mantissa (to the right of the decimal point) should be applied to the tables.

The procedure with log. tables is firstly to find the logarithm, on the principal part of the table, which is next lower than the given logarithm, then to calculate the difference, then to refer to the difference columns to find the number—exactly the reverse of the previous procedure.

For example, to find the number whose logarithm is 2.5712. The mantissa is .5712 and the nearest lower logarithm on the tables is 5705, the difference being 7 (in the fourth figure). The number whose log = 5705 is 3720, and to this must be added the figure 6 which corresponds to the difference of 7 in the fourth column; the number is therefore $3720 + 6 = 3726$. The decimal point must be placed so as to give $2 + 1 = 3$ digits to the left of the point, i.e. 372.6.

The application of logarithms

If two numbers are to be multiplied together, the answer may be found by adding their logarithms, and then finding the number whose logarithm is equal to their sum. For example, suppose that it is desired to multiply 371.6×58.24 ,

$$\begin{aligned}\log 371.6 &= 2.5701 \\ \log 58.24 &= 1.7652\end{aligned}$$

$$\text{sum} = 4.3353$$

The number whose log = .3353 is 2164.

The decimal point should be placed so as to give $4 + 1 = 5$ digits to the left of the point; i.e. 21 640.

*To the left of the decimal point.

Therefore $371.6 \times 58.24 = 21\,640$.

It should be remembered that the last figure of four figure logs. is correct to the nearest unit, and that slight errors creep into the calculations through additions and other manipulations. The first three digits of the answer will be exact, and the fourth only approximate.

If one number is to be **divided** by a second number, the answer may be found by subtracting the logarithm of the second from the logarithm of the first, then finding the number whose logarithm is equal to their difference.

Logarithms may also be used to find the **powers of numbers** For example, to find the value of $(3.762)^3$:

$$\begin{aligned}\log (3.762)^3 &= 3 \log 3.762 = 3 \times .5754 \\ &= 1.7262\end{aligned}$$

Therefore $(3.762)^3 = \text{antilog } 1.7262 = 53.23$.

For other applications of logarithms see Sect. 2(xvii)

(iv) The Slide Rule

The Slide Rule is a mechanical device to permit the addition and subtraction of logarithms so as to effect multiplication and division of the numbers. The small size of the normal slide rule does not give as high a degree of accuracy as four figure log. tables, but is sufficiently accurate for many calculations.

The usual 10 inch slide rule has four scales A, B, C, D of which B and C are on the slide. The scales C and D (the lower pair) are normally used for multiplication and division, and each covers from 1 to 10. The upper scales A and B cover from 1 to 100. The **square** of any number from 1 to 10 is found by adjusting the line on the cursor (runner) to fall on the number on the D scale, and reading the answer where the line cuts the A scale. The **cube** of a number from 1 to 10 may be found by squaring, and then multiplying the result by the original number on the B scale, reading off the answer on the A scale. If the number is not between 1 and 10, firstly break it up into factors, one of which should be a multiple of 10, and the other a number between 1 and 10, then proceed as before. For example

$$300^2 = (3 \times 100)^2 = (3)^2 \times (100)^2 = 3^2 \times 10^4.$$

The value of 3^2 is found in the normal way to be 9; this is then multiplied by 10^4 to give the answer $9 \times 10^4 = 90\,000$.

Square roots may be found by the reverse procedure. Firstly reduce the number to factors, one of which should be a multiple of 100 and the other between 1 and 100, then apply the cursor to the number on the A scale and read the answer on the D scale to be multiplied by the square root of the 100 factor. For example, to find the square root of 1600:

$$\sqrt{1600} = \sqrt{16 \times 100} = \sqrt{16} \times \sqrt{100} = \sqrt{16} \times 10.$$

The value of 4 on the D scale is then multiplied by 10 to give the answer 40.

Cube roots of numbers between 1 and 100 may be determined by setting the cursor to the number on the A scale, then moving the slide until the B scale cursor reading is the same as the D scale reading below 1 on the C scale.

Slide rules which have log/log scales may be used to determine any power of a number 1.1 or greater (up to a maximum value of 100 000). Set the cursor to the number on the upper log/log scale, then set 1 on the C scale to the same cursor line. Move the cursor to the required power on the C scale and read the answer on the log/log scale. If the number is too high to be on the upper log/log scale, carry out the same procedure on the lower log/log scale. If the number is found on the upper scale, but the answer is beyond the limits of this scale, set the mark* (e.g. W) on the slide immediately below the number on the upper scale, and read the answer on the lower scale, immediately below the power on the C scale.

If several figures are to be multiplied and divided, carry out multiplication and division alternately, e.g.

$$\begin{array}{r} 75 \times 23 \times 5 \\ 41 \times 59 \times 36 \end{array}$$

should be handled as $75 \div 41 \times 23 \div 59 \times 5 \div 36$.

*With slide rules having no special mark, use 10 on the C scale as the "mark."

In a complicated calculation, especially with very large and very small numbers, it is highly desirable to arrange the numerator and denominator in powers of 10. For example

$$\frac{75\,000 \times 0.0036 \times 5900}{160\,000 \times 0.000\,001\,7} = \frac{7.5 \times 10^4 \times 3.6 \times 10^{-3} \times 5.9 \times 10^3}{1.6 \times 10^5 \times 1.7 \times 10^{-6}} \\ = \frac{7.5 \times 3.6 \times 5.9 \times 10^5}{1.6 \times 1.7}$$

The slide rule does not indicate the position of the decimal point, and it is necessary to determine the latter by some method such as inspection; this is much easier when the individual numbers are all between 1 and 10 as in the example above. It is also possible to keep track of the decimal point by noting how often the manipulation passes from end to end of the rule.

To find the logarithm of a given number, move the 1 on C scale to the number on the D scale, then turn the rule over and read the logarithm on the L scale against the mark (this will be a number between 0 and 1).

To find the decibels corresponding to a ratio, proceed as for the logarithm, but multiply by 10 for a power ratio or 20 for a voltage ratio.

To find the sine or tangent of an angle, first set the angle on the S or T scale to the mark, then read the value on the B scale, below 1 on the A scale, and divide by 100.

There are countless special types of slide rules, and in all such cases the detailed instructions provided by the manufacturers should be studied.

Hints on special calculations on the slide rule

$$(1) Z = \sqrt{R^2 + X^2} = R\sqrt{1 + (X^2/R^2)}$$

Procedure: For example if $X = 3$ and $R = 2$ set cursor to 3 on D scale, move slide to give 2 on C scale. The value of $(X/R)^2$ is given by the value on A scale opposite 1 on B scale—in this case 2.25. Move the slide up to 3.25 ($= 2.25 + 1$) and then move the cursor to 2 on C scale, reading 3.61 on D scale as the answer.

(2) If a large number of figures is to be divided by one figure, divide unity or 10 (D scale) by the divisor (C scale) and then, with fixed slide, move the cursor to each dividend in turn on the C scale, reading the answer on the D scale.

(v) Short cuts in arithmetic

(a) Approximations involving π

- π^2 may be taken as 10 with an error less than 1.4%
- π may be taken as $25/8$ with an error less than 0.6%
- $1/\pi$ may be taken as $8/25$ with an error less than 0.6%
- 2π may be taken as $25/4$ with an error less than 0.6%
- $1/2\pi$ may be taken as $4/25$ with an error less than 0.6%
- $(2\pi)^2 = 39.5$ with an error less than 0.06%

(b) Approximations with powers and roots

General relation: $(x \pm \delta)^n \approx x^n \pm nx^{n-1}\delta$
where δ is small compared with x . Examples are given below.

Squares ($n = 2$)

$$10.1^2 = (10 + 0.1)^2 \approx 10^2 + 2 \times 10 \times 0.1 \approx 102 \text{ (error} = 0.01\%) \\ 10.2^2 = (10 + 0.2)^2 \approx 10^2 + 2 \times 10 \times 0.2 \approx 104 \text{ (error} = 0.04\%) \\ 9.9^2 = (10 - 0.1)^2 \approx 10^2 - 2 \times 10 \times 0.1 \approx 98 \text{ (error} = 0.01\%)$$

Square roots [$n = 0.5$; $(n - 1) = -0.5$]

$$\sqrt{x \pm \delta} \approx \sqrt{x} \pm \frac{0.5\delta}{\sqrt{x}} \\ \sqrt{101} = \sqrt{100 + 1} \approx \sqrt{100} + \frac{0.5 \times 1}{\sqrt{100}} \approx 10.05 \text{ (error} = 0.001\%) \\ \sqrt{110} = \sqrt{100 + 10} \approx \sqrt{100} + \frac{0.5 \times 10}{\sqrt{100}} \approx 10.5 \text{ (error} = 0.12\%)$$

$$\sqrt{50} = \sqrt{49 + 1} \approx \sqrt{49} + \frac{0.5 \times 1}{\sqrt{49}} \approx 7.0714 \text{ (error} = 0.004\%)$$

Cubes ($n = 3$)

$$(10.2)^3 = (10 + 0.2)^3 \approx 10^3 + 3 \times 10^2 \times 0.2 \approx 1060 \text{ (error} = 0.1\%)$$

Cube roots [$n = 0.333$; $(n - 1) = -0.667$]

$$\sqrt[3]{x \pm \delta} \approx \sqrt[3]{x} \pm \frac{\delta}{3(\sqrt[3]{x})^2}$$

$$\sqrt[3]{66} = \sqrt[3]{64 + 2} \approx \sqrt[3]{64} + \frac{2}{3 \times 4^2} \approx 4.042$$

For more accurate approximations see Sect. 2 eqns. (82) and (83).

(c) Approximations in multiplication

$a \times b \approx \frac{1}{4}(a + b)^2$ where a and b are close together

$$\text{e.g. } 49 \times 51 \approx \frac{1}{4}(49 + 51)^2 \approx \frac{1}{4}(100)^2 \approx 2500 \text{ (error } 0.04\%).$$

This may be put into the alternative form :

$$a \times b \approx (\text{arithmetical mean between } a \text{ and } b)^2$$

$$\text{e.g. } 68 \times 72 \approx (70)^2 \approx 4900 \text{ (error } 0.08\%).$$

(d) Exact multiplication

$$\begin{aligned} a \times b &= \frac{1}{4}\{(a + b)^2 - (a - b)^2\} \text{ (no error)} \\ &= (\text{arithmetical mean between } a \text{ and } b)^2 - \frac{1}{4}(a - b)^2. \end{aligned}$$

When $(a - b) = 1$, the second term in this expression becomes $\frac{1}{4}$ and we have the exact application :

$$3\frac{1}{2} \times 4\frac{1}{2} = 16 - \frac{1}{4} = 15\frac{3}{4} \text{ (exact).}$$

Another application is illustrated by the example

$$98 \times 102 = 100^2 - \frac{1}{4}(4)^2 = 10\,000 - 4 = 9996.$$

(e) To multiply by 11

To multiply a number by 11, write down the last figure, add the last and last but one and write down the result, carrying over any tens to the next operation, add the last but one and the last but two and so on, finishing by writing down the first

$$\text{e.g. } 11 \times 42\,736 = 470\,096 \text{ (no error)}$$

(f) For approximations based on the Binomial Theorem see Sect. 2(xviii).

(g) For general approximations see Sect. 2(xx).

SECTION 2 : ALGEBRA

(i) Addition (ii) Subtraction (iii) Multiplication (iv) Division (v) Powers (vi) Roots (vii) Brackets and simple manipulations (viii) Factoring (ix) Proportion (x) Variation (xi) Inequalities (xii) Functions (xiii) Equations (xiv) Formulae or laws (xv) Continuity and limits (xvi) Progressions, sequences and series (xvii) Logarithmic and exponential functions (xviii) Infinite series (xix) Hyperbolic functions (xx) General approximations.

See Section 6 for Complex Algebra.

Algebra is really only arithmetic, except that we use alphabetical symbols to stand for figures. It is frequently more convenient to put an expression into an algebraic form for general use, and then to apply it to a particular case by writing figures in place of the letters. All algebraic expressions are capable of being converted into arithmetical ones, and the fundamental mathematical processes of algebra may be used in arithmetic.

(i) Addition

If a , b , and c are all values of the one unit (e.g. all resistances in ohms) we can add them together to find the sum d , where d will also be in the same unit,

$$d = a + b + c$$

For example, if $a = 5$, $b = 10$, $c = 15$ ohms,
then $d = 5 + 10 + 15 = 30$ ohms.

(ii) Subtraction

Subtraction is the opposite of addition, or negative addition, and can only be applied when the quantity to be subtracted is in the same unit as the quantity from which it is to be taken. For example let

$$a = b - c$$

where a , b and c are all voltages.

If $b = 6$ volts and $c = 2$ volts, then

$$a = 6 - 2 = 4 \text{ volts.}$$

As another example, let a , b and c be readings of a thermometer in degrees—say $b = 10^\circ\text{C}$ and $c = 20^\circ\text{C}$, then $a = 10^\circ - 20^\circ = -10^\circ\text{C}$. This is commonly described as “10 degrees below zero” or “a temperature of minus 10 degrees.” Thus a negative temperature has a definite value and is readily understood. Its magnitude is given by the figure, while its direction above or below zero is given by the positive or negative sign.

Similarly a negative current is one with a magnitude as indicated by the figure but with a direction opposite to that of a positive current. In most cases the direction of a positive current is arbitrarily fixed, and if the answer comes out negative it merely indicates the actual direction of current flow is the opposite of the direction assumed. The same principle holds in all cases.

(iii) Multiplication

Multiplication is continued addition—

$$4 \times a = a + a + a + a$$

and is commonly written as $4a$. In the general sense we can write ba where b is any number; this has the same value as ab ,

$$\text{i.e. } ab = ba \text{ or } a.b = b.a.$$

It should be noted that

$$4 \times (-a) = -4a$$

$$\text{and } (-1) \times (-1) = +1.$$

(iv) Division

Division is the breaking up of a number of things into a given number of groups, e.g.

$$6a \div 3 = (2a + 2a + 2a) \div 3 = 2a.$$

We may write this in the alternative forms

$$\frac{6a}{3} = 2a, \text{ or } 6a/3 = 2a.$$

(v) Powers

Powers are continued multiplication,

$$\text{e.g. } a^3 = aaa = a \times a \times a$$

$$a^m = a \times a \times a \times a \dots (m \text{ factors})$$

$$a^n = a \times a \times a \times a \dots (n \text{ factors})$$

$$\text{Therefore } a^m \times a^n = a^{(m+n)}$$

(1)

We can write, as a convenience,

$$\frac{1}{a^n} \text{ in the form } a^{-n}$$

where the $-n$ is not a true index (or exponential) but merely a way of writing $1/a^n$.

$$\text{Therefore } \frac{a^m}{a^n} = a^m \times a^{-n} = a^{m-n}$$

(2)

which indicates that the $-n$ can be treated as though it were a true index.

The following can also be derived :

$$\frac{a^m}{a^m} = a^{(m-m)} = a^0 \quad (3)$$

$$\text{but } \frac{a^m}{a^m} = 1$$

$$\text{Therefore } a^0 = 1 \quad (4)$$

$$(a^m)^n = a^m \times n = a^{mn} \quad (5)$$

$$(ab)^n = a^n b^n \quad (7)$$

$$\left(\frac{b}{a}\right)^{-n} = \left(\frac{a}{b}\right)^n = \frac{a^n}{b^n} \quad (8)$$

$$(-a)^n = (-1)^n \times a^n \quad (9)$$

$$= +a^n \text{ if } n \text{ is even} \quad (9a)$$

$$\text{or } = -a^n \text{ if } n \text{ is odd} \quad (9b)$$

These identities hold even when m and n are negative or fractions.

(vi) Roots

$$\sqrt{a \times a} = a \text{ or } \sqrt{a^2} = a \quad (10)$$

$$\sqrt[3]{a \times a \times a} = a \text{ or } \sqrt[3]{a^3} = a \quad (11)$$

We may adopt as a convenience the form

$$\sqrt{a} = a^{1/2} \quad (12)$$

$$\sqrt[3]{a} = a^{1/3} \quad (13)$$

$$\sqrt[n]{a} = a^{1/n} \quad (14)$$

This may be extended to include

$$\sqrt[n]{a^m} = (a^m)^{1/n} = a^{m/n} \quad (15)$$

so that $a^{m/n}$ is the n th root of a^m .

$$\text{Note that } 1/\sqrt[3]{a} = \sqrt[3]{1/a}; \quad 1/\sqrt[n]{a} = \sqrt[n]{1/a} \quad (16)$$

(vii) Brackets and simple manipulations

$$a(a+b) = a \times a + a \times b = a^2 + ab \quad (17)$$

$$x(a+b-c) = xa + xb - xc \quad (18)$$

$$-x(a+b) = -xa - xb \quad (19)$$

$$-x(a-b) = -xa + xb = x(b-a) \quad (20)$$

$$-[(a-b) - (c+d)] = -(a-b) + (c+d) \quad (21)$$

$$= -a + b + c + d \quad (21a)$$

$$= (b+c+d) - a \quad (21b)$$

$$\frac{ax+bx}{cx+dx} = \frac{(a+b)x}{(c+d)x} = \frac{a+b}{c+d} \times \frac{x}{x} = \frac{a+b}{c+d} \quad (22)$$

$$(a+b)^2 = (a+b)(a+b) = a(a+b) + b(a+b) \quad (23)$$

$$= a^2 + 2ab + b^2 \quad (23a)$$

$$(a-b)^2 = (a-b)(a-b) = a(a-b) - b(a-b) \quad (24)$$

$$= a^2 - 2ab + b^2 \quad (24a)$$

$$(a+b)(a-b) = a(a-b) + b(a-b) = a^2 - b^2 \quad (25)$$

$$(a+b)(x+y) = ax + ay + bx + by \quad (26)$$

$$(a+b+c)^2 = a^2 + b^2 + c^2 + 2ab + 2bc + 2ca \quad (27)$$

$$\frac{a}{-b} = -\frac{a}{b}; \quad \frac{-12ac}{4a} = -3c; \quad \frac{a^3}{a^2} = a \quad (28)$$

$$+\frac{a}{b} = \frac{-a}{-b} = -\frac{-a}{b} = -\frac{a}{-b} \quad (29)$$

$$a \times 0 = 0; \quad \frac{a}{0} = \text{infinity}^* = \infty \quad (30)$$

(note that it is not possible to divide by 0 in algebraic computations).

*Infinity may be described as a quantity large without limit.

$$\frac{a}{c} \pm \frac{b}{d} = \frac{ad \pm bc}{cd}; \quad \frac{a}{c} \pm \frac{b}{c} = \frac{a \pm b}{c}; \quad \frac{a}{c} \pm \frac{a}{d} = \frac{a(d \pm c)}{cd} \quad (31)$$

The sign \pm means either plus or minus. When \pm and/or \mp signs are used on both sides of an equation, the upper signs in both cases are to be taken in conjunction as one case, while the lower signs are to be taken as the other case.

$$\frac{a}{b} \times \frac{c}{d} = \frac{ac}{bd}; \quad \frac{a}{\frac{1}{b}} = \frac{ac}{bc} \quad (32)$$

$$\frac{a}{b} \div \frac{c}{d} = \frac{a}{b} \times \frac{d}{c} = \frac{ad}{bc} \quad (33)$$

$$\frac{x}{y} - \frac{a+b}{c+d} = \frac{x(c+d)}{y(c+d)} - \frac{y(a+b)}{y(c+d)} \quad (34a)$$

$$= \frac{x(c+d) - y(a+b)}{y(c+d)} \quad (34b)$$

(viii) Factoring—Examples

$$6ab + 3ac = 3a(2b + c) \quad (35)$$

$$x^2 - 7xy + 12y^2 = (x - 4y)(x - 3y) \quad (36)$$

$$2x^2 + 7x + 6 = (2x + 3)(x + 2) \quad (37)$$

$$x^2y - 4y^3 = y(x^2 - 4y^2) = y(x + 2y)(x - 2y) \quad (38)$$

(ix) Proportion

$$(1) \text{ If } \frac{a}{b} = \frac{c}{d} \quad \text{then} \quad \frac{a}{c} = \frac{b}{d} \quad (39)$$

$$\text{also} \quad \frac{a}{b} - \frac{c}{d} = 0 \quad \text{therefore} \quad \frac{ad - bc}{bd} = 0 \quad (40)$$

$$\text{from which } ad - bc = 0 \quad \text{and thus } ad = bc \quad (41)$$

$$(2) \text{ If } \frac{a}{b} = \frac{c}{d} \text{ and also } \frac{e}{f} = \frac{g}{h}, \quad \text{then} \quad \frac{ae}{bf} = \frac{cg}{dh} \quad (42)$$

(x) Variation

If $y = kx$, then $y \propto x$
i.e. y is directly proportional to x .

If $y = \frac{k}{x}$, then $y \propto \frac{1}{x}$
i.e. y is inversely proportional to x .

If $y = kxz$, then y varies jointly as x and z .

If $y = k\frac{x}{z}$, then y varies directly as x and inversely as z

(xi) Inequalities

The letter symbols below are positive and finite.

$$\text{If } a > b \text{ then} \quad a + c > b + c, \quad b < a \quad (43a)$$

$$a - c > b - c, \quad c - a < c - b \quad (43b)$$

$$ac > bc, \quad bc < ac \quad (43c)$$

$$\frac{a}{c} > \frac{b}{c}, \quad \frac{c}{a} < \frac{c}{b} \quad (43d)$$

$$\text{If } a - c > b \text{ then } a > b + c \quad (44)$$

$$\begin{aligned} &\text{If } a > b \text{ and } c > d \\ &\text{then } a + c > b + d, \text{ and } ac > bd \end{aligned} \quad (45)$$

(xii) Functions

We may describe $3x + 4$ as "a function of x " because its value depends upon the value of x . This is usually written as

$$F(x) = 3x + 4.$$

Other typical functions of x are

$$\begin{aligned} &2x^2 + 3x + 5; \quad x(x^2 + 3x); \\ &\cos x; \quad \log x; \quad 1/x. \end{aligned}$$

In such functions, x is called the "independent variable." It is usual to write $F(a)$ as meaning " $F(x)$ where $x = a$."

(xiii) Equations

An equation is a statement of conditional equality between two expressions containing one or more symbols representing unknown quantities. The process of determining values of the unknowns which will satisfy the equation is called solving the equation.

An **Identical Equation** is one which holds for all values of its letter symbols.

A **Linear Equation** is one in which, after getting rid of fractions, the independent variable only occurs in the first degree (e.g. x).

Example: $y = 5x + 3$.

A **Quadratic Equation** is one in which, after getting rid of fractions, the independent variable occurs in the second degree (e.g. x^2) but not in higher degree.

Example: $y = 4x^2 + 5x + 3$.

A quadratic equation in one unknown has two roots, although both may be complex (i.e. with an imaginary term).

A **Cubic Equation** is one in which, after getting rid of fractions, the independent variable occurs in the third degree (e.g. x^3) but not in higher degree.

Example: $y = 3x^3 + 4x^2 + 2x + 5$.

Note: x and y are usually taken as unknowns; a, b, c and d as known constants.

Rules for solution of equations

1. The same quantity may be added to (or subtracted from) both sides.

Example: If $x + 3 = 2$; then $x + 5 = 4$ and $x + 1 = 0$.

2. A term can be moved from one side to the other provided that its sign is changed.

Example: If $a = b$; then $a - b = 0$.

3. All signs in the equation may be changed together.

Example: If $x - a = y - b$; then $a - x = b - y$.

This is equivalent to multiplication throughout by -1 .

4. Both sides can be multiplied (or divided) by the same quantity.

Example: If $x + 2 = 5$; then $2x + 4 = 10$.

5. The reciprocal of one side is equal to the reciprocal of the other.

Example: If $x = a$; then $\frac{1}{x} = \frac{1}{a}$.

6. Terms can be replaced by terms that are equal in value.

7. Both sides can be raised to the same power.

Example: If $x = a$; then $x^2 = a^2$.

8. Both sides can be replaced by the same root of the original.

Example: If $x = a$; then $\sqrt[3]{x} = \sqrt[3]{a}$, and

in general, $\sqrt[n]{x} = \sqrt[n]{a}$ if n is odd, but if n is even we must write

$$\sqrt[n]{x} = \pm \sqrt[n]{a}$$

which means that

$$\text{either } \sqrt[n]{x} = \sqrt[n]{a} \text{ or } \sqrt[n]{x} = -\sqrt[n]{a}.$$

In such cases two roots are obtained, and **both** should be tested in the original equation.

Warning

If both sides of an equation are squared, or if both sides are multiplied by a term containing the unknown, a new root may be introduced.

Solution of equations

(1) Linear equations with one unknown

Example : $ax + b = 0$.

Solution : $x = -b/a$. (46)

(2) Linear equations with two unknowns

Any linear relation between two variables, x and y , can be written in the general form

$$ax + by + c = 0 \quad (47)$$

or (provided that b is not zero) in the alternative form

$$y = mx + n \quad (48a)$$

This type of equation is not limited to one or two solutions, but has a corresponding value of y for every possible value of x . It is very helpful to plot the value of y against the value of x on squared paper—see Sect. 5(i). With any equation of this type, the graph will be a straight line, and it is only necessary to determine

(1) one point on the line

(2) the slope of the line at any point.

The most convenient point is usually $x = 0$, and in eqn. (48a) this will give

$$y = n$$

or in eqn. (47) this will give

$$y = -c/b$$

The slope of the line is given by the difference of the y values of two points, divided by the difference of their x values.

In eqn. (47) the slope is

$$-a/b$$

while in eqn. (48a) the slope is

$$m.$$

A particular form of eqn. (47) is

$$\frac{x}{a} + \frac{y}{b} = 1 \quad (48b)$$

and in this case the line cuts the x axis at $x = a$ and cuts the y axis at $y = b$. The slope is equal to $-b/a$.

An equation of the form

$$\frac{a}{x} + \frac{b}{y} = c \quad (49)$$

may be solved by regarding $1/x$ and $1/y$ as the unknowns, then following a similar procedure as for an equation in x and y , and solving for $1/x$ and $1/y$.

(3) Simultaneous linear equations (two unknowns)

$$\left. \begin{aligned} a_1x + b_1y &= c_1 \\ a_2x + b_2y &= c_2 \end{aligned} \right\} \quad x = \frac{c_1b_2 - c_2b_1}{a_1b_2 - a_2b_1} \quad (50a)$$

$$y = \frac{a_1c_2 - a_2c_1}{a_1b_2 - a_2b_1} \quad (50b)$$

provided that $(a_1b_2 - a_2b_1)$ is not zero.

Alternatively the solution may be derived by determining x in terms of y from the first equation, and then substituting in the second.

Checking solutions :

After any solution has been found, particularly with more than one solution, it is highly desirable to check these in the original equation.

(4) Three simultaneous equations (three unknowns)

$$\text{Given } \begin{cases} ax + by + cz + d = 0 \\ a_1x + b_1y + c_1z + d_1 = 0 \\ a_2x + b_2y + c_2z + d_2 = 0 \end{cases}$$

Then

$$\left. \begin{aligned} x &= \frac{d(b_2c_1 - b_1c_2) + d_1(bc_2 - b_2c) + d_2(b_1c - bc_1)}{a(b_1c_2 - b_2c_1) + a_1(b_2c - bc_2) + a_2(bc_1 - b_1c)} \\ y &= \frac{d(a_1c_2 - a_2c_1) + d_1(a_2c - ac_2) + d_2(ac_1 - a_1c)}{a(b_1c_2 - b_2c_1) + a_1(b_2c - bc_2) + a_2(bc_1 - b_1c)} \\ z &= \frac{d(a_2b_1 - a_1b_2) + d_1(ab_2 - a_2b) + d_2(a_1b - ab_1)}{a(b_1c_2 - b_2c_1) + a_1(b_2c - bc_2) + a_2(bc_1 - b_1c)} \end{aligned} \right\} \quad (51)$$

It will be noticed that the three denominators are identical.

(5) Quadratic equations

$$(x - a)(x + b) = 0; \quad x = a \text{ or } x = -b \quad (52)$$

$$ax^2 + bx + c = 0; \quad x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \quad (53)$$

Note that in eqn. (53)

when $b^2 = 4ac$, the two roots are equal

when $b^2 - 4ac$ is positive, the two roots are real.

when $b^2 - 4ac$ is negative, the roots are imaginary.

(6) Quadratic equations with two variables

Example: $y = ax^2 + bx + c$.

This type of equation is not limited to one or two solutions, but has a corresponding value of y for every possible value of x . It is helpful to plot part of the curve on squared paper—see Sect. 5(i). The curve may cut the x axis at two points, or it may touch at one point, or it may not touch it at all. Let $y = 0$, then

$$ax^2 + bx + c = 0$$

and the points at which the curve cuts the x axis will be

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \quad (54)$$

If $b^2 > 4ac$, the curve will cut at two points.

If $b^2 = 4ac$, the curve will touch at one point.

If $b^2 < 4ac$, the curve will not cut the x axis.

(xiv) Formulae or laws

A formula is a law, or rule, generally in connection with some scientific relationship, expressed as an equation by means of letter symbols (variables) and constants.

For example, Ohm's Law states that $E = RI$ where each of the letter symbols has a precise meaning. If we know any two of the variables, we can determine the third,

$$R = \frac{E}{I} \text{ and } I = \frac{E}{R}$$

Another example is

$$X_c = \frac{1}{2\pi fC}$$

which gives X_c for any desired values of f and C . Note that 2π is a constant.

All formulae or laws may be rearranged in accordance with the rules for the solution of equations, so as to give the value of any variable in terms of the others.

(xv) Continuity and limits

Some functions are "continuous," that is to say they are smooth and unbroken when plotted as curves. Other functions are said to be "discontinuous" if at some value of x the value of y is indeterminate or infinite, or there is a sharp angle in the plotted value of $y = F(x)$. Examples of points of discontinuity are:

(1) $y = 1/x$ is discontinuous at $x = 0$.

(2) $y = 10^{1/(x-1)}$ is discontinuous at $x = 1$.

Even when a function is discontinuous at one or more points, it may be described as continuous within certain limits.

It frequently happens that a function approaches very closely to a limiting value, although it never quite reaches it for any finite values of the independent variable. For example, the voltage gain of a resistance coupled amplifier is given by

$$A = \mu R_L / (R_L + r_p)$$

and it is required to find the limiting value of A when R_L is made very great.

The formula may be put in the form

$$A = \mu \frac{1}{1 + \frac{r_p}{R_L}} \quad (55)$$

and as R_L is made very much greater than r_p , the value of r_p/R_L becomes very small although it never actually reaches zero. We may express this in the form

$$\lim_{R_L \rightarrow \infty} \left(\frac{r_p}{R_L} \right) = 0 \quad (56)$$

which may be stated "the limit of (r_p/R_L) , as R_L approaches infinity, is zero." The limiting value of A , as R_L approaches infinity, is therefore

$$\lim_{R_L \rightarrow \infty} A = \mu \quad (57)$$

(xvi) Progressions, sequences and series

A **Sequence** is a succession of terms so related that each may be derived from one or more of the preceding terms in accordance with some fixed law.

A **Series** is the sum of terms of a sequence.

Arithmetical Progression is a sequence, each term of which (except the first) is derived from the preceding term by the addition of a constant number.

General form : $a, (a + d), (a + 2d), (a + 3d)$

Example : $2, 5, 8, 11, \text{etc.}$

(here $a = 2$ and $d = 3$).

The n th term $= a + (n - 1)d$ (58)

The sum of n terms is $S = \frac{1}{2}n[2a + (n - 1)d]$ (59)

When three numbers are in Arithmetical Progression, the middle number is called the "arithmetical mean." The **arithmetical mean** between a and b is $\frac{1}{2}(a + b)$.

Geometrical Progression is a sequence, each term of which (except the first) is derived from the preceding term by multiplying it by a constant ratio (r).

General form : $a, ar, ar^2, ar^3,$

Examples : $3, 6, 12, 24, \quad (r = 2)$
 $4, -2, +1, -\frac{1}{2} \quad (r = -\frac{1}{2})$

With the general form above,

the n th term $= ar^{n-1}$ (60)

and the sum of the first n terms is

$$S = a \left(\frac{r^n - 1}{r - 1} \right) \quad (61)$$

When three numbers are in Geometrical Progression, the middle number is called the Geometrical Mean. The **Geometrical Mean** of two numbers a and b is \sqrt{ab} .

If the ratio r is less than unity, the terms become progressively smaller, and the sum of a very large number of terms approaches

$$\lim_{n \rightarrow \infty} S = \frac{a}{1 - r} \quad (62)$$

Harmonic Progression : The terms a, b, c , etc. form a harmonic sequence if their reciprocals

$$\frac{1}{a}, \frac{1}{b}, \frac{1}{c}, \text{etc.}$$

form an arithmetical sequence.

Example : $1, \frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \frac{1}{5}$ is a Harmonic Progression

because $1, 2, 3, 4, 5$ is an Arithmetical Progression

The Harmonic Mean between a and b is $\frac{2ab}{a + b}$.

Note that the **Arithmetical Mean** between two numbers is greater than the **Geometrical Mean**, which in turn is greater than the **Harmonic Mean**.

With any form of progression or sequence, we are often concerned with the sum of a number of terms of which the general term is given. It is possible to write this sum in a shortened form, for example

$$1 + 2 + 3 + 4 + \dots + k + \dots + n = \sum_{k=1}^n k$$

where the Greek letter capital sigma is used to indicate the sum of a number of terms ; k is merely the general term ; and the values of k are to be taken from $k = 1$ (beneath sigma) to $k = n$ (written above sigma).

(xvii) Logarithmic and exponential functions

If $a^x = N$

then x is the logarithm to the base a of the number N . This may be put in the form

$$x = \log_a N$$

where the base a may be any positive number except 1 or 0.

The two principal systems of logarithms are

(1) The **Naperian** (or **natural**) system, using the base $e = 2.718\ 28 \dots$ (preferably written with the Greek ϵ), and

(2) The **Briggs** (or **common**) system, using the base 10.

Only one set of tables is required, for it is possible to convert a logarithm to one base (b) into a logarithm to any other base (a) :

$$\log_a y = \log_b y \times \log_a b$$

If it is required to find the logarithm to the base ϵ , given the logarithm to the base 10,

$$\log_{\epsilon} y = \log_{10} y \times \log_{\epsilon} 10 \quad (63a)$$

$$= \log_{10} y \times 2.3026 \quad (63b)$$

$$\log_{10} y = \log_{\epsilon} y \times 0.4343 \quad (63c)$$

Some properties of ϵ

The value of ϵ is given by the right hand side of eqn. (86).

Values shown below in brackets are to four decimal places.

$$\epsilon = 2.71828 (= 2.7183)$$

$$1/\epsilon = 0.367879 (= 0.3679)$$

$$\log_{10} \epsilon = 0.43429 (= 0.4343)$$

$$\log_{\epsilon} 10 = 2.30259 (= 2.3026)$$

$$\log_{\epsilon} 10 = 1/\log_{10} \epsilon$$

$$\log_{10} \epsilon^n = n \times 0.43429 (= n \times 0.4343)$$

Some manipulations with logarithmic functions

$$\log a/b = \log a - \log b \quad (64)$$

$$\log 1/a = -\log a \quad (65)$$

$$\log y^n = n \times \log y \quad (66)$$

$$\log y^{-1} = -\log y \quad (67)$$

$$\log y^{m/n} = (m/n) \times \log y \quad (68)$$

$$\log \sqrt{y} = \log y^{1/2} = (1/2) \log y \quad (69)$$

$$\log \sqrt[3]{y} = \log y^{1/3} = (1/3) \log y \quad (70)$$

To find the cube root of 125—

$$\sqrt[3]{125} = (125)^{1/3}$$

$$\text{Therefore } \log (125)^{1/3} = (1/3) \log 125 = (1/3) (2.0969) = 0.699.$$

Then antilog 0.699 = 5.00 (from tables).

$$\log \sqrt[4]{y^3} = \frac{3}{4} \log y \quad (71)$$

$$\log abc = \log a + \log b + \log c \quad (72)$$

$$\log (ab/cd) = \log a + \log b - \log c - \log d \quad (73)$$

$$\text{Arithmetic Mean of } a, b, c = \frac{a+b+c}{3} \quad (74)$$

The **Harmonic Mean** between a and b is $\frac{2ab}{a+b}$.

$$\log \sqrt{a^2 - b^2} = \frac{1}{2} \log (a + b) + \frac{1}{2} \log (a - b) \quad (77)$$

Logarithmic Functions are closely related to **Exponential Functions**, and any equation in one form may be put into the other form. If the curves are plotted, the two will be the same.

$$\begin{array}{ll} \text{Example : Exponential form} & y = r^x \\ \text{Logarithmic form} & x = \log_r y \end{array}$$

Numerical example :

If $r = 10$ and $x = 3$

Then $y = 10^3 = 1000$.

This may be handled by the logarithmic form of the equation,

$$x = \log_r y = \log_{10} 1000 = 3 \text{ as before.}$$

Logarithmic decrement : If the equation is of the form

$$y = ae^{-bx}$$

where $(-b)$ is negative, the value of y decreases as x is increased, and $(-b)$ is called the Logarithmic Decrement.

(xviii) Infinite series

It was noted, when dealing with Geometrical Progression, that it is possible to take the limit of the sum of a very large number of terms, as the number approaches infinity, provided that the terms become progressively smaller by a constant ratio. Such a series is called "convergent" and is defined as having a finite limit to the sum to infinity. Infinite series which do not comply with this definition may be "divergent" (these are not considered any further) or else they may be "oscillating."

(a) **Binomial series :**

$$1 + mx + \frac{m(m-1)}{1.2} x^2 + \frac{m(m-1)(m-2)}{1.2.3} x^3 + \text{etc.} \quad (78)$$

The n th term is

$$a_n = \frac{m(m-1)(m-2) \dots (m-n+2)}{1.2.3 \dots (n-1)} x^{n-1} \quad (79)$$

The denominator is usually written in the form

$$(n-1) !$$

which is called "factorial $(n-1)$."

This Binomial Series is convergent, provided that x is numerically less than 1.

(b) **Binomial theorem :**

Case 1 :

$$\begin{aligned} (1 \pm x)^m &= 1 \pm mx + \frac{m(m-1)}{2!} x^2 \pm \frac{m(m-1)(m-2)}{3!} x^3 + \dots \\ &\pm \frac{m(m-1) \dots (m-n+2)}{(n-1)!} x^{n-1} + \dots \end{aligned} \quad (80)$$

which holds for all values of x if m is a positive integer, and for all values of m provided that x is numerically less than 1.

The Binomial Theorem is useful in certain approximate calculations. If x is small compared with 1, and m is reasonably small,

$$\left. \begin{aligned} (1+x)^m &\approx 1+mx \\ (1-x)^m &\approx 1-mx \\ (1+x)^{-m} &\approx 1-mx \\ (1-x)^{-m} &\approx 1+mx. \end{aligned} \right\} \quad (81)$$

To a closer approximation (taking three terms),

$$\left. \begin{aligned} (1+x)^m &\approx 1+mx + \frac{1}{2} m(m-1) x^2 \\ (1-x)^m &\approx 1-mx + \frac{1}{2} m(m-1) x^2 \\ (1+x)^{-m} &\approx 1-mx + \frac{1}{2} m(m+1) x^2 \\ (1-x)^{-m} &\approx 1+mx + \frac{1}{2} m(m+1) x^2 \end{aligned} \right\} \quad (82)$$

Numerical example : To find the cube root of 220.

$$\sqrt[3]{220} = (216 + 4)^{1/3} = \left\{ 216 \left(1 + \frac{4}{216} \right) \right\}^{1/3} = 6 \left(1 + \frac{1}{54} \right)^{1/3}.$$

Applying the approximation from the Binomial Theorem,

$$(1 + x)^m \approx 1 + mx$$

to the evaluation of the quantity above, we may make $x = 1/54$ and $m = 1/3$, from which

$$\left(1 + \frac{1}{54} \right)^{1/3} \approx 1 + \frac{1}{3} \cdot \frac{1}{54} \approx 1 + \frac{1}{162} \approx 1.00617$$

Therefore $\sqrt[3]{220} \approx 6 \times 1.00617 \approx 6.037$.

Case 2 :

We can also expand $(a + x)^m$, which is convergent when x is numerically less than a :

$$(a \pm x)^m = a^m \pm ma^{m-1}x + \frac{m(m-1)}{2!} a^{m-2}x^2 \pm \frac{m(m-1)(m-2)}{3!} a^{m-3}x^3 + \dots \quad (83)$$

Approximation :

$$\frac{1}{a+1} = (a+1)^{-1} \approx \frac{1}{a} \left(1 - \frac{1}{a} \right) \text{ when } a > 1 \quad (84)$$

(c) Exponential series

From the Binomial Theorem, putting $x = 1/n$ and $m = nx$, we may derive

$$\left(1 + \frac{1}{n} \right)^{nx} = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \dots + \frac{x^{n-1}}{(n-1)!} + \dots \quad (85)$$

When $x = 1$ this becomes

$$\left(1 + \frac{1}{n} \right)^n = 1 + 1 + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \dots + \frac{1}{(n-1)!} + \dots \quad (86)$$

The right hand side of this equation is the value e , which is equal to 2.71828 (to five places of decimals). Taking the x th power of each side of this equation,

$$\left(1 + \frac{1}{n} \right)^{nx} = e^x$$

$$\text{Therefore } e^x = \left(1 + \frac{1}{n} \right)^{nx}$$

$$\text{and } e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \dots + \frac{x^{n-1}}{(n-1)!} + \dots \quad (87)$$

which is called the Exponential Series.

(d) Logarithmic series

The logarithmic series is the expansion of $\log_e (1 + x)$ in ascending powers of x :

$$\log_e (1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \dots \quad (88)$$

which is convergent if x is numerically less than 1.

(e) Trigonometrical series

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots \quad (89)$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots \quad (90)$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \frac{62x^9}{2835} + \dots (|x| < \pi/2) \quad (91)$$

For derivation of eqns. (89) and (90) see Sect. 6, eqns. (17) and (18).

(xix) Hyperbolic functions

These are combinations of the sum and difference of two exponential functions.

$$\frac{e^x - e^{-x}}{2} \text{ is called the hyperbolic sine of } x, \text{ designated by } \sinh x$$

$$\frac{e^x + e^{-x}}{2} \text{ is called the hyperbolic cosine of } x, \text{ designated by } \cosh x,$$

$\frac{e^x - e^{-x}}{e^x + e^{-x}}$ is called the hyperbolic tangent of x , designated by $\tanh x$

and similarly with the inverses

$$\operatorname{cosech} x = 1/\sinh x$$

$$\operatorname{sech} x = 1/\cosh x$$

$$\operatorname{coth} x = 1/\tanh x$$

$$\text{Note } e = 1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \dots \approx 2.718\ 28 \quad (92)$$

The following may be derived:

$$\cosh^2 x - \sinh^2 x = 1 \quad (93)$$

$$\operatorname{sech}^2 x + \tanh^2 x = 1 \quad (94)$$

$$\coth^2 x - \operatorname{cosech}^2 x = 1 \quad (95)$$

$$\sinh(-x) = -\sinh x; \cosh(-x) = \cosh x; \tanh(-x) = -\tanh x \quad (96)$$

$$\sinh x = \frac{\tanh x}{\sqrt{1 - \tanh^2 x}} = \sqrt{\cosh^2 x - 1} \quad (97)$$

$$\cosh x = \frac{1}{\sqrt{1 - \tanh^2 x}} = \sqrt{\sinh^2 x + 1} \quad (98)$$

$$\tanh x = \frac{\sinh x}{\cosh x} = \sqrt{1 - \operatorname{sech}^2 x} \quad (99)$$

$$\sinh x + \sinh y = 2 \sinh \frac{x+y}{2} \cosh \frac{x-y}{2} \quad (100)$$

$$\sinh x - \sinh y = 2 \sinh \frac{x-y}{2} \cosh \frac{x+y}{2} \quad (101)$$

$$\cosh x + \cosh y = 2 \cosh \frac{x+y}{2} \cosh \frac{x-y}{2} \quad (102)$$

$$\cosh x - \cosh y = 2 \sinh \frac{x+y}{2} \sinh \frac{x-y}{2} \quad (103)$$

$$\tanh x \pm \tanh y = \frac{\sinh(x \pm y)}{\cosh x \cosh y} \quad (104)$$

$$(\sinh x + \cosh x)^n = \cosh nx + \sinh nx \quad (105)$$

$$\sinh^{-1} x = \log_e (x + \sqrt{x^2 + 1}) = \cosh^{-1} \sqrt{x^2 + 1} \quad (106)$$

$$\cosh^{-1} x = \log_e (x + \sqrt{x^2 - 1}) = \sinh^{-1} \sqrt{x^2 - 1} \quad (107)$$

$$\tanh^{-1} x = \frac{1}{2} \log_e \frac{1+x}{1-x} \quad (108)$$

$$= \cosh^{-1} \frac{1}{\sqrt{1-x^2}} = \sinh^{-1} \frac{x}{\sqrt{1-x^2}} \quad (109)$$

$$\sinh(x \pm y) = \frac{e^{x \pm y} - e^{-(x \pm y)}}{2} = \sinh x \cosh y \pm \cosh x \sinh y \quad (110a)$$

$$\cosh(x \pm y) = \frac{e^{x \pm y} + e^{-(x \pm y)}}{2} = \cosh x \cosh y \pm \sinh x \sinh y \quad (110b)$$

$$\tanh(x \pm y) = \frac{e^{x \pm y} - e^{-(x \pm y)}}{e^{x \pm y} + e^{-(x \pm y)}} = \frac{\tanh x \pm \tanh y}{1 \pm \tanh x \tanh y} \quad (111)$$

$$\sinh 2x = 2 \sinh x \cosh x = \frac{2 \tanh x}{1 - \tanh^2 x} \quad (112)$$

$$\cosh 2x = \cosh^2 x + \sinh^2 x = \frac{1 + \tanh^2 x}{1 - \tanh^2 x} \quad (113)$$

$$\tanh 2x = \frac{2 \tanh x}{1 + \tanh^2 x} \quad (114)$$

$$\cosh x + \sinh x = e^x \quad (115a)$$

$$\cosh x - \sinh x = e^{-x} \quad (115b)$$

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \dots \quad (115c)$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \dots \quad (115d)$$

(these are convergent for all real values of x).

Also in complex form (see Section 6)

$$\sinh jx = j \sin x; \cosh jx = \cos x; \tanh jx = j \tan x \quad (116)$$

$$\sin jx = j \sinh x; \cos jx = \cosh x \quad (117)$$

$$\sinh(x \pm jy) = \sinh x \cos y \pm j \cosh x \sin y \quad (118)$$

Note that x and y in $\sin x$, $\cos x$, $\tan x$ etc. in eqns. 116 to 119 must be expressed in radians.

$$\cosh(x \pm jy) = \cosh x \cos y \pm j \sinh x \sin y \quad (119)$$

$$\sinh\left(\frac{x}{2}\right) = \sqrt{\frac{\cosh x - 1}{2}}; \quad \cosh\left(\frac{x}{2}\right) = \sqrt{\frac{\cosh x + 1}{2}} \quad (120)$$

$$\tanh\left(\frac{x}{2}\right) = \frac{\cosh x - 1}{\sinh x} = \frac{\sinh x}{\cosh x + 1} \quad (121)$$

(xx) General approximations

Let δ be an extremely small quantity and x be a quantity very large compared with δ , then

$$\frac{1}{1 - \delta} \approx 1 + \delta \quad \frac{1}{1 + \delta} \approx 1 - \delta \quad (122)$$

$$\frac{1 + \delta_1}{1 + \delta_2} \approx 1 + \delta_1 - \delta_2 \quad (123)$$

$$(1 \pm \delta)^n \approx 1 \pm n\delta \quad \left. \begin{array}{l} \text{where } n \text{ may be integral,} \\ \text{fractional or negative} \end{array} \right\} \quad (124)$$

$$\frac{1}{(1 \pm \delta)^n} \approx 1 \mp n\delta \quad (125)$$

$$\sqrt{1 + \delta} \approx 1 + \frac{1}{2}\delta \quad \sqrt{1 - \delta} \approx 1 - \frac{1}{2}\delta \quad (126)$$

$$\frac{1}{\sqrt{1 + \delta}} \approx 1 - \frac{1}{2}\delta \quad \frac{1}{\sqrt{1 - \delta}} \approx 1 + \frac{1}{2}\delta \quad (127)$$

$$(1 + \delta)^2 \approx 1 + 2\delta \quad (1 - \delta)^2 \approx 1 - 2\delta \quad (128)$$

$$(x \pm \delta)^n \approx x^n \pm nx^{n-1}\delta \quad (129)$$

Eqn. (129) is used in Sect. 1(v)b for approximations with powers and roots.

$$\sqrt{x(x + \delta)} \approx x + \frac{1}{2}\delta \quad \sqrt{x(x - \delta)} \approx x - \frac{1}{2}\delta \quad (130)$$

$$(1 + \delta_1)(1 \pm \delta_2) \approx 1 + \delta_1 \pm \delta_2 \quad (131)$$

$$(1 + \delta_1)(1 + \delta_2)(1 + \delta_3) \approx 1 + \delta_1 + \delta_2 + \delta_3 \quad (132)$$

where δ_1 , δ_2 and δ_3 are all extremely small quantities.

$$\epsilon^\delta \approx 1 + \delta \quad \epsilon^{-\delta} \approx 1 - \delta \quad (133)$$

$$\epsilon^{t/RC} \approx 1 + t/RC \quad \epsilon^{-t/RC} \approx 1 - t/RC \quad (134)$$

Eqn. (134) has an error less than 0.6% when t/RC does not exceed 0.1.

$$\log_e(x \pm \delta) \approx \log_e x \pm \frac{\delta}{x} - \frac{1}{2}\left(\frac{\delta}{x}\right)^2 \quad (135)$$

$$\log_e(1 \pm \delta) \approx \delta - \frac{1}{2}\delta^2 \quad (136)$$

$$\sinh \delta \approx \delta \quad \cosh \delta \approx 1 \quad \tanh \delta \approx \delta \quad (137)$$

$$\sinh^{-1} \delta \approx \delta \quad \tanh^{-1} \delta \approx \delta \quad (138)$$

$$\sinh(x + \delta) \approx \sinh x + \delta \cosh x; \sinh(x - \delta) \approx \sinh x - \delta \cosh x \quad (139)$$

$$\cosh(x + \delta) \approx \cosh x + \delta \sinh x; \cosh(x - \delta) \approx \cosh x - \delta \sinh x \quad (140)$$

$$\tanh(x + \delta) \approx \tanh x + \delta \operatorname{sech}^2 x; \tanh(x - \delta) \approx \tanh x - \delta \operatorname{sech}^2 x \quad (141)$$

When L is a large quantity

$$\sinh L \approx \frac{1}{2}\epsilon^L \quad \cosh L \approx \frac{1}{2}\epsilon^L \quad \tanh L \approx 1 \quad (142)$$

Trigonometrical relationships

When δ is an extremely small quantity, so that an angle of δ radians is a very small angle, and x is an angle very large compared with δ ,

$$\sin \delta \approx \delta \quad \cos \delta \approx 1 \quad \tan \delta \approx \delta \quad (143)$$

$$\sin^{-1} \delta \approx \delta \quad \cos^{-1} \delta \approx \frac{1}{2}\pi(4K-1) + \delta \quad \tan^{-1} \delta \approx \delta \quad (144)$$

where K is any integer. See Sect. 3(iii) for inverse functions.

$$\sin(x + \delta) \approx \sin x + \delta \cos x \quad \sin(x - \delta) \approx \sin x - \delta \cos x \quad (145)$$

$$\cos(x + \delta) \approx \cos x - \delta \sin x \quad \cos(x - \delta) \approx \cos x + \delta \sin x \quad (146)$$

$$\tan(x + \delta) \approx \tan x + \delta/\cos^2 x \quad \tan(x - \delta) \approx \tan x - \delta/\cos^2 x \quad (147)$$

SECTION 3 : GEOMETRY AND TRIGONOMETRY

(i) *Plane figures* (ii) *Surfaces and volumes of solids* (iii) *Trigonometrical relationships.*

(i) Plane figures

Angles

Two angles are complementary when their sum is equal to a right angle (90°).

Two angles are supplementary when their sum is equal to two right angles (180°).

The three angles of a triangle are together equal to two right angles (180°)

$$2\pi \text{ radians} = 360^\circ$$

$$\pi \text{ radians} = 180^\circ$$

$$1 \text{ radian} \approx 57.29578^\circ$$

$$1^\circ \approx 0.0174533 \text{ radian.}$$

When an angle is measured in radians, and incorporates the sign π , it is usual to omit the word "radians" as being understood—e.g. π , 2π .

Right Angle Triangles (Fig. 6.1)

$$\text{Sine : } \frac{a}{c} = \sin A \quad a = c \sin A \quad (1)$$

$$\text{Tangent : } \frac{a}{b} = \tan A \quad a = b \tan A \quad (2)$$

$$\text{Cosine : } \frac{b}{c} = \cos A \quad b = c \cos A \quad (3)$$

FIG. 6.1

$$\text{Cosecant : } \frac{c}{a} = \text{cosec } A = 1/\sin A \quad (4)$$

$$\text{Secant : } \frac{c}{b} = \sec A = 1/\cos A \quad (5)$$

$$\text{Cotangent : } \frac{b}{a} = \cot A = 1/\tan A \quad (6)$$

c is called the hypotenuse.

$$a^2 + b^2 = c^2 \quad (7)$$

$$a = \sqrt{(c+b)(c-b)} = \sqrt{mc} \quad (8)$$

$$a = c \sin A = b \tan A \quad (9)$$

$$b = \sqrt{(c+a)(c-a)} = \sqrt{nc} \quad (10)$$

$$b = c \cos A = a \cot A = a/\tan A \quad (11)$$

$$c = \sqrt{a^2 + b^2} = m + n \quad (12)$$

$$c = a \text{ cosec } A = a/\sin A = b \sec A = b/\cos A \quad (13)$$

$$\text{Area} = \frac{1}{2} ab = \frac{1}{2} a^2 \cot A = \frac{1}{2} b^2 \tan A \quad (14)$$

$$= \frac{1}{2} c^2 \sin 2A = \frac{1}{2} bc \sin A = \frac{1}{2} ac \sin B \quad (15)$$

The perpendicular (p) to the hypotenuse is the mean proportional (or mean geometrical progression) between the segments of the hypotenuse,

*See Sect. 3(iii) for trigonometrical relationships.

$$\frac{m}{p} = \frac{p}{n}, \quad p = \sqrt{mn} \quad (16)$$

$$\text{also } \frac{m}{a} = \frac{a}{c}, \quad \frac{n}{b} = \frac{b}{c}. \quad (17)$$

Any triangle inscribed in a semicircle, with the diameter forming one side, is a right angle triangle.

Equilateral Triangle (Fig. 6.2a)

FIG. 6.2A

Each side = a

Each angle = 60°

$$m = \frac{1}{2} a$$

$$h = \sqrt{3} m = (\sqrt{3}/2)a \approx 0.866a \quad (18)$$

$$\text{area} = \frac{1}{2} ah = (\sqrt{3}/4)a^2 \approx 0.433a^2 \quad (19)$$

Any triangle (Fig. 6.2b)

$$\text{Area} = \frac{1}{2} bh = \sqrt{s(s-a)(s-b)(s-c)} \quad (20)$$

where b = base, h = height, $s = \frac{1}{2}(a+b+c)$.

FIG. 6.2B

$$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C} \quad (21)$$

$$a^2 = b^2 + c^2 - 2bc \cos A \quad (22)$$

$$b^2 = c^2 + a^2 - 2ca \cos B \quad (23)$$

$$c^2 = a^2 + b^2 - 2ab \cos C \quad (24)$$

$$a = b \cos C + c \cos B \quad (25)$$

$$b = c \cos A + a \cos C$$

$$c = a \cos B + b \cos A.$$

Rectangle (Fig. 6.3)

$$\text{Area} = ab \quad (26)$$

$$d = \text{diagonal} = \sqrt{a^2 + b^2} \quad (27)$$

Parallelogram (Fig. 6.4)

$$\text{Area} = bh = ab \sin C; \quad a = c; \quad b = d. \quad (28)$$

$$\text{Angle } A = \text{angle } C; \quad \text{angle } B = \text{angle } D. \quad (29)$$

Trapezoid (Fig. 6.5).

Side d is parallel to side b .

$$\text{Area} = \frac{1}{2}(b+d)h. \quad (30)$$

FIG. 6.3

FIG. 6.4

FIG. 6.5

Polygons and Quadrilaterals

To find area, divide into triangles, calculate the area of each, and add.

Circle

$$\text{Circumference} = \pi \times \text{diameter} \approx 3.1416 \times \text{diameter} \quad (31)$$

$$= 2\pi \times \text{radius} \approx 6.2832 \times \text{radius} \quad (32)$$

$$\text{Area} = \pi \times (\text{radius})^2 = \frac{1}{4}(\text{circumference} \times \text{radius}) \quad (33)$$

$$= (\pi/4) \times (\text{diameter})^2 \approx 0.7854 (\text{diameter})^2 \quad (34)$$

Sector (Fig. 6.6)

$$A = \text{angle subtended at centre} = s/r \text{ radians} \quad (35)$$

$$c = 2\sqrt{r^2 - a^2} = 2r \sin(A/2) = 2a \tan(A/2) = 2\sqrt{2hr - h^2} \quad (36)$$

$$a = \frac{1}{2}\sqrt{4r^2 - c^2} = \frac{1}{2}\sqrt{d^2 - c^2} = r \cos(A/2) = \frac{1}{2}c \cot(A/2) \quad (37)$$

FIG. 6.6

FIG. 6.7

$$s = \text{length of arc} = rA \quad (A \text{ in radians}) \quad (38)$$

$$= \pi r A / 180 \quad (A \text{ in degrees}) \quad (39)$$

$$h = r - a = r(1 - \cos A/2) \quad (40)$$

$$\text{Area of sector} = \frac{1}{2}rs = \frac{1}{2}r^2A \quad (A \text{ in radians}) \quad (41)$$

$$= \pi r^2 A / 360 \quad (A \text{ in degrees}) \quad (42)$$

$$\text{Area of segment (bounded by chord } c, \text{ curve } s) \quad (43)$$

$$= \frac{1}{2}r^2(A - \sin A) \quad (A \text{ in radians}) \quad (43)$$

$$= \frac{1}{2}r(s - r \sin s/r) \quad (s/r \text{ in radians}) \quad (44)$$

$$= \frac{1}{2}[r(s - c) + ch] \text{ for segments less than half a circle.} \quad (45)$$

Ellipse (Fig. 6.7)

The ellipse has two foci, F and F', and for any point P on the perimeter,

$$FP + PF' \text{ is constant} = FB + BF' = FA + AF' \quad (46)$$

$$\text{Major axis} = AB = 2a; \text{ minor axis} = CD = 2b \quad (47)$$

$$\text{Area of ellipse} = \pi ab \approx 0.7854 \text{ major axis} \times \text{minor axis} \quad (48)$$

$$\text{Perimeter} \approx a(4 + 1.1m + 1.2m^2), \text{ where } m = b/a \quad (49)$$

An ellipse may be drawn by putting a pin into the paper at each focus (F, F'), tying the ends of a short length of cotton thread around the pins leaving a slack portion in the middle, and running a pencil point around in the loop of the thread.

To find the foci, draw an arc with centre at C and radius a to intersect the X axis (AB) at F and F'.

Parabola (Fig. 6.8)

The parabola has a focus (F) and a directrix (MN) and for any point P on the parabola,

$$FP = PM \text{ where PM is the perpendicular to the directrix} \quad (50)$$

$$\text{Area of segment cut off by chord } PP' = (2/3)ch. \quad (51)$$

FIG. 6.8

FIG. 6.9

Hyperbola (Fig. 6.9)

The hyperbola has two foci (F, F') and two asymptotes, and for any point P on either curve,

$$FP - F'P = \text{constant} \quad (52)$$

General rules for areas

Areas bounded by straight sides may be calculated by dividing the area into triangles, calculating the area of each and adding.

Areas bounded by irregular curves may be divided into parallel strips and the area calculated by one of the following approximations :

Trapezoid rule

$$\text{Area} = d(\frac{1}{2}y_1 + y_2 + y_3 + \dots + y_{n-1} + \frac{1}{2}y_n) \quad (53)$$

where d = width of each strip

and $y_1, y_2, y_3, \dots, y_n$ are measured lengths of each of the equidistant parallel chords. Note that the first (y_1) and the last (y_n) do not cut the area, and may be zero if the surface is sharply curved.

Simpson's Rule

$$\text{Area} = \frac{d}{3} (y_1 + 4y_2 + 2y_3 + 4y_4 + 2y_5 + \dots + 2y_{n-2} + 4y_{n-1} + y_n) \quad (54)$$

where n must be odd

d = width of each strip

and $y_1 \dots y_n$ are measured lengths of equidistant parallel chords.

(ii) Surfaces and volumes of solids

Cube (length of side = a)

$$\text{Volume} = a^3 \quad (55)$$

$$\text{Surface area} = 6a^2 \quad (56)$$

$$\text{Length of diagonal} = a\sqrt{3} \quad (57)$$

Rectangular prism

(length = l , breadth = b , height = h)

$$\text{Volume} = lbh \quad (58)$$

$$\text{Surface area} = 2(lb + lh + bh) \quad (59)$$

$$\text{Diagonal} = \sqrt{b^2 + l^2 + h^2} \quad (60)$$

Cylinder, solid right circular

(length l , radius r)

$$\text{Volume} = \pi r^2 l \approx 0.7854 d^2 l \quad (61)$$

$$\text{Area of curved portion} = 2\pi rl = \pi dl \quad (62)$$

$$\text{Area of each end} = \pi r^2 \quad (63)$$

$$\text{Total surface area} = 2\pi r(l + r) \quad (64)$$

Hollow cylinder, right circular

(length l , outer radius R , inside radius r)

$$\text{Volume} = \pi l (R^2 - r^2) \quad (65)$$

Any pyramid or cone

$$\text{Volume} = 1/3 (\text{area of base} \times \text{distance from vertex to plane of base}) \quad (66)$$

Sphere

$$\text{Volume} = \frac{4}{3} \pi r^3 = \pi d^3/6 \approx 4.1888 r^3 \approx 0.5236 d^3 \quad (67)$$

$$\text{Surface area} = 4\pi r^2 = \pi d^2 \quad (68)$$

(iii) Trigonometrical relationships

We have already introduced the sine, cosine and tangent of an angle, and their inverses, under the subject Angles (Fig. 6.1). The following table may readily be derived with the assistance of Fig. 6.10 :

Angle	Sine	Cosine	Tangent
0	0	1	0
30°	1/2	$\sqrt{3}/2$	$1/\sqrt{3}$
45°	$1/\sqrt{2}$	$1/\sqrt{2}$	1
60°	$\sqrt{3}/2$	1/2	$\sqrt{3}$
90°	1	0	∞ *

*Approaches infinity as angle approaches 90°.

The values for any angle between 0° and 90° may be found from Table 72, Trigonometrical Relationships, in Chapter 38 Sect. 21, or from any book of Mathematical Tables.

Angles of any magnitude

If the line OX (Fig. 6.11) revolves about O to a new position OP , the amount of rotation is the angle XOP between its original position OX and its new position OP . Such a counter-clockwise rotation is called positive, while the opposite direction of rotation is called negative.

FIG. 6.10

FIG. 6.11

Examples of angles in all four sectors are shown in Fig. 6.12. It will be seen that, for any angle A , the position of OP is the same for a movement of angle A in a positive direction, or for a negative movement of $(360^\circ - A)$; for example,

$$+ 330^\circ = -(360^\circ - 330^\circ) = -30^\circ$$

In the case of angles greater than 360° we are generally only concerned with the final position of OP , so that for these cases we may subtract 360° , or any multiple of 360° , from the angle so as to give a value less than 360° . For example $390^\circ = 360^\circ + 30^\circ$; $800^\circ = 720^\circ + 80^\circ$; $1125^\circ = 1080^\circ + 45^\circ$.

In trigonometry it is also necessary to define the polarity of the three sides of the triangles from which we derive the sine, cosine and tangent. The hypotenuse (OP_1) is always positive (see Fig. 6.13). The base (OX_1) is positive when X is to the right hand side of O , and negative when X is to the left of O (e.g. OX_2). The perpendicular is positive when P is above X (e.g. $P_1 X_1$) and negative when P is below X (e.g. $P_4 X_4$).

FIG. 6.12

FIG. 6.13

1st Quadrant : All sides positive ($OX_1 P_1$).

Sine, cosine, tangent all positive.

2nd Quadrant : OX_2 negative, other sides positive.

Sine = $X_2 P_2 / OP_2$ which is positive.

Cosine = OX_2 / OP_2 which is negative.

Tangent = $X_2 P_2 / OX_2$ which is negative.

3rd Quadrant : OX_3 , $X_3 P_3$ negative; OP_3 positive.

Sine = $X_3 P_3 / OP_3$ which is negative.

Cosine = OX_3 / OP_3 which is negative.

Tangent = $X_3 P_3 / OX_3$ which is positive.

4th Quadrant : OX_4 , OP_4 positive, $X_4 P_4$ negative.

Sine = $X_4 P_4 / OP_4$ which is negative.

Cosine = OX_4 / OP_4 which is positive.

Tangent = $X_4 P_4 / OX_4$ which is negative.

A convenient method for determining graphically the value of the sine, cosine and tangent of an angle is shown in Fig. 6.14, where the circle is drawn with radius 1 (to any convenient scale, say 1 inch). To the same scale, PX gives the value of the sine, OX the cosine and AT the tangent.

"Inverse" functions

If $\sin \theta = n$, we may describe θ as the angle whose sine is n . This is conventionally written in the form

$$\theta = \sin^{-1} n,$$

where the " \sin^{-1} " is to be regarded purely as an abbreviation for "the angle whose sine is."

The same system is used with all trigonometrical functions— \cos^{-1} , \tan^{-1} , $\operatorname{cosec}^{-1}$, \sec^{-1} , \cot^{-1} .

These are occasionally written as arc sin, arc cos, arc tan, etc.

FIG. 6.14

FIG. 6.15

Summary of trigonometrical relationships

$$1. \operatorname{cosec} A = 1/\sin A = \cot A/\cos A \quad (69)$$

$$\sec A = 1/\cos A = \tan A/\sin A \quad (70)$$

$$\cot A = 1/\tan A = \cos A/\sin A \quad (71)$$

$$2. \tan A = (\sin A)/(\cos A) = \sin A \sec A \quad (72)$$

$$3. \sin A = \cos(90^\circ - A) = \sin(180^\circ - A) \quad (73)$$

$$\cos A = \sin(90^\circ - A) = -\cos(180^\circ - A) \quad (74)$$

$$\tan A = \cot(90^\circ - A) = -\tan(180^\circ - A) \quad (75)$$

$$\operatorname{cosec} A = \sec(90^\circ - A) = \operatorname{cosec}(180^\circ - A) \quad (76)$$

$$\sec A = \operatorname{cosec}(90^\circ - A) = -\sec(180^\circ - A) \quad (77)$$

$$\cot A = \tan(90^\circ - A) = -\cot(180^\circ - A) \quad (78)$$

$$4. \sin^2 A + \cos^2 A = 1; \sec^2 A - \tan^2 A = 1 \quad (79)$$

(Note: $\sin^2 A$ is the square of $\sin A$)

$$\sin A = \pm \sqrt{1 - \cos^2 A} = \pm \frac{\tan A}{\sqrt{1 + \tan^2 A}} = \pm \frac{1}{\sqrt{1 + \cot^2 A}} \quad (80)$$

$$\cos A = \pm \sqrt{1 - \sin^2 A} = \pm \frac{1}{\sqrt{1 + \tan^2 A}} = \pm \frac{\cot A}{\sqrt{1 + \cot^2 A}} \quad (81)$$

the choice of signs being determined by the quadrant.

$$5. \sec^2 A = 1/\cos^2 A = 1 + \tan^2 A \quad (82)$$

$$\operatorname{cosec}^2 A = 1/\sin^2 A = 1 + \cot^2 A \quad (83)$$

$$6. \sin(A + B) = \sin A \cos B + \cos A \sin B \quad (84)$$

$$\cos(A + B) = \cos A \cos B - \sin A \sin B \quad (85)$$

$$\tan(A + B) = \frac{\tan A + \tan B}{1 - \tan A \tan B} \quad (86)$$

$$7. \sin(A - B) = \sin A \cos B - \cos A \sin B \quad (87)$$

$$\cos(A - B) = \cos A \cos B + \sin A \sin B \quad (88)$$

$$\tan(A - B) = \frac{\tan A - \tan B}{1 + \tan A \tan B} \quad (89)$$

8. Negative angles (Fig. 6.15)

$$\sin(-A) = XP_4/OP_4 = -(XP_1/OP_1) = -\sin A \quad (90)$$

$$\cos(-A) = OX/OP_4 = OX/OP_1 = \cos A \quad (91)$$

$$\tan(-A) = XP_4/OX = -(XP_1/OX) = -\tan A \quad (92)$$

$$\operatorname{cosec}(-A) = OP_4/XP_4 = -(OP_1/XP_1) = -\operatorname{cosec} A \quad (93)$$

$$\sec(-A) = OP_4/OX = OP_1/OX = \sec A \quad (94)$$

$$\cot(-A) = OX/XP_4 = -(OX/XP_1) = -\cot A \quad (95)$$

$$9. \sin 2A = 2 \sin A \cos A = \frac{2 \tan A}{1 + \tan^2 A} \quad (96)$$

$$\cos 2A = \cos^2 A - \sin^2 A = 1 - 2 \sin^2 A = 2 \cos^2 A - 1 \quad (97)$$

$$\tan 2A = \frac{2 \tan A}{1 - \tan^2 A}; \cot 2A = \frac{\cot^2 A - 1}{2 \cot A} \quad (98)$$

$$10. \sin \frac{1}{2}A = \pm \sqrt{\frac{1 - \cos A}{2}} = \pm \left(\frac{1}{2} \sqrt{1 + \sin A} - \frac{1}{2} \sqrt{1 - \sin A} \right) \quad (99)$$

$$\cos \frac{1}{2}A = \pm \sqrt{\frac{1 + \cos A}{2}} = \pm \left(\frac{1}{2} \sqrt{1 + \sin A} + \frac{1}{2} \sqrt{1 - \sin A} \right) \quad (100)$$

$$\tan \frac{1}{2}A = \frac{1 - \cos A}{\sin A} = \frac{\sin A}{1 + \cos A} \quad (101)$$

$$11. \sin 3A = 3 \sin A - 4 \sin^3 A \quad \tan 3A = \frac{3 \tan A - \tan^3 A}{1 - 3 \tan^2 A} \quad (102)$$

$$12. \sin^2 A = \frac{1}{2}(1 - \cos 2A) \quad (103)$$

$$\cos^2 A = \frac{1}{2}(1 + \cos 2A) \quad (104)$$

$$13. \sin^3 A = \frac{1}{4}(3 \sin A - \sin 3A) \quad (105)$$

$$\cos^3 A = \frac{1}{4}(\cos 3A + 3 \cos A) \quad (106)$$

14. Approximations for small angles :

where A is measured in radians

$$\sin A \approx A - (A^3)/6 \quad \text{error for } 30^\circ \text{ is } 0.06\% \quad (107)$$

$$\cos A \approx 1 - (A^2)/2 \quad \text{error for } 30^\circ \text{ is } 0.35\% \quad (108)$$

$$\tan A \approx A + (A^3)/3 \quad \text{error for } 30^\circ \text{ is } 1.03\% \quad (109)$$

$$\text{and for very small angles } \sin A \approx A \quad (110)$$

$$\cos A \approx 1 \quad (111)$$

$$\tan A \approx A. \quad (112)$$

See also Sect. 2(xx).

$$15. \sin A = \frac{e^{jA} - e^{-jA}}{2j} \quad [\text{Sect. 6, eqn. (19)}] \quad (113)$$

$$\cos A = \frac{e^{jA} + e^{-jA}}{2} \quad [\text{Sect. 6, eqn. (20)}] \quad (114)$$

$$16. \text{versine } A' = 1 - \cos A = 2 \sin^2 (A/2) \quad (115)$$

SECTION 4 : PERIODIC PHENOMENA

The rotation of a wheel and a train of waves are two examples of periodic phenomena, that is to say the same action takes place repeatedly, each of such phenomena being called a "cycle." The number of cycles which occur in 1 second is called the frequency, and is expressed in one of the forms

cycles per second	c/s
kilocycles per second	Kc/s
megacycles per second	Mc/s.

If we take a point (P in Fig. 6.16) which is rotating with uniform angular velocity* about the point O, we can plot the height PX against the angle of rotation (θ). When P is at A (which we may regard as the zero point, since here $\theta = 0$), $PX = 0$, and we mark point B. When P is at angle θ , the perpendicular PX gives point C, and $CK = PX$. When $\theta = 90^\circ$, P will be at the top of the circle, giving D on the curve. When $\theta = 180^\circ$, P will be at the extreme left hand side of the circle, and the height above OA will be zero, thus giving point E. When $\theta = 270^\circ$, P will be at the bottom of the circle, giving point F on the curve. Lastly, P will return to point A (the zero point) and the height will be zero, point G. If the process is continued, the curve (GH etc.) will repeat the shape of the first cycle (BD etc.) and so on indefinitely. Thus BCDEFG represents one cycle.

FIG. 6.16

The length $PX = r \sin \theta$, so that its projected height CK is proportional to the sine of θ . The curve is therefore called a "sine curve" or "sine wave." A cosine curve has exactly the same shape, except that it begins at D (since $\cos 0^\circ = 1$) and the cycle ends at H.

The motion of the point X, as it oscillates about O between the extremes A and A' is called **Simple Harmonic Motion**.

Angular velocity (usually represented by the small Greek letter omega— ω) is the number of radians per second through which the point P travels. In each revolution

*i.e. uniform rate of rotation.

(360°) it will pass through 2π radians, and if it makes f revolutions per second, then the angular velocity will be

$$\omega = 2\pi f \text{ radians per second}$$

where f = frequency in cycles per second.

In most mathematical work it is more convenient to write ω than to write $2\pi f$.

SECTION 5 : GRAPHICAL REPRESENTATION AND j NOTATION

(i) *Graphs* (ii) *Finding the equation to a curve* (iii) *Three variables* (iv) *Vectors and j notation.*

(i) Graphs

Graphs are a convenient representation of the relationships between functions. For example, Ohm's Law

$$E = RI$$

may be represented by a graph (Fig. 6.17) in which I is plotted horizontally (on the X axis) and E vertically (on the Y axis) for a constant value of R .

Any point P on the plotted "curve" has its position fixed by coordinates. The horizontal, or x -coordinate (OQ) is called the abscissa, while the vertical, or y -coordinate (QP) is called the ordinate. The position of the point is written as a, b , thus indicating that $x = a$ and $y = b$, where $a = OQ$ and $b = QP$.

Any function of the form

$$y = mx + n \quad (m \text{ and } n \text{ being constants})$$

is a linear equation, since the plotted curve is a straight line. It only passes through the origin (O) if $n = 0$

In the general case, the axes extend in both directions about the origin (Fig. 6.18) forming four quadrants and allowing for negative values of both x and y . These are known as "Cartesian Coordinates."

When the two variable quantities in an equation can be separated into

"cause" and "effect," the "cause" (known as the independent variable) is plotted horizontally on the x axis, and the "effect" (known as the dependent variable) vertically on the y axis. In other cases the choice of axes is optional.

Any convenient scales may be used, and the x and y scales may differ.

The procedure to be adopted to plot a typical equation

$$y = 2x^2 + 4x - 5$$

is as follows. Select suitable values of x (which will be regarded as the independent variable) and calculate the value of y for each:

$x = 3$	$y = 18 + 12 - 5 = +25$
$x = 2$	$y = 8 + 8 - 5 = +11$
$x = 1$	$y = 2 + 4 - 5 = +1$
$x = 0$	$y = 0 + 0 - 5 = -5$
$x = -1$	$y = 2 - 4 - 5 = -7$
$x = -2$	$y = 8 - 8 - 5 = -5$
$x = -3$	$y = 18 - 12 - 5 = +1$

Then plot these points, as in Fig. 6.19A and draw a smooth curve through them.

FIG. 6-17

FIG. 6-18

The tangent at any point (e.g. P in Fig. 6.19A) is a straight line which is drawn so as to touch the curve at the point. The slope of the tangent, which is the same as that of the curve at the point, is defined as the tangent of the angle θ which it makes with the X axis. Between points B and C on the curve, θ is positive, therefore $\tan \theta$ is positive and the slope is called positive. Between points B and A the angle θ is negative, and the slope negative. At point B , $\theta = 0$ and the slope is zero. It is important to remember that the curve normally extends in both directions indefinitely unless it has limits, or turns back on itself. It is therefore advisable, when plotting an unknown function, to take very large positive and negative values of x and calculate the corresponding values of y , even though the points cannot be plotted on the graph paper. This will indicate the general trend of the curve beyond the limits of the graph paper.

FIG. 6.19A

The equations of some common curves are :

Straight line through origin

$$y = mx \quad (1)$$

Straight line not through origin

$$y = mx + n \quad (2)$$

Circle with centre at origin

$$y^2 = r^2 - x^2 \quad (3)$$

Circle with centre at (h, k)

$$(x - h)^2 + (y - k)^2 = r^2 \quad (4)$$

General equation of circle

$$x^2 + y^2 + dx + ey + f = 0 \quad (5)$$

Ellipse

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \quad (6)$$

Hyperbola

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1 \quad (7)$$

Parabola (origin at vertex)

$$y^2 = 2px \quad (8)$$

Focus is at

$$x = p/2, y = 0 \quad (9)$$

Areas and average heights

The average height of a curve (i.e. the average length of the ordinates) may be determined by dividing the area beneath the curve into strips of equal width, and then using either the Trapezoid Rule or Simpson's Rule [see Sect. 3 eqn. (54)] to determine the area, and dividing the area by the length (abscissa).

Logarithmic paper

Logarithmic ruled paper is frequently used in the plotting of curves, particularly when the x or y coordinates cover a range of 100 : 1 or more. Single cycle* paper accommodates a range of 10 : 1, and may be drawn by hand, using the whole of the C scale, or half the B scale on a slide rule. Two "cycle" log paper accommodates a range of 100 : 1, and may be drawn with the whole B scale on a slide rule. Each

*Strictly this should be called single decade.

of the "cycles" has the same linear length. Additional "cycles" may be added as desired (for examples see a.v.c. characteristics in Chapter 27).

Occasionally it is desirable to use log. ruled paper; this is ruled logarithmically on both X and Y axes. An important feature of this form of representation is that a curve of the type

$$y = ax^n$$

is shown as a straight line with a slope of n where the slope is measured as the number of "cycles" on the Y axis per "cycle" on the X axis (see Fig. 6.19B).

In plotting readings (say for a valve I_b , E_b characteristic) which are likely to follow a power law, it is often helpful to use log. paper. A straight line indicates a true power law, and its slope gives the value of the exponential—usually not an integer. A slightly curving line indicates a close approach to a power law, and a tangent or chord may be drawn to give the slope at a point or the average over a region.

(ii) Finding the equation to a curve

A method which may be used to find the equation to a curve is given by K. R. Sturley in his book "Radio Receiver Design—Part 1" (Chapman and Hall, London, 1943) pages 419-421.

(iii) Three variables

The plate current of a triode is given approximately by

$$I_b = K(\mu E_c + E_b)^{3/2}.$$

In one typical case $K = 10 \times 10^{-6}$ mhos (the perveance)

$$\text{and } \mu = 20.$$

Here there are three variables, E_c , E_b , and I_b . We can select a suitable value of E_b , calculate the curve, and then repeat the process for other values of E_b . Here E_b is called the **parameter**.

FIG. 6.20

If $E_b = 250$ volts, the plate current in milliamperes will be

$$I_b = 10^{-2} (20 \times E_c + 250)^{3/2} \text{ mA}$$

If $E_c = 0$, $I_b = 10^{-2} (0 + 250)^{3/2} = 10^{-2} (250)^{3/2} \approx 39 \text{ mA}$

$$E_c = -4, I_b = 10^{-2} (-80 + 250)^{3/2} = 10^{-2} (170)^{3/2} \approx 22 \text{ mA}$$

$$E_c = -8, I_b = 10^{-2} (-160 + 250)^{3/2} = 10^{-2} (90)^{3/2} \approx 8.5 \text{ mA}$$

$$E_c = -12, I_b = 10^{-2} (-240 + 250)^{3/2} = 10^{-2} (10)^{3/2} \approx 0.3 \text{ mA}$$

These points have been plotted in Fig. 6.20, and a curve has been drawn through them marked $E_b = 250 \text{ V}$.

Similarly, for $E_b = 150 \text{ V}$,

$$\text{If } E_c = 0, I_b = 10^{-2} (0 + 150)^{3/2} = 10^{-2} (150)^{3/2} \approx 18 \text{ mA}$$

$$E_c = -2, I_b = 10^{-2} (-40 + 150)^{3/2} = 10^{-2} (110)^{3/2} \approx 11.5 \text{ mA}$$

$$E_c = -4, I_b = 10^{-2} (-80 + 150)^{3/2} = 10^{-2} (70)^{3/2} \approx 5.8 \text{ mA}$$

$$E_c = -6, I_b = 10^{-2} (-120 + 150)^{3/2} = 10^{-2} (30)^{3/2} \approx 1.6 \text{ mA}$$

Cut off occurs at $E_c = -(150/20) = -7.5$ volts.

These points have been plotted and a smooth curve drawn through them. Similar curves could be drawn for any other plate voltage, thus forming a "family" of curves. This is actually a three-dimensional graphical diagram reduced to a form suitable for a flat surface.

(iv) Vectors and j notation

Any physical quantity which possesses both magnitude and direction is called a vector. Vectors may be represented on paper by means of straight lines with arrow-heads. The length of the line indicates (to some arbitrary scale) the magnitude of the quantity, and the direction of the line and arrow-head indicates the direction in which the vector is operating. The position of the line on the paper is of no consequence.

Addition of vectors

Vectors may be added by drawing them in tandem, and taking the resultant from the beginning of the first one to the end of the last one. Fig. 6.21A shows two vectors, \mathbf{a} and \mathbf{b} , which are added together to give the resultant \mathbf{c} . Exactly the same result is obtained by placing \mathbf{a} and \mathbf{b} together, as in Fig. 6.21B, completing the parallelogram, and taking \mathbf{c} as the diagonal. Vectors are generally printed in bold face type, to distinguish them from scalar values, which have no direction, although they have magnitude and sign (i.e. positive or negative).

FIG. 6.21

FIG. 6.22

Vector negative sign

A vector ($-\mathbf{a}$) has the same magnitude as a vector (\mathbf{a}) but its direction is reversed.

Subtraction of vectors

The vector to be subtracted is reversed in direction, and then the vectors are added.

In Fig. 6.22, to find $\mathbf{a} - \mathbf{b}$, the direction of \mathbf{b} is reversed to give $(-\mathbf{b})$ and then \mathbf{a} and $(-\mathbf{b})$ are added to give the resultant $(\mathbf{a} - \mathbf{b})$.

Multiplication of a vector by a number (n)

The resultant vector has the same direction, but its length is increased n times
e.g. $\mathbf{a} \times n = n\mathbf{a}$

FIG. 6.23

FIG. 6.24

The scalar product of two vectors

The scalar product of two vectors (\mathbf{a} and \mathbf{b} in Fig. 6.23) is $ab \cos \theta$, where θ is the angle between them. This may be written

$$\mathbf{a} \cdot \mathbf{b} = ab \cos \theta$$

where $\mathbf{a} \cdot \mathbf{b}$ indicates the multiplication of two vectors. From Fig. 6.23 it will be seen that the scalar product is the product of the magnitude of one vector and the "projection" of the other on it.

Components of a vector

Any vector can be resolved into two component vectors in any two desired directions. For example, in Fig. 6.21 the vector c can be resolved into the component vectors a and b . If the component vectors are at right angles to one another they are called rectangular components; in such a case they are usually taken horizontally (along the X axis) and vertically (along the Y axis). The vector OA in Fig. 6.24 can be resolved into two rectangular components OB and OC where

$$|OB| = |OA| \cos \theta, |OC| = |OA| \sin \theta.$$

Polar coordinates

An alternative form of defining a vector OP is

$$OP = r \angle \theta$$

where r is the magnitude of OP , and $\angle \theta$ indicates that there is an angle θ between it and OX (Fig. 6.25).

A graphical device has been described* for the conversion from complex to polar forms.

Rotating vectors** (j notation)

If a vector X (OA in Fig. 6.26) is rotated 90° in a positive direction to a position OB , the new vector is called jX , and j is described as an "operator" which rotates a vector by 90° without changing its magnitude.

If the vector jX (OB in Fig. 6.26) is operated upon by j , it will be rotated 90° to the position OC , where it is called j^2X , the j^2 indicating that it has been rotated $2 \times 90^\circ = 180^\circ$ from its original position OA .

If the vector j^2X (OC in Fig. 6.26) is operated upon by j , it will be rotated 90° to the position OD , where it is called j^3X , the j^3 indicating that it has been rotated $3 \times 90^\circ = 270^\circ$ from its original position OA .

If the vector j^3X (OD in Fig. 6.26) is operated upon by j , it will be rotated 90° to the position OA where it would be called j^4X , the j^4 indicating that it has been rotated $4 \times 90^\circ = 360^\circ$ from its original position OA .

There is an important deduction which is immediately obvious. j^2 indicates a reversal of direction which is the same as a change of sign. The operator j^2 is therefore equivalent to multiplication by -1 .

If the operator j^2 is applied twice in succession, the result should be equivalent to multiplication by -1 twice in succession, i.e. $(-1) \times (-1) = +1$. This is so, because the operator j^4 brings the vector back to its original direction.

Since the operator j^2 is equivalent to multiplication by -1 , we may deduce that the operator j is equivalent to multiplication by $\sqrt{-1}$, even though this in itself does not mean anything.

FIG 6.26

Operator	Equivalent to multiplication by
j	$\sqrt{-1}$
j^2	-1
j^3	$-\sqrt{-1}$
j^4	$+1$
$-j$	$-\sqrt{-1}$ (same as operator j^3)

*Snowdon, C. "A vector calculating device," Electronic Eng. 17.199 (Sept. 1944) 146.

**Also called "radius vectors." In pure mathematics " i " is used in place of " j ."

Operator

$$\frac{1}{j}$$

$$\frac{1}{-j} = -\frac{1}{j}$$

Equivalent to multiplication by

$$-\sqrt{-1} \quad (\text{same as operator } -j)$$

$$\sqrt{-1} \quad (\text{same as operator } j)$$

See Chapter 4 Sects. 4(v), 5(v) and 6 for the application of the j notation to a.c. circuits.

The direction of any vector can be defined in terms of the j notation. In Fig. 6.25, OX represents the axis of reference, OP the vector, and θ the angle of rotation of OP from OX. The perpendicular PA may be drawn from P to OX and then, by the simple theory of vectors, OP is the sum of the vectors OA and AP. Using j notation, we may say that

$$\mathbf{OP} = a + jb$$

which means that the vector OP is the vector sum of a and b , where a is in the direction of the reference axis OX and b is rotated 90° from OX. In other words, a is the component of OP in the direction OX, and b is the component of OP in the direction OY. The values of a and b are given by

$$a = \text{OP} \cos \theta, \quad b = \text{OP} \sin \theta,$$

$$\text{where } \theta = \tan^{-1} b/a.$$

This is sometimes called the Argand Diagram.

In electrical a.c. circuit theory (Chapter 4) it is well known that the current through an inductance lags behind the applied voltage, while the current through a capacitance leads the voltage. This is most clearly shown by rotating vectors. It should be borne in mind that all the vectors are rotating at the same angular velocity—one revolution per cycle of the applied voltage—and that the pictorial representation is for any one instant. Fig. 6.27 shows the vector diagram for peak a.c. current (I) flowing through a resistance (R) and an inductance (L) in series. The current vector (I) may be placed in any convenient direction—say horizontally (Fig. 6.27); a solid arrow head is used to distinguish it from voltage vectors. The peak voltage drop (\mathbf{RI}) in the resistance must be “in phase” with the current, and is so shown. The scale to which the voltage vectors are drawn has no connection with the scale to which the current (I) is drawn—in fact we are here, only concerned with the direction of I . The peak voltage drop across L is $\omega L I = X_L I$, and this vector is drawn vertically so as to lead the current I by 90° . The total peak voltage drop (\mathbf{E}) is found by “completing the parallelogram of vectors” as previously. It will be seen that I lags behind \mathbf{E} by the angle θ .

A similar procedure applies with a capacitance instead of an inductance (Fig. 6.28) except that the capacitive reactance is X_C instead of X_L and the vector of peak voltage drop across C ($\mathbf{X}_C I$) is drawn vertically downwards, since it must be opposite to $\mathbf{X}_L I$. The current (I) here leads the voltage (\mathbf{E}) by the angle θ .

SECTION 6: COMPLEX ALGEBRA AND DE MOIVRE'S THEOREM

(i) *Complex algebra with rectangular coordinates* (ii) *Complex algebra with polar coordinates* (iii) *De Moivre's Theorem.*

(i) Complex algebra with rectangular coordinates

Complex algebra should preferably be called "the algebra of complex quantities," and it is really quite simple to understand for anyone who has even a limited knowledge of mathematics.

It was explained in Section 5 that the letter j^* in front of a vector indicated that it had been rotated 90° from the reference, or positive X , axis (Fig. 6.29). We can make use of this procedure to indicate the magnitude and direction of any vector. In Fig. 6.30 the vector OP , with magnitude 5, has been resolved into the rectangular components—

$OA = 4$ in the $+X$ direction

and $AP = 3$ in the jX direction (90° to X).

The X axis is taken horizontally through O , and is sometimes called the "real" axis, while the jX direction is called "imaginary." It is therefore possible to describe OP in both magnitude and direction by the expression $4 + j3$.

Its magnitude is the vector sum of 4 and 3, which is $\sqrt{4^2 + 3^2} = \sqrt{25} = 5$. Its direction is given by the angle θ from the X axis, where $\cos \theta = 4/5$.

Any other vector, such as a in Fig. 6.31, can similarly be resolved into its components:

$b = a \cos \theta$ in the X direction
and $c = a \sin \theta$ in the jX direction

and be written as

$b + jc$
 $b = a \cos \theta$
and $c = a \sin \theta$.

where

The expression $b + jc$ is called a complex quantity, the word "complex" indicating that the addition is not to be made algebraically, but by vector addition.

This use of a complex quantity such as $b + jc$ is not limited to true vectors, but is found useful in many applications in electrical engineering. Its application to alternating currents is covered in Chapter 4, and the following treatment is a general introduction to the methods of handling complex quantities.

Modulus

The modulus is the magnitude of the original vector (a in Fig. 6.31) and is numerically equal to the square root of the sum of the squares of the magnitudes of the two components,

$$|a| = \sqrt{b^2 + c^2} \quad (1)$$

Addition and subtraction of complex quantities

The primary rule is to place all "real" numbers together in one group and all "imaginary" numbers in another. These two groups must be kept entirely separate and distinct throughout. The final form should be

$$(\dots) + j(\dots).$$

*Or i in pure mathematics.

Example : Add $A + jB$, $C + jD$, $E - jF$.

$$\begin{aligned}\text{Total is } & A + C + E + jB + jD - jF \\ &= (A + C + E) + j(B + D - F).\end{aligned}$$

Multiplication of complex quantities

The multiplication is performed in accordance with normal algebraic laws for real numbers, j^2 being treated as -1 .

$$\begin{aligned}(x_1 + jy_1)(x_2 + jy_2) &= x_1x_2 + jy_1x_2 + jy_2x_1 + j^2y_1y_2 \\ &= (x_1x_2 - y_1y_2) + j(x_1y_2 + x_2y_1)\end{aligned}\quad (2)$$

Division of complex quantities

The denominator should be made a real number by multiplying both the numerator and the denominator by the conjugate of the denominator (i.e. the denominator with the opposite sign in front of the j term).

$$\begin{aligned}\frac{x_1 + jy_1}{x_2 + jy_2} &= \frac{(x_1 + jy_1)(x_2 - jy_2)}{(x_2 + jy_2)(x_2 - jy_2)} = \frac{x_1x_2 + jy_1x_2 - jx_1y_2 + y_1y_2}{x_2^2 + y_2^2} \\ &= \left(\frac{x_1x_2 + y_1y_2}{x_2^2 + y_2^2}\right) - j\left(\frac{x_1y_2 - y_1x_2}{x_2^2 + y_2^2}\right)\end{aligned}\quad (3)$$

Similarly

$$\frac{1}{x + jy} = \frac{(1)(x - jy)}{(x + jy)(x - jy)} = \left(\frac{x}{x^2 + y^2}\right) - j\left(\frac{y}{x^2 + y^2}\right)\quad (4)$$

Square root of complex quantities

To find the square root of $(a + jb)$, assume that the square root is $(x + jy)$ and then proceed to find x and y .

$$(x + jy)^2 = (x + jy)(x + jy) = x^2 - y^2 + 2jxy$$

$$\text{Therefore } a + jb = (x^2 - y^2) + 2jxy = (x^2 - y^2) + j(2xy)$$

$$\text{Therefore } (x^2 - y^2) = a$$

$$\text{and } 2xy = b.$$

$$\text{Modulus } = r = \sqrt{a^2 + b^2}$$

$$\text{Square of modulus of } (x + jy) = x^2 + y^2$$

$$\text{Therefore } x^2 + y^2 = r$$

$$\text{But } x^2 - y^2 = a \text{ (see above)}$$

$$\text{Therefore } x^2 = \frac{1}{2}(r + a) \text{ and } y^2 = \frac{1}{2}(r - a)$$

$$\text{Therefore } x = \pm \sqrt{\frac{1}{2}(r + a)} \text{ and } y = \pm \sqrt{\frac{1}{2}(r - a)}\quad (5)$$

The signs should be checked to see which are applicable

(ii) Complex algebra with polar coordinates

In complex numbers we can write (Fig. 6.31)

$$a = b + jc$$

$$\text{but } b = |a| \cos \theta$$

$$\text{and } c = |a| \sin \theta$$

$$\text{Therefore } a = |a| \cos \theta + j |a| \sin \theta$$

$$\text{Therefore } a = |a| (\cos \theta + j \sin \theta)\quad (6)$$

Here $|a|$ is the magnitude of the vector and $(\cos \theta + j \sin \theta)$ may be called the **trigonometrical operator** which rotates the vector through the angle θ in a positive (counter-clockwise) direction from the x axis.

As explained in Sect. 5(iv), a vector may be defined by

$$r \angle \theta$$

where r is the magnitude and $\angle \theta$ the angle between the vector and the reference axis. It will therefore be seen that the trigonometrical operator $(\cos \theta + j \sin \theta)$ is effectively the same as $\angle \theta$ with polar coordinates.

$$\text{i.e. } \angle \theta = \cos \theta + j \sin \theta\quad (7)$$

Pure mathematical polar form

By the use of the Exponential Series we can express e^z in the form (Sect. 2, eqn. 87)

$$e^z = 1 + z + \frac{z^2}{2!} + \frac{z^3}{3!} + \frac{z^4}{4!} + \dots$$

Putting $j\theta$ for x we obtain

$$\begin{aligned} e^{j\theta} &= 1 + j\theta + \frac{(j\theta)^2}{2!} + \frac{(j\theta)^3}{3!} + \frac{(j\theta)^4}{4!} + \frac{(j\theta)^5}{5!} + \dots \\ &= 1 + j\theta - \frac{\theta^2}{2!} - j\frac{\theta^3}{3!} + \frac{\theta^4}{4!} + j\frac{\theta^5}{5!} - \dots \end{aligned}$$

Grouping the j terms,

$$e^{j\theta} = (1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \dots) + j(\theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \dots)$$

$$\text{But } \cos \theta = 1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \dots \text{ from eqn. (17) below}$$

$$\text{and } \sin \theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \dots \text{ from eqn. (18) below.}$$

$$\text{Therefore } e^{j\theta} = \cos \theta + j \sin \theta \quad (8)$$

Thus the pure mathematical polar form is

$$|a| e^{j\theta}$$

and is called the Exponential Form.

The vector can thus be written in the various forms

$$a = b + jc \quad (9)$$

$$a = |a| \angle \theta \quad (10)$$

$$a = |a| e^{j\theta} \quad (11)$$

$$a = |a| (\cos \theta + j \sin \theta) \quad (12)$$

$$a = |a| \cos \theta + j|a| \sin \theta \quad (13)$$

A graphical method for converting from the complex form $(b + jc)$ to the polar form and vice versa has been described.* It will therefore be seen that there is a connection with the operator j :

$$\left. \begin{array}{l} j \text{ turns a vector through a right angle} \\ (\cos \theta + j \sin \theta) \\ \text{or } e^{j\theta} \end{array} \right\} \text{turns a vector through an angle } \theta.$$

Addition and subtraction in polar form

Addition and subtraction may be done either graphically, or by expressing each in rectangular components and proceeding as for rectangular coordinates.

Multiplication of polar vectors

The product is found by multiplying their magnitudes and adding their angles.

Division of polar vectors

The quotient is found by dividing their magnitudes and subtracting the angle of the divisor from the angle of the dividend.

Square root of polar vectors

The root is found by taking the square root of the magnitude and half the angle.

(iii) De Moivre's Theorem

De Moivre's Theorem states that

$$(\cos \theta + j \sin \theta)^n = \cos n\theta + j \sin n\theta \quad (14)$$

where n may be positive or negative, fractional or integral.

It was explained in (ii) above that $(\cos \theta + j \sin \theta)$ may be regarded as a trigonometrical operator which rotates the vector through an angle θ . If this is applied twice in succession, the trigonometrical operator becomes

$$(\cos \theta + j \sin \theta)(\cos \theta + j \sin \theta) = (\cos \theta + j \sin \theta)^2$$

giving a total rotation of an angle 2θ .

Similarly if this is applied three times in succession, the trigonometrical operator becomes

$$(\cos \theta + j \sin \theta)(\cos \theta + j \sin \theta)(\cos \theta + j \sin \theta) = (\cos \theta + j \sin \theta)^3$$

giving a total rotation of an angle 3θ .

*Snowdon, C. "A vector calculating device" *Electronic Eng.* 17.199 (Sept. 1944) 146.

Thus, in the general case, the trigonometrical operator $(\cos \theta + j \sin \theta)^n$ gives a rotation of an angle $n\theta$ which, as explained above, is equivalent to a trigonometrical operator

$$(\cos n\theta + j \sin n\theta).$$

We have, in this way, proved De Moivre's Theorem for the case when n is a positive integer, and indicated the significance of the Theorem.

Application of De Moivre's Theorem :

1. To express $\cos n\theta$ and $\sin n\theta$ in terms of $\cos \theta$ and $\sin \theta$, where n is a positive integer.

$$\begin{aligned} \cos n\theta + j \sin n\theta &= (\cos \theta + j \sin \theta)^n \\ &= \cos^n \theta + nj \cos^{n-1} \theta \cdot \sin \theta + \frac{n(n-1)}{2} j^2 \cos^{n-2} \theta \cdot \sin^2 \theta + \dots \end{aligned}$$

(as in Sect. 2, eqn. 83).

Then equate the real and imaginary parts of the equation, giving

$$\cos n\theta = \cos^n \theta - \frac{n(n-1)}{2} \cos^{n-2} \theta \cdot \sin^2 \theta + \frac{n(n-1)(n-2)(n-3)}{4!} \cos^{n-4} \theta \cdot \sin^4 \theta + \dots \quad (15)$$

$$\begin{aligned} \sin n\theta &= n \cos^{n-1} \theta \cdot \sin \theta - \frac{n(n-1)(n-2)}{3!} \cos^{n-3} \theta \cdot \sin^3 \theta + \\ &\quad \frac{n(n-1)(n-2)(n-3)(n-4)}{5!} \cos^{n-5} \theta \cdot \sin^5 \theta + \dots \end{aligned} \quad (16)$$

2. To express $\cos \theta$ and $\sin \theta$ in terms of θ , write θ in the form $n(\theta/n)$ and expand the sine and cosine as in eqns. (15) and (16). When n becomes large, $\cos(\theta/n)$ may be taken as unity and $\sin(\theta/n)$ as (θ/n) itself. In the limit as n tends to infinity it can then be shown that

$$\cos \theta = 1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \frac{\theta^6}{6!} + \dots \quad (17)$$

$$\sin \theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \frac{\theta^7}{7!} + \dots \quad (18)$$

where θ is expressed in radians.

3. To express $\sin \theta$ and $\cos \theta$ in terms of $e^{j\theta}$.

By substituting $j\theta$ in place of x in the Exponential Series (Sect. 2, eqn. 87), and by using the relationship

$$e^{j\theta} = \cos \theta + j \sin \theta$$

and equations (17) and (18) we may obtain

$$\sin \theta = \frac{e^{j\theta} - e^{-j\theta}}{2j} \quad (19)$$

$$\text{and } \cos \theta = \frac{e^{j\theta} + e^{-j\theta}}{2} \quad (20)$$

SECTION 7: DIFFERENTIAL AND INTEGRAL CALCULUS

(i) *Slope and rate of change* (ii) *Differentiation* (iii) *Integration* (iv) *Taylor's Series* (v) *Maclaurin's Series*.

(i) Slope and rate of change

The **slope** of any straight line is the ratio of the lengths of the vertical and horizontal projections of any segment of the line. In Fig. 6.32 the line QP has its vertical projection MN and horizontal projection AB; its slope is therefore MN/AB. Its slope could equally well be based on the projections of its segment CP, and its slope BP/CB. In both cases the result is the same, and is equal to the tangent of the angle of inclination which the line makes with the horizontal axis—

$$\text{slope} = \text{MN/AB} = \text{BP/CB} = \tan \theta.$$

The lengths of the projections must be measured in terms of the scales to which the line is drawn. Thus horizontal projections such as CB must be measured, not in inches, but in the equivalent number of units corresponding to the length CB on the X axis. Similarly with the vertical projections on the Y axis, which usually has quite a different scale from that for the X axis.

If the line QP in Fig. 6.32 is rotated approximately 90° in the counter-clockwise direction, the result will be as shown in Fig. 6.32A, the angle θ being more than 90° . The vertical projection is RS and the horizontal projection is DE. The slope is therefore RS/DE or OF/GO, the latter applying to the segment FG. It is important in all this work to consider the directions as well as the magnitudes of the lines: OF is in a positive direction but GO is in a negative direction. We can therefore replace GO by $-OG$; the slope of QP will then be given by $-(OF/OG)$ which is described as a negative slope. The loadlines on valve plate characteristics are examples of lines with negative slope (e.g. Fig. 2.22).

When a line is curved, its slope varies from point to point. The slope at any point is given by the slope of the tangent at that point. In Fig. 6.33 the curve is QPR, and the slope at P is given by BP/CB or $\tan \theta$.

Rate of change

One of the most important relationships between the variables in any law, formula or equation is the rate of change of the whole function with its independent variable.

Definition

The rate of change is the amount of change in the function, per unit change in the value of the independent variable. The rate of change of the function is therefore the ratio of change in the function to the change in the variable which produces it.

Consider the equation for a straight line

$$y = ax + b$$

where a and b are constants. Let us take two values of x , one equal to x_1 and the other ($x_1 + \Delta x$), where Δx is a small increment of x .

$$\text{Point 1: } x = x_1 \quad \therefore y_1 = ax_1 + b \quad (1)$$

$$\text{Point 2: } x = (x_1 + \Delta x) \quad \therefore y_2 = a(x_1 + \Delta x) + b \quad (2)$$

$$\text{Subtracting (1) from (2),} \quad (y_2 - y_1) = a \Delta x$$

$$\text{Putting } (y_2 - y_1) = \Delta y, \quad \Delta y = a \Delta x$$

$$\text{Dividing both sides by } \Delta x, \quad \frac{\Delta y}{\Delta x} = a \quad (3)$$

Here Δy is the amount of change in the function for a change Δx in the independent variable. The "rate of change" is defined as the amount of change in the function per unit change in the independent variable, that is

$$\text{rate of change} = \Delta y / \Delta x \quad (4)$$

Referring to Fig. 6.34, we have a graph of $y = ax + b$ which is, of course, a straight line cutting the Y axis at a height b above the origin. The first point (x_1, y_1) is at P , and the second point ($x_1 + \Delta x, y_1 + \Delta y$) is at Q . In the preceding argument we found that $\Delta y / \Delta x = a$. In Fig. 6.34 $\Delta x = PR$ and $\Delta y = RQ$, so that $\Delta y / \Delta x = RQ / PR$, which is the slope of the line $y = ax + b$. Thus

$$\text{slope} = \frac{RQ}{PR} = \frac{\Delta y}{\Delta x} = a \quad (5)$$

Equations (4) and (5) prove that **the rate of change is the same as the slope for a straight line.**

We now proceed to consider the general case when the function is not linear. In Fig. 6.35 there is plotted a function which may be of the form

$$y = ax^2 + bx + c$$

where a, b and c are constants. As before, the independent variable (x) is plotted horizontally, while the dependent variable (y) is plotted vertically. The vertical coordinate of any point P (i.e. AP in Fig. 6.35) represents, to its proper scale, the value of $ax^2 + bx + c$ which is a function of x , while the horizontal coordinate (OA) represents, to its own scale, the value of x .

As with the simpler case of the straight line, take a second point (Q) with its x coordinate increased by Δx . Also, as before, call the increment in the y coordinate Δy . It will therefore be seen that, commencing at point P , an increment ($\Delta x = PC$) in the value of x results in an increment ($\Delta y = CQ$) in the value of y .

The **average rate of change** over this increment is, as before, $\Delta y / \Delta x$ which is the slope of the chord PQ and the tangent of the angle θ_2 which PQ makes with the horizontal. If now, leaving point P unchanged, we gradually move Q along the curve

towards P we will see that, as Q approaches P, θ_2 approaches θ_1 until in the limiting case the slope of the chord approaches the slope of the tangent (PT). The tangent to a curve at any point shows the instantaneous slope of the curve at that point and therefore the instantaneous rate of increase of the function at that point.

(ii) Differentiation

We may express the foregoing argument in the mathematical form of limits—

$$\lim_{\Delta x \rightarrow 0} (\Delta y / \Delta x) = \tan \theta_1 \quad (6)$$

which says that the limit (as Δx is made smaller and approaches zero) of $\Delta y / \Delta x$ is $\tan \theta_1$ or the slope of the tangent PT, which is the instantaneous rate of increase at point P.

This is given the symbol dy/dx which is “the **differential coefficient** (or derivative) of y with regard to x ,” and is spoken of as “dee y by dee x .”

It should be noted that dy/dx is a single symbol, not a fraction, and is merely a short way of writing

$$\lim_{\Delta x \rightarrow 0} (\Delta y / \Delta x).$$

Differentiation is the process of finding the differential coefficient (or derivative). Some examples are given below and in each case the result may be obtained by considering the increase in the function which results from an increase Δx in the independent variable.

Note : u and v are functions of x ; a , b and c are constants.

1. Derivative of a constant [$y = c$] $dy/dx = 0$ (7)

2. Derivative of a variable with respect to itself
[$y = x$] : $dy/dx = dx/dx = 1$ (8)

3. Derivative of a variable multiplied by a constant
[$y = cx$] : $dy/dx = c$ (9)

4. Derivative of powers of a variable
[$y = x^2$] : $dy/dx = 2x$ (10)

$$[y = x^3] : dy/dx = 3x^2 \quad (11)$$

$$[y = x^4] : dy/dx = 4x^3 \quad (12)$$

$$[y = x^n] : dy/dx = nx^{n-1} \quad (13)$$

This applies for n negative as well as positive.

5. Derivative of a constant times a function of a variable
[$y = cx^2$] : $dy/dx = 2cx$ (14)

$$[y = c.u] : dy/dx = c.du/dx \quad (15)$$

6. Derivative of fractional powers of a variable
[$y = x^{\frac{1}{2}}$] : $dy/dx = \frac{1}{2}x^{-\frac{1}{2}}$ (16)

$$[y = x^{1/n}] : dy/dx = (1/n)x^{(1/n)-1} \quad (17)$$

7. Derivative of a sum or difference
[$y = u \pm v$] : $dy/dx = du/dx \pm dv/dx$ (18)

$$[y = ax^3 + bx^2 - cx] : dy/dx = 3ax^2 + 2bx - c \quad (19)$$

8. Derivative of a product of two functions
[$y = u.v$] : $dy/dx = u \frac{dv}{dx} + v \frac{du}{dx}$ (20)

$$[y = (x + 1)x^2] : dy/dx = (x + 1).2x + x^2.1 = 3x^2 + 2x \quad (21)$$

9. Derivative of a quotient of two functions
[$y = u/v$] : $\frac{dy}{dx} = \frac{v \frac{du}{dx} - u \frac{dv}{dx}}{v^2}$ (22)

10. Differentiation of a function of a function
[$y = F(u)$ where $u = F(x)$] : $\frac{dy}{dx} = \frac{dy}{du} \cdot \frac{du}{dx}$ (23)

$$[y = u^2 \text{ where } u = ax^2 + b] : dy/dx = 2(ax^2 + b)(2ax) \quad (24)$$

11.	$[y = e^x]:$	$dy/dx = e^x$	(25)
	$[y = a.e^{mx}]:$	$dy/dx = a.m.e^{mx}$	(26)
	$[y = e^u]:$	$dy/dx = e^u \cdot du/dx$	(27)
12.	$[y = \log_e x]:$	$dy/dx = 1/x$	(28)
	$[y = \log_e u]:$	$dy/dx = (1/u)(du/dx)$	(29)
	$[y = \log_{10} u]:$	$dy/dx = (1/u)(du/dx) \log_{10} e$	(30)
		$= (0.4343)(1/u)(du/dx)$	(31)
13.	$[y = \sin x]:$	$dy/dx = \cos x$	(32)
	$[y = \cos x]:$	$dy/dx = -\sin x$	(33)
	$[y = \tan x]:$	$dy/dx = \sec^2 x$	(34)
	$[y = \cot x]:$	$dy/dx = -\operatorname{cosec}^2 x$	(35)
	$[y = \sec x]:$	$dy/dx = \sec x \cdot \tan x$	(36)
	$[y = \operatorname{cosec} x]:$	$dy/dx = -\operatorname{cosec} x \cdot \cot x$	(37)
14.	$[y = \sin^{-1} x]:$	$dy/dx = 1/\sqrt{1-x^2}^\dagger$	(38)
	$[y = \cos^{-1} x]:$	$dy/dx = -1/\sqrt{1-x^2}^\ddagger$	*(39)
	$[y = \tan^{-1} x]:$	$dy/dx = 1/(1+x^2)^\dagger$	(40)
15.	$[y = \sinh x]:$	$dy/dx = \cosh x$	(41)
	$[y = \cosh x]:$	$dy/dx = \sinh x$	(42)
	$[y = \tanh x]:$	$dy/dx = \operatorname{sech}^2 x$	(43)

Successive differentiation

If y is a function of x , then dy/dx will also be a function of x and can therefore be differentiated with respect to x , giving

$$\frac{d}{dx}\left(\frac{dy}{dx}\right) \text{ which is written as } \frac{d^2y}{dx^2}$$

and spoken of as “dee two y by dee x squared.” Here again this is only a symbol which must be handled in accordance with its true meaning. The same procedure may be applied again and again.

Example: $y = x^n \dots \dots \dots$ function $F(x)$

$$\frac{dy}{dx} = nx^{n-1} \dots \dots \dots \text{derivative } F'(x)$$

$$\frac{d^2y}{dx^2} = n(n-1)x^{n-2} \dots \dots \dots \text{second derivative } F''(x)$$

$$\frac{d^3y}{dx^3} = n(n-1)(n-2)x^{n-3} \dots \dots \dots \text{third derivative } F'''(x)$$

Application of differentiation

The plate current versus grid voltage characteristic of a triode valve (for constant plate voltage) is a function of the grid voltage, and follows approximately the law

$$I_p = K(\mu E_g + E_p)^{3/2}$$

where K , μ and E_p are constants. The derivative with regard to E_g is dI_p/dE_g , which is the mutual conductance. The second derivative is the rate of change of the mutual conductance with regard to E_g , and is useful when we want to find the conditions for maximum or minimum mutual conductance.

In Fig. 6.36 there is a curve with a **maximum** at point M and a **minimum** at point N. It will be seen that the instantaneous slope of the curve at both points M and N is zero, that is $dy/dx = 0$.

Part of curve:	P to M	M	M to N	N	N to Q
Slope (dy/dx):	+ve	O	-ve	O	+ve

d^2y/dx^2 :	-ve		+ve	
---------------	-----	--	-----	--

A maximum is indicated by: $\begin{cases} dy/dx = 0 \\ d^2y/dx^2 \text{ negative} \end{cases}$

A minimum is indicated by: $\begin{cases} dy/dx = 0 \\ d^2y/dx^2 \text{ positive} \end{cases}$

† x measured in radians.

*Positive sign if $\sin^{-1} x$ lies in first or fourth quadrant, negative sign if $\sin^{-1} x$ lies in second or third quadrant.

‡ Negative sign if $\cos^{-1} x$ lies in first or second quadrant, positive sign if $\cos^{-1} x$ lies in third or fourth quadrant.

A point of inflection* is indicated by :

$$d^2y/dx^2 = 0$$

Curve concave upwards indicated by : d^2y/dx^2 positive

Curve concave downwards indicated by : d^2y/dx^2 negative

Examples

(1) To find the maximum value of

$$y = 2x - x^2 + 4$$

$$dy/dx = 2 - 2x$$

For a maximum $dy/dx = 0$, therefore $2 - 2x = 0$, and $x = 1$.

This is the value of x at which a maximum, or a minimum, or a point of inflection occurs.

To see which it is, take the second derivative—

$$d^2y/dx^2 = -2 \text{ which is negative.}$$

Therefore the point is a maximum.

To find the value of y at this point, put the value

$$(x = 1) \text{ into } y = 2x - x^2 + 4.$$

$$\text{Therefore } y = 2 - 1 + 4 = 5.$$

(2) To find the points of inflection in the curve

$$y = x^4 - 6x^2 - x + 16.$$

$$dy/dx = 4x^3 - 12x - 1$$

$$d^2y/dx^2 = 12x^2 - 12.$$

For points of inflection, $d^2y/dx^2 = 0$, therefore $12x^2 - 12 = 0$

$$\text{Therefore } 12x^2 = 12, \text{ Thus } x = \pm 1.$$

There are thus two points of inflection, one at $x = +1$, the other at -1 . The values of y at these points are given by substituting these values of x in the function :

$$x = +1 : y = 1 - 6 - 1 + 16 = +10.$$

$$x = -1 : y = 1 - 6 + 1 + 16 = +12.$$

It is always wise to make a rough plot of the curve to see its general shape. Some curves have more than one value of maximum and minimum.

Partial differentiation

Partial differential coefficients, designated in the form $\partial y/\partial x$ (the symbol ∂ may be pronounced "der" to distinguish from "d" in dy/dx) are used in considering the relationship between two of the variables in systems of more than two variables such as the volume of an enclosure having rectangular faces, the sides being of length x , y and z respectively :

$$v = x y z \quad (44)$$

Thus, the rate of change of volume with the change in length of the side x , while the sides y and z remain constant, is

$$\partial v/\partial x = y z \quad (45)$$

Similarly $\partial v/\partial y = z x$, where z and x are constant

$$\text{And } \partial v/\partial z = xy \text{ where } x \text{ and } y \text{ are constant} \quad (46)$$

In three-dimensional differential geometry, the equation representing a surface may be represented generally in the form

$$y = F(x, z) \quad (48)$$

In this case, the partial differential coefficient $\partial y/\partial x$ represents the slope at the point (x, y, z) of the tangent to the curve of intersection of the surface with a plane parallel to the plane passing through the x and y axes and separated by a fixed distance z from the latter.

Thus $\partial y/\partial x$ represents the slope of a tangent to a cross section of a three-dimensional solid, the partial derivative reducing the three-dimensional body to a form suitable for two-dimensional consideration. " $\partial y/\partial x$ " is equivalent to " dy/dx (z constant)" when there are three variables, x , y and z .

*A point of inflection is one at which the curvature changes from one direction to the other (e.g. S in Fig. 6.36). It is necessarily a point of maximum or minimum slope.

Partial differentials are therefore particularly valuable in representing Valve Coefficients [see Chapter 2 Sect. 9(ix)].

Total differentiation

When there are three independent variables (x, y, z) which are varying simultaneously but independently of each other,

$$u = F(x, y, z) \quad (49)$$

the total differential is

$$du = \frac{\partial u}{\partial x} dx + \frac{\partial u}{\partial y} dy + \frac{\partial u}{\partial z} dz \quad (50)$$

and similarly for two, or any larger number of independent variables.

When the independent variables are functions of a single independent variable (t) the total differential with respect to t is

$$\frac{du}{dt} = \frac{\partial u}{\partial x} \cdot \frac{dx}{dt} + \frac{\partial u}{\partial y} \cdot \frac{dy}{dt} + \frac{\partial u}{\partial z} \cdot \frac{dz}{dt} \quad (51)$$

(iii) Integration

Integration is merely the inverse of differentiation. For example—

$$\text{Differentiation—} \frac{d}{dx}(4x^3 + 2) = 12x^2$$

$$\text{Integration—} \int 12x^2 dx = 4x^3 + C$$

The sign \int (called “integral”) before a quantity indicates that the operation of integration is to be performed on the expression which follows.

The dx which follows the expression is merely a short way of writing “with respect to x .” Just as the constant 2, in the function above, disappeared during the process of differentiation, so it is necessary to replace it in the inverse procedure of integration. But when we are given the integral alone, we do not know what was the value of the constant, so we add an unknown constant C , the value of which may be determined in some cases from other information available.

Useful rules for integrals

$a, b, c = \text{constants}$; $C = \text{constant of integration}$; u and v are functions of x .

$$1. \int a.F(x) dx = a \int F(x) dx; \int a dx = ax + C \quad (52)$$

$$2. \int (u \pm v) dx = \int u dx \pm \int v dx \text{ (similarly for more than two)} \quad (53)$$

$$3. \int x^n dx = \frac{1}{n+1} x^{n+1} + C \quad (n \neq -1) \quad (54)$$

$$4. \int a^x dx = (a^x / \log_e a) + C \quad (55)$$

$$5. \int e^x dx = e^x + C; \int e^{ax} dx = (1/a) e^{ax} + C \quad (56)$$

$$\int x e^x dx = e^x(x-1) + C; \int x^m e^x dx = x^m e^x - m \int x^{m-1} e^x dx + C^* \quad (57)$$

$$6. \int u \frac{dv}{dx} dx = uv - \int v \frac{du}{dx} dx \text{ (integration by parts)} \quad (58)$$

$$7. \int \frac{dx}{x} = \int \frac{1}{x} dx = \log_e x + C = \log_e c x \quad (59)$$

$$8. \int a^x \log_e a dx = a^x + C; \int \log_a x dx = x \log_a (x/e) + C \quad (60)$$

$$9. \int (ax+b)^n dx = \frac{(ax+b)^{n+1}}{a(n+1)} + C \quad (n \neq -1) \quad (61)$$

* $m > 0$.

$$10. \int \frac{dx}{ax+b} = \int \frac{1}{ax+b} dx = (1/a) \log_e(ax+b) + C \quad (62)$$

$$11. \int \frac{x dx}{ax+b} = \int \frac{x}{ax+b} dx = (1/a^2) [ax+b - b \log_e(ax+b)] + C \quad (63)$$

$$12. \int \frac{x dx}{(ax+b)^2} = \int \frac{x}{(ax+b)^2} dx = \frac{1}{a^2} \left[\frac{b}{ax+b} + \log_e(ax+b) \right] + C \quad (64)$$

$$13. \int \frac{x^2 dx}{ax+b} = \int \frac{x^2}{ax+b} dx = \frac{1}{a^3} \left[\frac{(ax+b)^2}{2} - 2b(ax+b) + b^2 \log_e(ax+b) \right] + C \quad (65)$$

$$14. \int \frac{dx}{x^2+a^2} = \int \frac{1}{x^2+a^2} dx = \frac{1}{a} \tan^{-1} \frac{x}{a} + C = -\frac{1}{a} \cot^{-1} \frac{x}{a} + C \quad (66)$$

$$15. \int \frac{dx}{x^2-a^2} = \int \frac{1}{x^2-a^2} dx = \frac{1}{2a} \log \frac{x-a}{x+a} + C = \frac{1}{2a} \log_e \frac{a-x}{a+x} + C \quad (67)$$

$$16. \int \frac{dx}{\sqrt{a^2-x^2}} = \int \frac{1}{\sqrt{a^2-x^2}} dx = \sin^{-1}(x/a) + C = -\cos^{-1}(x/a) + C \quad (68)$$

$$17. \int \frac{dx}{\sqrt{x^2 \pm a^2}} = \int \frac{1}{\sqrt{x^2 \pm a^2}} dx = \log_e(x + \sqrt{x^2 \pm a^2}) + C \quad (69)$$

$$18. \int \sin ax dx = -(1/a) \cos ax + C \quad (70)$$

$$19. \int \cos ax dx = (1/a) \sin ax + C \quad (71)$$

$$20. \int \tan ax dx = -(1/a) \log_e \cos ax + C = (1/a) \log_e \sec ax + C \quad (72)$$

$$21. \int \operatorname{cosec} ax dx = (1/a) \log_e (\operatorname{cosec} ax - \cot ax) + C \quad (73)$$

$$= (1/a) \log_e \tan(ax/2) + C \quad (74)$$

$$22. \int \sec ax dx = (1/a) \log_e (\sec ax + \tan ax) + C \quad (75)$$

$$= (1/a) \log_e \tan[(ax/2) + \pi/4] + C \quad (76)$$

$$23. \int \cot ax dx = (1/a) \log_e \sin ax + C = -(1/a) \log_e \operatorname{cosec} ax + C \quad (77)$$

$$24. \int \sin^2 ax dx = x/2 - (1/2a) \sin ax \cos ax + C \quad (78)$$

$$= x/2 - (1/4a) \sin 2ax + C \quad (79)$$

$$25. \int \cos^2 ax dx = x/2 + (1/4a) \sin 2ax + C \quad (80)$$

$$26. \int \sinh x dx = \cosh x \quad (81)$$

$$27. \int \cosh x dx = \sinh x \quad (82)$$

Rules to assist integration

1. If the function is the sum of several terms, or can be put into this form, integrate term by term.
2. If the function is in the form of a product or a power, it is usually helpful to multiply out or expand before integrating.
3. Fractions may be either divided out, or written as negative powers.
4. Roots should be treated as fractional powers.
5. A function of x may be replaced by u , and then

$$\int F(x) dx = \int F(x) \frac{dx}{du} du.$$

Areas by integration

If the area under a given portion of a curve is A (Fig. 6.37), then a small increase Δx on the horizontal axis causes an increase ΔA in area, where

$$\Delta A = \Delta x(y + \frac{1}{2}\Delta y).$$

As Δx and Δy are made smaller, in the limiting case as Δx approaches zero, the value of $(y + \frac{1}{2}\Delta y)$ approaches y ,

i.e.

$$\lim_{\Delta x \rightarrow 0} \left[\frac{\Delta A}{\Delta x} \right] = y$$

$$\text{Therefore } \frac{dA}{dx} = y = F(x)$$

$$\text{Therefore } dA = y \cdot dx = F(x) \, dx$$

$$\text{Thus } A = \int y \, dx = \int F(x) \, dx \quad (83)$$

The area is therefore given by the integral of the function, over any desired range of values of x .

Example

To find the area under the curve $y = 3x^2$ from $x = 1$ to $x = 4$.

$$A = \int 3x^2 \, dx = x^3 + C$$

when $x = 1$, $A = 0$, therefore $x^3 + C = 0$, therefore $C = -1$

when $x = 4$, $A = x^3 - 1 = 4^3 - 1 = 63$.

Definite integrals

When it is desired to indicate the limits in the value of x between which the integral is desired, the integral is written, as for the example above,

$$\int_{x=1}^{x=4} 3x^2 \, dx \text{ or } \int_1^4 3x^2 \, dx.$$

These limits are called the **limits of integration**, and the integral is called the **definite integral**. For distinction, the unlimited integral is called the **indefinite integral**.

The definite integral is the difference between the values of the integral for $x = b$ and $x = a$ —

$$\int_a^b f(x) \, dx = \left[F(x) \right]_a^b = F(x = b) - F(x = a) \quad (84)$$

Owing to the subtraction, the constant of integration does not appear in definite integrals.

Special properties of definite integrals

$$\int_a^b f(x) \, dx = - \int_b^a f(x) \, dx \quad (85)$$

$$\int_a^c f(x) \, dx = \int_a^b f(x) \, dx + \int_b^c f(x) \, dx \quad (86)$$

Examples :

$$\int_0^{\pi/2} \sin \theta \, d\theta = \left[-\cos \theta \right]_0^{\pi/2} = [-\cos \pi/2 + \cos 0] = 0 + 1 = 1 \quad (87)$$

$$\int_0^{\pi/2} \cos \theta \, d\theta = \left[\sin \theta \right]_0^{\pi/2} = [\sin \pi/2 - \sin 0] = 1 - 0 = 1 \quad (88)$$

$$\int_0^{\pi} \sin \theta \, d\theta = \left[-\cos \theta \right]_0^{\pi} = [-\cos \pi + \cos 0] = 1 + 1 = 2 \quad (89)$$

$$\int_0^{\pi} \cos \theta \, d\theta = \left[\sin \theta \right]_0^{\pi} = [\sin \pi - \sin 0] = 0 - 0 = 0 \quad (90)$$

$$\int_0^{2\pi} \sin \theta \, d\theta = \left[-\cos \theta \right]_0^{2\pi} = [-\cos 2\pi + \cos 0] = -1 + 1 = 0 \quad (91)$$

$$\int_0^{2\pi} \cos \theta \, d\theta = \left[\sin \theta \right]_0^{2\pi} = [\sin 2\pi - \sin 0] = 0 - 0 = 0 \quad (92)$$

$$\int_0^{\pi} \sin^2 n\theta \, d\theta = \frac{1}{2} \left[\theta - (1/2n) \sin 2n\theta \right]_0^{\pi} = \pi/2 \quad (93)$$

$$\int_0^{\pi} \cos^2 n\theta \, d\theta = \int_0^{\pi} (1 - \sin^2 n\theta) \, d\theta = \left[\theta \right]_0^{\pi} - \pi/2 = \pi/2 \quad (94)$$

The following may also be derived* where $m \neq n$

$$\int_0^{2\pi} \sin n\theta \, d\theta = 0 \quad \int_0^{2\pi} \cos n\theta \, d\theta = 0 \quad (95)$$

$$\int_0^{2\pi} \sin^2 n\theta \, d\theta = \pi \quad \int_0^{2\pi} \cos^2 n\theta \, d\theta = \pi \quad (96)$$

$$\int_0^{2\pi} \sin m\theta \cos n\theta \, d\theta = 0 \quad \int_0^{2\pi} \sin m\theta \sin n\theta \, d\theta = 0 \quad (97)$$

$$\int_0^{2\pi} \cos m\theta \cos n\theta \, d\theta = 0 \quad \int_0^{2\pi} d\theta = 2\pi \quad (98)$$

$$\int_0^{2\pi} \sin n\theta \cos n\theta \, d\theta = 0 \quad (99)$$

Average values by definite integral

The value of the definite integral is the area under the curve between the limits on the horizontal (x) axis. The average value of the height is determined by dividing the area by the length, or in other words the average value of y is determined by dividing the definite integral by the difference in the limiting values of x .

Examples :

1. $y = 3x^2$ from $x = 1$ to $x = 4$.

$$y_{av} = \frac{1}{4-1} \int_1^4 3x^2 \, dx = \frac{1}{3} \left[x^3 \right]_1^4 = \frac{1}{3} [64 - 1] = \frac{63}{3} = 21.$$

2. $e = E_m \sin \theta$ from $\theta = 0$ to $\theta = \pi$.

$$E_{av} = E_m \frac{1}{\pi} \int_0^{\pi} \sin \theta \, d\theta = E_m \frac{1}{\pi} \left[-\cos \theta \right]_0^{\pi} = \frac{2}{\pi} E_m.$$

*This also applies with limits from k to $(k + 2\pi)$.

This is the average value of a sine wave voltage. It was taken from 0 to π since this is the range over which it is positive. The other half cycle is similar but negative, so that the average over the whole cycle is zero.

$$\begin{aligned}
 3. \quad (I_{rms})^2 &= \frac{1}{2\pi} \int_0^{2\pi} (I_m \sin \theta)^2 d\theta \\
 &= \frac{I_m^2}{2\pi} \left[\frac{\theta}{2} - \frac{\sin 2\theta}{4} \right]_0^{2\pi} \\
 &= \frac{I_m^2}{2\pi} [\pi - 0 - 0 + 0] \\
 &= \frac{I_m^2}{2\pi} \cdot \pi = \frac{I_m^2}{2}
 \end{aligned}$$

Therefore $I_{rms} = I_m / \sqrt{2} \approx 0.707 I_m$.

This is the root mean square value of the current with sine waveform.

(iv) Taylor's Series

If $f(x)$ be a function with first derivative $f'(x)$, second derivative $f''(x)$, third derivative $f'''(x)$, etc., and if the function and its first n derivatives are finite and continuous from $x = a$ to $x = b$, then the following expansion holds true in the interval from $x = a$ to $x = b$:

$$\begin{aligned}
 f(x) &= f(a) + \frac{x-a}{1!} f'(a) + \frac{(x-a)^2}{2!} f''(a) + \frac{(x-a)^3}{3!} f'''(a) \\
 &\quad + \dots + \frac{(x-a)^{n-1}}{(n-1)!} f^{n-1}(a) + \frac{(x-a)^n}{n!} f^n(x_n)
 \end{aligned} \quad (100)$$

where $a < x_n < b$.

The final term is called the **remainder**; if this can be made as small as desired by making n sufficiently large, the series becomes a convergent infinite series, converging to the value $f(x)$.

Another form of Taylor's Series is:

$$\begin{aligned}
 f(a+h) &= f(a) + \frac{h}{1!} f'(a) + \frac{h^2}{2!} f''(a) + \frac{h^3}{3!} f'''(a) + \dots \\
 &\quad \dots + \frac{h^{n-1}}{(n-1)!} f^{n-1}(a) + \frac{h^n}{n!} f^n(a) + \dots
 \end{aligned} \quad (101)$$

The sum of the first few terms of Taylor's Series gives a good approximation to $f(x)$ for values of x near $x = a$.

Examples of the use of Taylor's Series:

- (1) To expand $\sin(a+h)$ in powers of h .

$$f(a) = \sin a \text{ and } f(h) = \sin h$$

Differentiating in successive steps we get

$$\begin{aligned}
 f'(a) &= \cos a \\
 f''(a) &= -\sin a \\
 f'''(a) &= -\cos a \\
 f^{(4)}(a) &= \sin a
 \end{aligned}$$

Applying the alternative form of Taylor's Series,

$$\sin(a+h) = \sin a + h \cos a - \frac{h^2}{2!} \sin a - \frac{h^3}{3!} \cos a + \frac{h^4}{4!} \sin a + \dots \quad (102)$$

- (2) Similarly

$$\cos(a+h) = \cos a - h \sin a - \frac{h^2}{2!} \cos a + \frac{h^3}{3!} \sin a + \frac{h^4}{4!} \cos a + \dots \quad (103)$$

(v) Maclaurin's Series

Maclaurin's Series is a special case of Taylor's Series where $a = 0$.

$$f(x) = f(0) + \frac{f'(0)x}{1!} + \frac{f''(0)x^2}{2!} + \frac{f'''(0)x^3}{3!} + \dots \quad (104)$$

The sum of the first few terms of Maclaurin's Series gives a good approximation to $f(x)$ for values of x near $x = 0$.

Example of the use of Maclaurin's Series :

$$f(x) = \cos x$$

$$\text{then } \cos x = f(0) + \frac{f'(0)x}{1!} + \frac{f''(0)x^2}{2!} + \frac{f'''(0)x^3}{3!} + \frac{f^{(4)}(0)x^4}{4!}$$

$$\text{where } f(0) = \cos 0 = 1$$

$$f'(0) = -\sin 0 = 0$$

$$f''(0) = -\cos 0 = -1$$

$$f'''(0) = \sin 0 = 0$$

$$f^{(4)}(0) = \cos 0 = 1$$

The series may then be written down as

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \frac{x^8}{8!} - \dots \quad (105)$$

Similarly

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \frac{x^9}{9!} - \dots \quad (106)$$

$$j \sin x = j(x - \frac{x^3}{3!} + \frac{x^5}{5!} - \dots)$$

$$\begin{aligned} \cos x + j \sin x &= \left(1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots\right) + j\left(x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots\right) \\ &= 1 + jx + \frac{j^2 x^2}{2!} + \frac{j^3 x^3}{3!} + \frac{j^4 x^4}{4!} + \dots \end{aligned} \quad (107)$$

Also it may be proved that

$$\log_e (1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \dots \quad (108)$$

$$\begin{aligned} \text{and } e^{jx} &= 1 + jx + \frac{j^2 x^2}{2!} + \frac{j^3 x^3}{3!} + \frac{j^4 x^4}{4!} + \dots \\ &= \cos x + j \sin x \text{ (see eqn. 107)} \end{aligned} \quad (109)$$

SECTION 8 : FOURIER SERIES AND HARMONICS

(i) *Periodic waves and the Fourier Series* (ii) *Other applications of the Fourier Series* (iii) *Graphical Harmonic Analysis.*

(i) Periodic waves and the Fourier Series

The equation for any periodic wave can be written by substituting the correct values in Fourier's Series :

$$y = F(\theta) = B_0/2 + A_1 \sin \theta + A_2 \sin 2\theta + A_3 \sin 3\theta + \dots + B_1 \cos \theta + B_2 \cos 2\theta + B_3 \cos 3\theta + \dots \quad (1)$$

where $B_0/2$ is a constant which is zero if the wave is balanced about the x axis ; its value is the average value of y over one cycle and may be determined by putting $n = 0$ in the expression for B_n below,

$$\begin{aligned} A_n &= \frac{1}{\pi} \int_0^{2\pi} F(\theta) \sin n\theta \, d\theta \text{ where } n = 1, 2, 3, \text{ etc.} \\ &= 2 \times \text{average value of } F(\theta) \sin n\theta \text{ taken over 1 cycle,} \end{aligned}$$

$$B_n = \frac{1}{\pi} \int_0^{2\pi} F(\theta) \cos n\theta \, d\theta \text{ where } n = 0, 1, 2, 3, \text{ etc.}$$

= 2 × average value of $F(\theta) \cos n\theta$ taken over 1 cycle,

$\theta = \omega t = 2\pi f t$: f = fundamental frequency

$2\theta = 2\omega t = 2\pi(2f)t$: $(2f)$ = second harmonic frequency

and $3\theta = 3\omega t = 2\pi(3f)t$: $(3f)$ = third harmonic frequency
etc.

Special cases

(1) $F(\theta)$ is an even function

If the waveform is symmetrical about the y axis (e.g. Fig. 6.39), $F(\theta)$ is called an even function and $A_n = 0$, giving the simplified form

$$F(\theta) = B_0/2 + B_1 \cos \theta + B_2 \cos 2\theta + B_3 \cos 3\theta + \dots \quad (2)$$

This is the equation which applies to all types of distortion introduced by valves.

(2) $F(\theta)$ is an odd function

If the waveform is such that the value of y is equal in magnitude but opposite in sign for plus and minus values of x (e.g. Fig. 6.40), $F(\theta)$ is called an odd function and $B_n = 0$, giving the simplified form:

$$F(\theta) = A_1 \sin \theta + A_2 \sin 2\theta + A_3 \sin 3\theta + \dots \quad (3)$$

This is the equation for the condition when the fundamental and all the harmonics commence together at zero.

(3) $F(\theta) = -F(\theta \pm \pi)$

If the waveform (Fig. 6.41) is such that the value of y is equal in magnitude but opposite in sign for $x = x_1$ and $x = (x_1 \pm \pi)$, the expansion contains only odd harmonics:

$$F(\theta) = A_1 \sin \theta + A_3 \sin 3\theta + A_5 \sin 5\theta + \dots + B_1 \cos \theta + B_3 \cos 3\theta + B_5 \cos 5\theta + \dots \quad (4)$$

(4) $F(\theta)$ is an even function, with the positive and negative portions identical and symmetrical (Fig. 6.42):

$$F(\theta) = B_1 \cos \theta + B_3 \cos 3\theta + B_5 \cos 5\theta + \dots \quad (5)$$

or if the origin is taken at A ,

$$F(\theta) = B_1 \sin \theta - B_3 \sin 3\theta + B_5 \sin 5\theta - \dots \quad (6)$$

This is the equation for a balanced push-pull amplifier.

The general equation (1) can also be expressed in either of the alternative forms:

$$F(\theta) = B_0/2 + C_1 \sin(\theta + \phi_1) + C_2 \sin(2\theta + \phi_2) + \dots \quad (7)$$

$$F(\theta) = B_0/2 + C_1 \cos(\theta - \phi_1') + C_2 \cos(2\theta - \phi_2') + \dots \quad (8)$$

where $C_n = \sqrt{A_n^2 + B_n^2}$
and $\tan \phi_n = B_n/A_n$; $\tan \phi_n' = A_n/B_n$.

The angles ϕ_1, ϕ_2, \dots in eqn. (7) are the angles of lead between the harmonics of the sine series and the corresponding sine components in eqn. (1). The angles ϕ_1', ϕ_2', \dots in eqn. (8) are the angles of lag between the harmonics of the cosine series and the corresponding cosine components in eqn. (1). All the angles ϕ and ϕ' in equations (7) and (8) are measured on the scales of angles for the harmonics

Harmonic composition of some common periodic waves (Fig. 6.43)

Square wave (A)

$$y = \frac{4E}{\pi} \left(\cos \theta - \frac{\cos 3\theta}{3} + \frac{\cos 5\theta}{5} - \frac{\cos 7\theta}{7} + \dots \right) \quad (9)$$

Triangular wave (B)

$$y = \frac{8E}{\pi^2} \left(\cos \theta + \frac{\cos 3\theta}{9} + \frac{\cos 5\theta}{25} + \dots \right) \quad (10)$$

Sawtooth wave (C)

$$y = \frac{2E}{\pi} \left(\sin \theta - \frac{\sin 2\theta}{2} + \frac{\sin 3\theta}{3} - \frac{\sin 4\theta}{4} + \dots \right) \quad (11)$$

FIG. 6.43

Short rectangular pulse (D)

$$y = E \left[k + \frac{2}{\pi} \left(\sin k\pi \cos \theta + \frac{\sin 2k\pi \cos 2\theta}{2} + \dots \right. \right. \\ \left. \left. + \frac{\sin nk\pi \cos n\theta}{n} + \dots \right) \right] \quad (12)$$

Half-wave rectifier output (E)

$$y = \frac{E}{\pi} \left(1 + \frac{\pi \cos \theta}{2} + \frac{2 \cos 2\theta}{3} - \frac{2 \cos 4\theta}{15} + \frac{2 \cos 6\theta}{35} - \dots \right. \\ \left. \dots (-1)^{n/2+1} \frac{2}{n^2-1} \cos n\theta \dots \right) \quad (n \text{ even}) \quad (13)$$

Full wave rectifier output (F)

$$y = \frac{2E}{\pi} \left(1 + \frac{2 \cos 2\theta}{3} - \frac{2 \cos 4\theta}{15} + \frac{2 \cos 6\theta}{35} - \dots \right. \\ \left. \dots (-1)^{n/2+1} \frac{2 \cos n\theta}{n^2-1} \dots \right) \quad (n \text{ even}) \quad (14)$$

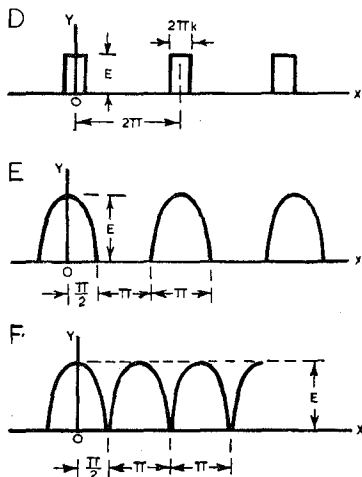

Fig. 6.43

(ii) Other applications of the Fourier Series

The Fourier Series is particularly useful in that it may be applied to functions having a finite number of discontinuities within the period, such as rectangular and saw-tooth periodic pulses.

The Fourier Series may be put into the exponential form, this being useful when the function lacks any special symmetries.

The Fourier Series may also be applied to non-periodic functions.

For information on these applications, see the list of references—Sect. 9(B).

(iii) Graphical Harmonic Analysis

Any irregular waveform may be analysed to determine its harmonic content, and the general method is to divide the period along the X axis into a suitable number of divisions (e.g. Fig. 6.44 with 24 ordinates), the accuracy increasing with the number of divisions.

Ordinates are drawn at each point on the X axis and the height of each ordinate is measured. The minimum number of ordinates over the cycle must be at least twice the power of the highest harmonic which it is desired to calculate. Various

methods for carrying out the calculations have been described. Some are based on equal divisions of time (or angle) while others are on equal divisions of voltage.

In the harmonic analysis of the distortion introduced by valves on resistive loads, it is possible to make use of certain properties which simplify the calculations :

(1) All such distortion gives a waveform which is symmetrical on either side of the vertical lines (ordinates) at the positive and negative peaks.

(2) It is therefore only necessary to analyse over half the cycle, from one positive peak to the following negative peak, or *vice versa*.

(3) Even harmonic distortion results in positive and negative half cycles of different shape and area, thus causing a steady ("rectified") component.

(4) Odd harmonic distortion results in distorted waveform, but with the positive and negative half cycles similar in shape.

(5) Even harmonics are in phase with the positive fundamental peak, and out of phase with the negative peak, or *vice versa* ; they are always maxima when the fundamental is zero.

(6) Odd harmonics are always exactly in phase or 180° out of phase with both positive and negative fundamental peaks, and are zero when the fundamental is zero.

The relative phases of the fundamental (H_1) and the harmonics (up to H_5) are shown in Fig. 6.45. The fundamental and third, fifth and higher order odd harmonics have zero amplitude at 0° , 180° and 360° on the fundamental scale. The second,

fourth, and higher order even harmonics reach their maximum values (either positive or negative) at 0° , 90° , 180° , 270° and 360° on the fundamental scale.

The amplitudes of the harmonics as drawn in Fig. 6.45 have been exaggerated for convenience in drawing, while their relative magnitudes are quite arbitrary. Their relative phases are, however, quite definite.

In proceeding with Graphical Harmonic Analysis it may be shown that it is possible to select **thirteen points** on the X axis which will enable the exact values of the first, second, third and fourth harmonics to be calculated (Ref. C9) on the assumption that there are no harmonics of higher order than the fifth, or that these are negligibly small. These points are limited to the range from 90° to 270° on the fundamental scale, as in Fig. 6.45. They may be expressed in terms of the grid voltage E_c , the static operating point being $-E_c$ and the operating point swinging from $E_c = 0$ on the one side to $2E_c$ on the other side.

It is only necessary to determine the plate currents at the specified grid voltages, to insert these into the formulae given in the article and to calculate the values of the harmonics.

The preceding exact method has been approximated by R.C.A. (Ref. C10) to give greater ease in handling. In the approximation there are **eleven specified points** in place of 13 in the exact form, the values of the grid voltages being (see Fig. 6.45): 0 ; $-0.191E_c$; $-0.293E_c$; $-0.5E_c$; $-0.691E_c$; $-E_c$; $-1.309E_c$; $-1.5E_c$; $-1.707E_c$; $-1.809E_c$; $-2.0E_c$.

These have been approximated by R.C.A. to the nearest decimal point, and the approximate values have been used in the "eleven selected ordinate method" of Chapter 13 Sect. 3(iv)D and Fig. 13.24.

The equation giving the second harmonic distortion—eqn. (28) in Chapter 13 Sect. 3(iv)—only requires the values of plate current at three points. This is an exact form and is used for triodes in Chapter 13 Sect. 2(i) eqns. (6) to (7b) inclusive and Fig. 13.2.

The "**five selected ordinate method**," described in Chapter 13 Sect. 3(iv)A and used for calculating second and third harmonic distortion in pentodes, is exact provided that there is no harmonic higher than the third. It is, however, a very close approximation under all normal conditions. The same remarks also apply to the **simple method for calculating third harmonic distortion** in balanced push-pull amplifiers, described in Chapter 13 Sect. 5(iii) eqn. (23) and Fig. 13.37.

An alternative method, based on **equal grid voltage divisions**, has been devised by Espley (Ref. C6). This gives harmonics up to one less than the number of voltage points. Two applications are described in Chapter 13 Sect. 3(iv)—**five ordinates** giving second, third and fourth harmonic distortion, and **seven ordinates** giving up to sixth harmonic distortion.

When the loadline is a closed loop, as occurs with a partially reactive load, these conditions and equations do not apply, or are only approximated.

SECTION 1 : FUNDAMENTAL TYPES OF FEEDBACK

(i) *Feedback, positive and negative* (ii) *Negative voltage feedback at the mid-frequency* (iii) *Negative current feedback at the mid-frequency* (iv) *Bridge negative feedback at the mid-frequency* (v) *Combined positive and negative feedback at the mid-frequency* (vi) *Comparison between different fundamental types at the mid-frequency.*

(i) Feedback, positive and negative

Feedback may be applied to any amplifier, at any frequency, and may be either positive or negative. The application is illustrated in Fig. 7.1 where an amplifier, with voltage amplification A , develops a voltage E_o across its load. Portion of the voltage across the load (βE_o) is fed back in series with the input terminals, so that the input voltage E_i' differs from the voltage (E_i) across the input terminals of the amplifier itself. It is obvious that

$$E_o = AE_i \text{ and that } E_i' = E_i \pm \beta E_o,$$

the sign in front of βE_o taking account of phase relationships. The quantity β is sometimes called the transfer coefficient.

FIG. 7.1

Fig. 7.1. Block diagram of an amplifier with feedback.

The effective overall amplification with feedback is therefore

$$A' = \frac{E_o}{E_i'} = \frac{E_o}{E_i \pm \beta E_o}.$$

If the effect of feedback is to increase the gain, the feedback is positive* ; if it decreases the gain, the feedback is negative. Positive feedback is used to convert

* If βE_o is much greater than E_i , then the gain will theoretically be reduced irrespective of the sign in front of βE_o .

an amplifying valve into an oscillator (see Chapter 24). Negative feedback is used mainly in amplifiers, both at radio and audio frequencies, although this Handbook covers only low frequency applications.

The voltage βE_o may be proportional to E_o , in which case it is described as **voltage feedback**; or it may be proportional to the current through the load, when it is called **current feedback**. These two are, of course, identical if the load is a constant resistance, since the voltage and current are then proportional.

Bridge feedback is a combination of voltage and current feedback.

A network may be inserted in the feedback circuit to change the phase of the feedback voltage, or to change its magnitude and/or phase so as to discriminate between different frequencies.

Use of symbols

Black (Ref. A1) and others use the symbols $\mu\beta$ to indicate the same quantity which is here indicated by βA . Some authorities use the symbols $A\beta$, but in certain equations (e.g. those involving effective plate resistance) it is necessary to introduce $\beta\mu$ or $\mu\beta$ where μ is the amplification factor of the final valve. The latter form might be confused with Black's $\mu\beta$ which has an entirely different significance. Hence the use of βA in this chapter. A further, but minor, advantage from the use of βA is that the beginner, in considering operation at the mid-frequency, is able to regard the magnitude for β as being simply a fraction.

FIG. 7.2A

FIG. 7.2B

FIG. 7.2C

FIG. 7.2D

Fig. 7.2. Block diagrams of amplifiers with negative feedback. It is assumed that $(R_1 + R_2)$ has a resistance very much greater than the load impedance; (A) and (B) have feedback external to the amplifier connected in series with the input voltage (C) has feedback connected in shunt with the input voltage (D) has the feedback connected to a cathode in the amplifier.

(ii) Negative voltage feedback at the mid-frequency

Block diagrams of two conventional forms for applying negative voltage feedback are shown in Figs. 7.2A and B. The polarities marked on the diagrams are instantaneous values at an arbitrary time. In each case the feedback voltage is derived from a voltage divider $R_1 R_2$ across the output and is **applied in series with the input voltage** so as to give negative feedback. In Fig. 7.2A the polarity of the output voltage is opposite that of the input voltage—this is regarded in network analysis as being equivalent to an amplification of $-A$. The amplifier of Fig. 7.2A may consist, for example, of one, or any other odd number of resistance-coupled stages.

In Fig. 7.2B the polarity of the output voltage is the same as that of the input voltage—this being regarded as equivalent to an amplification of $+A$. In Fig. 7.2B the feedback voltage is marked $|\beta E_o|$ thus indicating the magnitude of the voltage and leaving its polarity to be indicated by the positive and negative signs.

In this section the treatment is limited to the mid-frequency at which the amplifier has maximum gain and zero phase shift.

The combined amplifier and feedback circuit, from input back to input, is called the **feedback loop**.

The magnitude of β is equal to $R_1/(R_1 + R_2)$. In all cases, for negative feedback, βA must be negative and the feedback network must be arranged to give this result.

An alternative method of applying the feedback voltage to produce degeneration (Fig. 7.2C) connects the **feedback voltage in shunt with the input voltage**. In this case the amplification must be negative, that is to say there must be an odd number of stages unless a transformer is incorporated (Ref. A17), and β must therefore be positive.

A still further variation is **when the feedback voltage is applied to the cathode of one of the stages in the amplifier** (Fig. 7.2D). In this case the amplification must be positive, for example an even number of r.c.c. stages with the feedback returned to the cathode of the first stage, which must have some impedance between cathode and earth. Alternatively the feedback may be returned to the cathode of the penultimate stage of a multi-stage r.c.c. amplifier. The value of β should be considered as negative on account of the method of connection of the feedback loop.

The following treatment is based on the circuit of Fig. 7.2B but the results may also be applied to any amplifier with the feedback applied externally to the amplifier and in series with the input voltage. It is understood that in all cases the polarity of the feedback voltage is arranged to give negative feedback.

(A) Gain without feedback

$$A = E_o/E_i \quad (1)$$

and if feedback is applied and the input voltage increased to E_i' to give the same output voltage E_o as without feedback, then follows

(B) Gain with feedback

$$A' = \frac{E_o}{E_i'} = \frac{E_o}{E_i - \beta E_o} \quad (2a)$$

Combining (1) and (2a),

$$A' = \frac{A}{1 - \beta A} = \frac{1}{(1/A) - \beta} = \frac{A}{1 + [AR_1/(R_1 + R_2)]} \quad (2b)$$

(for chart showing relationship between A' and A see Ref. A21),

and if $|\beta A| \gg 1$

$$\text{then } A' \approx 1/(-\beta) \quad (2c)$$

The value of β is given by

$$\beta = -R_1/(R_1 + R_2) \quad (3a)$$

The effect of feedback on gain is therefore

$$\frac{A}{A'} = \frac{E_o/E_i}{E_o/(E_i - \beta E_o)} = 1 - \frac{\beta E_o}{E_i} = 1 - \beta A \quad (3b)$$

The quantity βA is negative for negative feedback; $A/A' = 1 - \beta A$ is always greater than unity.

The quantity $(1 - \beta A)$ is called the **feedback factor***. The degree of feedback is indicated by the reduction in gain. For example, an amplifier with "20 db feedback" is one in which gain has been reduced 20 db by feedback.

In the general case, when the phase angle displacement is not restricted,

$$A' = \frac{A}{\sqrt{1 + |\beta A|^2 - 2|\beta A| \cos \phi}} \quad (3c)$$

[which becomes $A' = A/(1 - \beta A)$ when $\phi = 180^\circ$]

where ϕ = phase angle displacement of amplifier and feedback circuit loop.

(C) Effect of feedback on harmonic distortion†

Let the input voltage E_i' be expressed in the form $E_{i_m'} \cos \omega t$.

Then the output voltage (E_o) will be given by

$$E_{o_m} \cos \omega t + E_{2_m} \cos 2\omega t + E_{3_m} \cos 3\omega t \quad (4)$$

*Some authorities call βA the feedback factor, and care should therefore be taken in the use of this term.

†Treatment adapted from K. R. Sturley.

where E_{0m} = peak value of fundamental frequency,

E_{2m} = peak value of second harmonic,

and E_{3m} = peak value of third harmonic.

The feedback voltage ($-\beta E_o$) will therefore be

$$-\beta(E_{0m} \cos \omega t + E_{2m} \cos 2\omega t + E_{3m} \cos 3\omega t).$$

The voltage applied to the input of the amplifier will be

$$\begin{aligned} E_i' + \beta E_o \\ = E_{im}' \cos \omega t + \beta(E_{0m} \cos \omega t + E_{2m} \cos 2\omega t + E_{3m} \cos 3\omega t) \\ = (E_{im}' + \beta E_{0m}) \cos \omega t + \beta E_{2m} \cos 2\omega t + \beta E_{3m} \cos 3\omega t. \end{aligned}$$

The output voltage will therefore be

$$\begin{aligned} AE_i + \text{harmonic distortion} \\ = A[(E_{im}' + \beta E_{0m}) \cos \omega t + \beta E_{2m} \cos 2\omega t + \beta E_{3m} \cos 3\omega t] \\ + A(E_{im}' + \beta E_{0m})(H_2 \cos 2\omega t + H_3 \cos 3\omega t) \end{aligned} \quad (5)$$

where H_2 = ratio second harmonic to fundamental voltages in amplifier without feedback,

and H_3 = ratio third harmonic to fundamental voltages in amplifier without feedback.

But we already have the output voltage in (4) above.

Equating fundamental components in (4) and (5),

$$\begin{aligned} E_{0m} &= A(E_{im}' + \beta E_{0m}) \\ E_{im}' &= (1 - \beta A)E_{0m}/A \end{aligned} \quad (6)$$

Equating the second harmonic components in (4) and (5),

$$E_{2m} = \beta A E_{2m} + A(E_{im}' + \beta E_{0m})H_2.$$

Inserting the value of E_{im}' from (6) above,

$$E_{2m} = \beta A E_{2m} + [(1 - \beta A)E_{0m} + \beta A E_{0m}]H_2$$

Therefore $E_{2m}(1 - \beta A) = E_{0m}H_2$

$$\text{Therefore } \frac{E_{2m}}{E_{0m}} = \frac{H_2}{1 - \beta A} \quad (7)$$

Similarly for the third or any higher harmonic,

$$\frac{E_{3m}}{E_{0m}} = \frac{H_3}{1 - \beta A} \quad (8)$$

That is, the magnitudes of all the harmonics (and of course the intermodulation products) introduced by the amplifier are reduced by negative voltage feedback in the same proportion that the gain is reduced.

This result is based on the assumptions :

- (1) that E_o is exactly 180° out of phase, or exactly in phase, with E_i
- (2) that the amplification A is the same for the harmonics as for the fundamental
- (3) that the intermodulation voltages are negligibly small. The presence of intermodulation* has no effect on the second harmonic, but in certain cases the higher order harmonics can increase owing to a small amount of negative feedback; when the feedback is raised sufficiently these harmonics will decrease again. When $H_2 = 0$, H_3 with feedback will be as indicated by eqn. (8). In any case, the effect is small if the amplifier distortion is initially fairly small.

(D) Effect of feedback on hum or noise introduced by the amplifier

Following a similar method—

$$\begin{aligned} \text{Input voltage} &= E_i' = E_{im}' \cos \omega t \\ \text{Output voltage} &= E_o = E_{om} \cos \omega t + E_{nm}' \cos \omega_n t \end{aligned} \quad (9)$$

where E_{nm}' = peak value of noise or hum output voltage introduced by the amplifier with feedback,

and ω_n = $2\pi \times$ frequency of noise or hum voltage.

*Tellegen, B. D. H., and V. C. Henriquez "Inverse feed-back," W.E. 14.167 (Aug. 1937) 409—quoting R. Feldtkeller; also correspondence by R. W. Sloane and J. Frommer "Distortion in negative feedback amplifiers" W.E. 14.164 (May 1937) 259; 14.166 (July 1937) 369; 14.170 (Nov. 1937) 607; 15.172 (Jan. 1938) 20.

The feedback voltage is therefore

$$-\beta E_0 = -\beta(E_{0m} \cos \omega t + E_{nm}' \cos \omega_n t).$$

The voltage applied to the input of the amplifier is

$$\begin{aligned} E_i &= E_i' + \beta E_0 = E_{im}' \cos \omega t + \beta(E_{0m} \cos \omega t + E_{nm}' \cos \omega_n t) \\ &= (E_{im}' + \beta E_{0m}) \cos \omega t + \beta E_{nm}' \cos \omega_n t. \end{aligned}$$

The output voltage is therefore

$$\begin{aligned} E_0 &= AE_i + \text{noise voltage without feedback} \\ &= A(E_{im}' + \beta E_{0m}) \cos \omega t + \beta AE_{nm}' \cos \omega_n t + E_{nm} \cos \omega_n t \end{aligned} \quad (10)$$

Equating the fundamental components in (9) and (10),

$$E_{0m} = A(E_{im}' + E_{0m}).$$

Therefore $E_{im}' = (1 - \beta A) E_{0m}/A$ (11)

Equating the noise components in (9) and (10),

$$\begin{aligned} E_{nm}'(1 - \beta A) &= E_{nm} \\ \frac{E_{nm}'}{E_{nm}} &= \frac{1}{1 - \beta A} \end{aligned} \quad (12)$$

Thus the feedback reduces noise or hum voltages introduced by the amplifier in the same proportion that the gain is reduced, provided the following conditions are fulfilled :

- (1) That the signal input voltage is increased with feedback, to maintain the signal output voltage constant.
- (2) That β and A have the same values for the hum (or noise) frequency as for the signal frequency.
- (3) The voltage fed back does not include any voltages other than the fraction of the amplifier output voltage. In many circuit arrangements this condition is not satisfied ; the most important of these are covered in Sect. 2.

When all noise is considered as originating at the input (e.g. thermal noise), the signal-to-noise ratio is unchanged by the feedback.

(E) Effect of voltage feedback on the output resistance of the amplifier

Every linear network which has a pair of output terminals may, as regards its external effects, be replaced by its equivalent open-circuit voltage in series with its equivalent resistance.

Fig. 7.3. Equivalent circuit diagrams of amplifier and load resistance (A) without feedback (B) with feedback.

The following treatment is based on a single stage, but may be applied to any amplifier provided that the values of μ and r_p are as defined below.

Fig. 7.3A shows the equivalent circuit of the amplifier **without feedback** :

$$E_o = \mu E_i \left(\frac{R_L}{r_p + R_L} \right) \quad (13)$$

$$A = \frac{E_o}{E_i} = \frac{\mu R_L}{r_p + R_L} \quad (14a)$$

where μ = amplification factor (i.e. amplification with an infinite load resistance) and r_p = plate resistance of final stage.

If the amplifier has more than one stage μ must be defined by

$$\mu = A_1 \mu_2 \quad (14b)$$

where A_1 = amplification between input and grid of final stage (with due regard to phase reversal)

and μ_2 = amplification factor of final stage.

Fig. 7.3B shows the equivalent circuit of the amplifier **with voltage feedback** :

$$E_o = \mu' E_i' \left(\frac{R_L}{r_p' + R_L} \right). \quad (15)$$

**Based on B. D. H. Tellegen "Inverse feed-back" Philips Tec. Rev. 2.10 (Oct. 1937) 289.

But $E_0 = A'E_i' = \frac{E_i'}{(1/A) - \beta}$ from eqn. (2b).

Applying the value of A from (14a),

$$E_0 = \frac{\mu R_L E_i'}{r_p + R_L(1 - \beta\mu)} \quad (16)$$

This may be arranged in the form

$$E_0 = \left(\frac{\mu E_i'}{1 - \beta\mu} \right) \left(\frac{R_L}{r_p/(1 - \beta\mu) + R_L} \right) \quad (17)$$

which is the same as eqn. (15) except that

$$\mu' = \frac{\mu}{1 - \beta\mu} \quad (18)$$

$$\text{and } r_p' = \frac{r_p}{1 - \beta\mu}. \quad (19)$$

Equations (18) and (19) give the effective amplification factor and plate resistance respectively with feedback. It will be seen that these are each equal to the corresponding value without feedback divided by $(1 - \beta\mu)$, whereas the gain, internally produced hum or noise, and distortion are divided by $(1 - \beta A)$. If the amplifier has more than one stage, the value of μ must be as defined by eqn. (14b), while the plate resistance r_p will be that of the final stage.

However, it is important to remember that the actual valve characteristics are not changed by feedback, since feedback is external to the valve; while the optimum value of load resistance is also unchanged by feedback except under certain very special conditions.

It may be shown that negative voltage feedback as a method for reducing the effective plate resistance, when compared with a transformer giving the same reduction of gain, is more effective than the transformer with low feedback factors, is equally effective with a particular feedback factor, and is less effective than the transformer with feedback factors greater than this value.

Example: 6V6-GT with $\mu = 218$, and $A = 17$.

Gain	$ \beta A $	$ \beta \mu $	r_p' / r_p	Transformer impedance ratio
1/2	1	12.8	1/13.8	1/4
1/10	9	115	1/116	1/100
1/100	99	1270	1/1271	1/10000

The “looking-backwards” output terminal impedance of the amplifier is equal to r_p' in parallel with R_L ,

$$R_0' = \frac{r_p' R_L}{r_p' + R_L} = \frac{r_p R_L}{r_p + R_L(1 - \beta\mu)} \quad (19a)$$

If r_p' is very much less than R_L , eqn. (17) becomes

$$E_0 \approx \frac{\mu E_i'}{1 - \beta\mu} \quad (20)$$

that is to say, the output voltage is independent of the value of R_L . This is an indication of good regulation.

(F) Effect of voltage feedback on the input resistance

The effect of feedback on the input resistance depends on the method of application of the feedback and not on whether it is voltage or current feedback. For example, consider the amplifier of Fig. 7.2B. Let the input resistance of the amplifier without feedback be r_i .

Then $r_i = E_i / I_1$.

With feedback, the same current will flow, but the input voltage will be

$$E_i' = E_i(1 - \beta A)$$

$$\text{Therefore } r_i' = E_i'/I_1 = (E_i/I_1)(1 - \beta A)$$

$$\text{Therefore } r_i' = r_i(1 - \beta A). \quad (21)$$

Thus in this case the input resistance is increased by feedback in the same proportion that the gain is decreased. This applies to all cases in which the feedback voltage is applied in series with the input voltage, including the current feedback case of Fig. 7.4, as will be shown later.

On the other hand, if the feedback voltage is applied in shunt with the input voltage the input resistance will be decreased as proved below for Fig. 7.2C—

The input resistance of the amplifier without feedback is

$$r_i = E_i/I_1.$$

With feedback, the current I_1 will be unchanged, but there will be an additional current I_2 through R_4 and of direction such as to increase the current from the source, which will therefore become $(I_1 + I_2)$. The input voltage applied to the input terminals of the amplifier will be the same as without feedback

$$\text{Therefore } r_i' = r_i \frac{I_1}{I_1 + I_2}$$

which is less than r_i .

Other special cases are covered in Sect. 2.

(iii) Negative current feedback at the mid-frequency

The block diagram of an amplifier with negative current feedback is shown in Fig. 7.4. In this case the feedback voltage is derived from the voltage drop across a resistor R_3 in series with the load impedance. The resistance of R_3 should be very small compared with the load impedance. This diagram also is for the case with the polarity of the output voltage opposite that of the input voltage.

FIG. 7.4

FIG. 7.5

Fig. 7.4. Block diagram of an amplifier with negative current feedback. The resistance R_3 is very much smaller than the load impedance.

Fig. 7.5. Block diagram of an amplifier with bridge feedback.

Without feedback but with R_3 in position (Fig. 7.4)

$$A = \frac{E_o}{E_i} = \frac{\mu R_L}{r_p + R_3 + R_L} \quad (22)$$

With current feedback,

$$A' = \frac{E_o}{E_i'} = \frac{E_o}{E_i + R_3 I_o} = \frac{E_o}{E_i + (R_3/R_L) E_o} = \frac{1}{(E_i/E_o) + R_3/R_L}$$

$$\text{Therefore } A' = \frac{\mu R_L}{(\mu + 1)R_3 + r_p + R_L} \quad (23)$$

$$\text{Therefore } A' = \frac{A}{1 + AR_3/R_L} = \frac{A}{1 + \mu R_3/(r_p + R_3 + R_L)} \quad (24a)$$

It is sometimes helpful to substitute

$$-\gamma = R_3/R_L$$

where γ has an application similar to that of β in the case of voltage feedback. Eqn. (24a) may thus be put into the form

$$A' = A/(1 - \gamma A). \quad (24b)$$

Equation (23) indicates that for a single stage amplifier

(A) **the amplification factor with current feedback** is the same (μ) as without feedback

(B) **the effective plate resistance with current feedback** is

$$r_p' = r_p + (\mu + 1)R_3 \quad (25a)$$

$$\text{and } r_p'/r_p = 1 + (\mu + 1)R_3/r_p \quad (25b)$$

The increase in plate resistance (eqn. 25b) is proportionally greater than the decrease in gain (eqn. 24a).

When the voltage is fed back over more than one stage, the effective plate resistance with feedback is given by

$$r_p' = r_p + A_1 (\mu_2 + 1)R_3, \quad (25c)$$

where A_1 = amplification between input and grid of final stage (with due regard to phase reversal)

and μ_2 = amplification factor of final stage.

The “**looking-backwards**” output terminal impedance of the amplifier is equal to r_p' in parallel with R_L ,

$$R_0' = \frac{r_p' R_L}{r_p' + R_L} = \frac{[r_p + (\mu + 1)R_3] R_L}{r_p + (\mu + 1)R_3 + R_L} \text{ for single stage}$$

$$\text{or } R_0' = \frac{[r_p + A_1 (\mu_2 + 1) R_3] R_L}{r_p + A_1 (\mu_2 + 1) R_3 + R_L} \text{ for more than one stage.}$$

(C) **The ratio of amplification with and without feedback** is given by

$$\frac{A}{A'} = \frac{(\mu + 1)R_3 + r_p + R_L}{R_3 + r_p + R_L} \quad (26)$$

which may be put into the form

$$A/A' = 1 + A(R_3/R_L) = 1 - \gamma A. \quad (27)$$

(D) **Approximations when μ is very large**

If μ is very large,

$$A' \approx R_L/R_3 \approx 1/(-\gamma) \quad (28)$$

which is independent of the amplifier characteristics.

Also, if μ is very large,

$$I_0 \approx E_0/R_L \approx E_i'/R_3 \quad (29)$$

which gives an output current which is constant, irrespective of R_L .

(E) **Input resistance with negative current feedback**

In the circuit of Fig. 7.4—

Without feedback

$$r_i = E_i/I_1$$

With feedback

$$r_i' = \frac{E_i'}{I_1} = \frac{E_i + (R_3/R_L)E_0}{I_1} = \frac{E_i + (R_3/R_L)AE_i}{I_1}$$

$$\text{Therefore } r_i' = r_i(1 + AR_3/R_L) = r_i(1 - \gamma A) \quad (30)$$

which indicates that with this circuit the input resistance is increased with negative current feedback in the same proportion that the gain is decreased (eqn. 27) and the effect is therefore the same as with Fig. 7.3.

(F) **Harmonic distortion with negative current feedback**

It may readily be shown that, as with negative voltage feedback, the harmonic distortion is reduced in the same proportion that the gain is reduced, subject to the conditions enumerated above (following eqn. 8) :

$$\text{e.g., } \frac{E_{2m}}{E_{0m}} = \frac{H_2}{1 + AR_3/R_L} = \frac{H_2}{1 - \gamma A} \quad (31)$$

(iv) **Bridge negative feedback at the mid-frequency**

Bridge feedback is a combination of voltage and current feedback, as shown in Fig. 7.5. It is assumed that $(R_1 + R_2) \gg R_L$ and that $R_3 \ll R_L$.

Without feedback : $A = E_0/E_i = \mu R_L/(r_p + R_3 + R_L)$.

With feedback :

$$\text{Feedback voltage} = R_1 E_0/(R_1 + R_2) + I_0 R_3$$

$$\text{Therefore } E_i' = E_i + R_1 E_0/(R_1 + R_2) + I_0 R_3$$

$$\text{Therefore } A' = \frac{AE_i}{E_i'} = \frac{AE_i}{E_i + AE_i R_1 / (R_1 + R_2) + R_3 AE_i / R_L}$$

$$\text{Therefore } A' = \frac{A}{1 + AR_1 / (R_1 + R_2) + AR_3 / R_L} \quad (32)$$

Comparing this with (2b) and (24a), it will be seen that the denominator in (32) includes the second terms of the denominators of both (2b) and (24a). Equation (32) may be put into the alternative forms

$$A' = \frac{\mu R_L}{r_p + (\mu + 1)R_3 + R_L(1 + \mu R_1 / (R_1 + R_2))} \quad (33)$$

$$\text{and } A' = \frac{\mu}{1 + \mu R_1 / (R_1 + R_2)} \cdot \frac{R_L}{\frac{r_p + (\mu + 1)R_3}{1 + \mu R_1 / (R_1 + R_2)} + R_L} \quad (34)$$

Equation (34) indicates that—

- (1) the amplification factor is reduced by the factor

$$\frac{1}{1 + \mu R_1 / (R_1 + R_2)} = \frac{1}{1 - \beta \mu} \quad \text{which is the same as for voltage feedback alone (equation 18).}$$

- (2) the effective plate resistance is given by

$$r_p' = \frac{r_p + (\mu + 1)R_3}{1 + \mu R_1 / (R_1 + R_2)} = \frac{r_p - (\mu + 1)(\gamma R_L)}{1 - \beta \mu} \quad (35a)$$

Compare this with equation (25a) for current feedback alone and (19) for voltage feedback alone.

If the amplifier has more than one stage, μ must be defined as

$$\mu = A_1 \mu_2 \quad (35b)$$

where A_1 = amplification between input and grid of final stage (with due regard to phase reversal)

and μ_2 = amplification factor of final stage, thus giving the expression for effective plate resistance

$$r_p' = \frac{r_p + (A_1 \mu_2 + 1)R_3}{1 - A_1 \mu_2 \beta} = \frac{r_p - (A_1 \mu_2 + 1)(\gamma R_L)}{1 - A_1 \mu_2 \beta} \quad (35c)$$

where $\gamma = -R_3 / R_L$.

Special applications of bridge feedback (Ref. A9)

(A) The output resistance may be adjusted so as to equal the load resistance.

If the voltage and current feedback resistors are adjusted so that

$$R_1 / (R_1 + R_2) = R_3 / R_L, \text{ that is } \beta = \gamma,$$

then $r_p' \approx R_L$.

provided that $(-\beta \mu) \gg 1$

and that $(-\beta \mu R_L) \gg r_p$.

(B) Negative voltage feedback may be combined with positive current feedback to decrease the plate resistance r_p' to zero or even to make it negative. This is little used in amplifiers because the positive current feedback increases the harmonic distortion. However, it is possible to combine negative feedback in the output stage with positive feedback in an earlier stage to give very useful results—see Sect. 2(xi). This somewhat resembles one form of the balanced feedback in (v) below, except that the design is less restricted.

(C) Negative current feedback may be combined with positive voltage feedback to give very high effective plate resistance.

(v) Combined positive and negative feedback at the mid-frequency

The distortion in a two or three stage amplifier is mainly in the output stage, and the distortion in a well designed first stage will be relatively quite small. It is practicable to apply positive voltage feedback to the first stage only, and then to apply negative voltage feedback over two or three stages in order to secure very low distortion and low output resistance.

This arrangement is shown in the simplified block diagram of Fig. 7.6. The effect of positive feedback on A_1 is to increase its gain from A_1 without feedback to A' with positive feedback. The effect on the whole amplifier, so far as effective plate resistance, distortion in the final stage and gain are concerned, is the same as though A_1 with positive feedback were replaced by another amplifier without feedback but with gain A' . The positive feedback in A_1 will increase the distortion of this stage, but

Fig. 7.6. Simplified block diagram illustrating one possible arrangement of combined positive and negative feedback.

will decrease the distortion of the whole amplifier provided that the initial distortion in A_1 is small in comparison with that in A_2 . A general purpose triode may be used in the first stage, and yet have an effective stage gain greater than that of a pentode with a plate load resistor of 0.25 megohm.

Practical amplifiers using this principle are described in Sect. 2(xi).

Balanced feedback amplifiers

A balanced feedback amplifier is one using both positive and negative feedback in such proportions that the overall gain with feedback is equal to that without any feedback (Ref. A20). There does not seem to be any real advantage in achieving exact balance between the two feedback systems and the designer will generally prefer complete liberty on this point.

(vi) Comparison between different fundamental types at the mid-frequency

Negative feedback :		Effect
Voltage Feedback	Current Feedback	
decreases	decreases	gain
decreases	decreases	effect of variations of valves and other components on gain
decreases	increases	effective plate resistance
increases	increases	
or	or	input resistance*
decreases	decreases	harmonic distortion
decreases	increases	effect of load impedance on output voltage
increases	decreases	effect of load impedance on output current
increases	decreases	damping on loudspeaker
increases	increases	frequency response (band width)
decreases	decreases	hum and unwanted voltages introduced in the amplifier (subject to certain conditions).
Positive feedback :		Effect
Voltage Feedback	Current Feedback	
increases	increases	gain
increases	decreases	effective plate resistance
increases	increases	harmonic distortion

*The effect on the input resistance depends on the method of applying the input voltage.

Characteristics of amplifiers with negative feedback

Characteristic	No feedback	Voltage feedback	Current feedback†
Voltage gain	$\frac{\mu R_L}{r_p + R_L}$	$\frac{\mu R_L}{r_p + R_L(1 - \beta\mu)}$	$\frac{\mu R_L}{r_p + R_L[1 - \gamma(\mu + 1)]}$
or	A	$\frac{A}{1 - \beta A}$	$\frac{A}{1 - \gamma A}$
Effective amplification factor‡	μ	$\frac{\mu}{1 - \beta\mu}$	μ
Effective plate resistance of final stage‡	r_p	$\frac{r_p}{1 - \beta\mu}$	$r_p + (\mu + 1)R_s = r_p - \gamma(\mu + 1)R_L$
Input resistance	r_i	$r_i(1 - \beta A)^*$	$r_i(1 - \gamma A)^{**}$
Second harmonic distortion	H_2	$\frac{H_2}{1 - \beta A}$	$\frac{H_2}{1 - \gamma A}$
Hum or noise introduced by amplifier	E_n	$\frac{E_n}{1 - \beta A}$	$\frac{E_n}{1 - \gamma A}$

Note: β is negative throughout.

γ is defined by $-\gamma = R_s/R_L$.

SECTION 2 : PRACTICAL FEEDBACK CIRCUITS

(i) The cathode follower (ii) The cathode degenerative amplifier and phase splitter (iii) Voltage feedback from secondary of output transformer (iv) Voltage feedback from plate—transformer input (v) Voltage feedback from plate—r.c.c. input (vi) Voltage feedback over two stages (vii) Voltage feedback over three stages (viii) Cathode coupled phase inverters and amplifiers (ix) Hum (x) Some special features of feedback amplifiers (xi) Combined positive and negative feedback (xii) Choke-coupled phase inverter.

The idealized conditions assumed in Section 1 do not always hold. At very low and very high audio (or ultrasonic) frequencies, the reactances cause phase angle displacements tending to nullify the “negative” feedback which, in extreme cases, may even become positive. The resulting effects may be evident as poor response to transients (damped oscillations), parasitic oscillations extending over a portion of a cycle of sine waveform or, in extreme cases, oscillation at a very low or very high frequency. This aspect is considered in further detail in Section 3 for those who wish to have anything beyond the most elementary understanding of the problem.

Other complications arise from (a) certain circuit connections affecting the amount of hum, and (b) the application of feedback in parallel with an impedance within the amplifier.

(i) The cathode follower

With a cathode follower the load impedance is connected between cathode and earth instead of between plate and earth in the more conventional arrangement. It is there-

*Applies only to circuits such as Fig. 7.2A or 7.2B in which the feedback voltage is applied in series with the input voltage.

†Over single stage.

‡If the amplifier has more than one stage, the amplification factor must be defined by $\mu = A_1\mu_2$ where A_1 = amplification between point at which feedback is introduced and grid of final stage and μ_2 = amplification factor of final stage.

**Applies only to circuits such as Fig. 7.4 in which the feedback voltage is applied in series with the input voltage.

fore frequently referred to as "cathode loading" in distinction to the conventional "plate loading." As a result of 100 per cent. negative voltage feedback inherent in a cathode follower, both the distortion and the output impedance may be very low.

The basic circuit of a triode cathode follower is shown in Fig. 7.7. It is understood that the input circuit must be conductive to provide a grid return path, and that a suitable grid bias value is achieved by inserting an appropriate battery at, say, point D. The input voltage is applied between grid and earth while the load resistance (R_k) is connected between cathode and earth. The voltage developed across R_k is the output voltage, and the maximum output voltage is slightly greater than for the conventional case with R_k as the plate load resistor. The stage gain, however, is necessarily less than 1 since the input voltage is equal to the grid-to-cathode voltage plus the output voltage (with a medium- μ valve the voltage gain normally approximates 0.9). Since the stage gain is always less than unity, the input voltage is always greater than the output voltage. Thus the input voltage may be very much greater than the grid bias, but grid current will not flow until the instantaneous difference between the input and the output voltage exceeds the bias.* In some cases the input voltage will be very high as, for example, when a high power output is required from a cathode-loaded low- μ triode operated with a high plate voltage. In extreme cases there may be difficulty in obtaining sufficient voltage in the preceding stage to excite fully the cathode follower.

FIG. 7.7

Fig. 7.7. Basic circuit of a cathode follower.

Since a cathode follower does not amplify the input voltage it might, at first sight, be thought that the arrangement fulfilled no useful purpose. Its principal usefulness, however, lies in its impedance characteristics. The input impedance is high while the output impedance (R_o') is low, and the whole device may therefore be regarded as a kind of Impedance Transformer—see (F1) below.

The low output impedance of the cathode follower makes it particularly useful as a driver stage for Class AB_2 or Class B amplifiers, or for pulse techniques where a low impedance source is required.

With the cathode follower, the grid and cathode are in phase with one another, so that there is no reversal of polarity as with plate-loaded amplifiers—this characteristic is sometimes useful in amplifiers, and particularly with pulse techniques.

A cathode follower will work into practically any value of load resistance, although there is a broad optimum value for any particular application.

The effect of interelectrode and wiring capacitances on the gain is generally negligible up to a frequency of 1 Mc/s.

It is important to remember that all electrode voltages must be stated with respect to the cathode; these will normally have the same values as for plate loading.

The graphical treatment is given on pages 390-394.

(A) Voltage gain at low frequencies

The voltage gain without feedback would be

$$A = \frac{\mu R_k}{R_k + r_p}.$$

The value of the transfer coefficient β will be $\beta = -1$.

*More precisely, the difference between the bias and the voltage of the grid current cross-over point.

The gain with feedback will therefore be

$$A' = \frac{A}{1 - \beta A} = \frac{A}{1 + A}$$

$$\text{Therefore } A' = \frac{\mu R_k}{(\mu + 1)R_k + r_p} \quad (1a)$$

which may be written in the form

$$A' = \frac{\mu}{\mu + 1} \cdot \frac{R_k}{R_k + r_p/(\mu + 1)} \quad (1b)$$

Equation (1a) may also be written in the form

$$A' = \frac{R_k}{\left(\frac{\mu + 1}{\mu}\right)R_k + \frac{1}{g_m}} \quad (1c)$$

where g_m = mutual conductance in mhos.

If $\mu \gg 1$, the gain with feedback will be approximately

$$A' \approx \frac{g_m R_k}{1 + g_m R_k} \quad (2)$$

R_k is the resultant of all resistances between cathode and earth, whether internal or external to the amplifier itself. There is very little increase in gain through making R_k greater than about twice r_p ; provided that μ is not less than 10, then the increase of gain through any further increase in R_k is always less than 5 per cent. (It is assumed that the input voltage is small enough to avoid grid current and/or plate current cut-off).

Charts giving gain

Voltage gain (exact) based on μ , R_k and r_p —Ref. C19.

Voltage gain (approx.) based on g_m and R_k for pentodes—Ref. C21.

Gain in decibels (approx.)—Ref. C24.

(B) Effective plate resistance (r_p') at low frequencies

The effective plate resistance in the arrangement of Fig. 7.7, as with any case of voltage feedback, is equal to r_p divided by $(1 - \beta\mu)$, i.e.

$$r_p' = \frac{r_p}{1 - \beta\mu} = \frac{r_p}{1 + \mu} = \frac{1}{g_m} \cdot \frac{\mu}{\mu + 1} \quad (3)$$

If μ is very much greater than 1, then $r_p' \approx 1/g_m$ with an error not exceeding 5 per cent. if μ is not less than 20. (4a)

As with the gain, so too with the effective plate resistance, there is very little change brought about by an increase in R_k beyond $2r_p$, provided that μ is not less than 20. Chart of r_p' (approx.)—Ref. C24.

(C) Equivalent valve characteristics

The results obtained with a cathode follower (e.g. eqn. 1b) are equivalent to those which would be obtained from an equivalent plate-loaded triode* having :

plate resistance = $r_p' = r_p/(\mu + 1)$

amplification factor = $\mu/(\mu + 1)$

mutual conductance = g_m (unchanged)

and working into a load resistance $R_L = R_k$ (unchanged).

Example 1 : type 6J7 (triode connection)

For 250 volts between plate and cathode, $\mu = 20$, $g_m = 1900$ micromhos and $r_p = 10\,500$ ohms. The value of R_k for greatest power output may be assumed to be approximately equal to $2r_p$, so that a value of 20 000 ohms may be adopted (see Sect. 5 for graphical treatment). The effective plate resistance is therefore

$$r_p' = r_p/(\mu + 1) = 10\,500/21 = 500 \text{ ohms,}$$

and the gain will be

*See Sect. 5(i) for graphical treatment.

$$A' = \frac{20\,000}{(21/20)(20\,000) + 525} = 0.93.$$

Example 2 : type 6V6 (triode connection)

With 250 volts between plate and cathode, $\mu = 9.6$, $g_m = 4000$ micromhos and $r_p = 2400$ ohms. If R_k is made equal to 5000 ohms we have

$$r_p' = 2400/(9.6 + 1) = 2400/10.6 = 226 \text{ ohms, and the gain will be}$$

$$A' = \frac{5000}{(10.6/9.6)5000 + 250} = 0.866.$$

(D) Distortion

The distortion, within the limits of plate-current cut-off on one hand, and grid current on the other, is reduced by the same factor that the gain is reduced, namely $1/(1 + A)$ where A is the gain without feedback. In a practical case, if $\mu = 20$ and $R_k = 2r_p$, then the distortion is reduced to 3/43 of the distortion with plate loading.

The **maximum input voltage** which may be handled without distortion may be calculated graphically (see Sect. 5).

(E) Calculated operating conditions

The following treatment is based on ideal valve characteristics with straight lines instead of curves, and is therefore only approximate (Ref. C31). It is assumed that the bias is adjusted to allow for maximum voltage swing over the whole loadline.

$$\text{Operating point : } I_b = \frac{1}{2} E_{bb}/(r_p + R_k) \quad (4b)$$

$$E_k = \frac{1}{2} E_{bb} R_k / (r_p + R_k) \quad (4c)$$

$$E_c = -E_{bb}/(2\mu) \quad (4d)$$

where E_k = voltage across R_k .

If the circuit of Fig. 7.10 is used to provide grid bias :

$$R_2 = (r_p + R_k)/\mu = R_k/A = (1 + R_k/r_p)g_m \quad (4e)$$

where $A = \mu R_k/(r_p + R_k)$

= amplification of valve with plate loading.

Example : Type 6J7 (triode connection)

$$I_b = 125/30\,500 = 4.1 \text{ mA}$$

$$E_k = 125 \times 20\,000/30\,500 = 82 \text{ V}$$

$$E_c = -250/40 = -6.25 \text{ V}$$

$$A = 20 \times 20\,000/30\,500 = 13.1$$

$$R_2 = 30\,500/20 = 1525 \text{ ohms.}$$

In the general case, use may be made of the following table, based on eqn. (4e) :

when $R_k = 0.1/r_p$	$1.0r_p$	$2r_p$	$3r_p$	$4r_p$	$5r_p$
then $R_2 = 1.1/g_m$	$2/g_m$	$3/g_m$	$4/g_m$	$5/g_m$	$6/g_m$

The peak amplitude of the voltage E_k is given by

$$E_{km} = \frac{1}{2} E_{bb} R_k / (r_p + R_k) \quad (4f)$$

Special case (1)

If it is desired to use the minimum value of R_k to give a specified peak output voltage E_{km} , the value of R_k is given by

$$R_k = 2E_{km}r_p/(E_{bb} - 2E_{km}) \quad (4g)$$

and the optimum value of bias resistor (Fig. 7.10) is given by

$$R_2 = \frac{E_{bb}}{g_m(E_{bb} - 2E_{km})} \quad (4h)$$

If E_{km} is small compared with E_{bb} , R_2 is thus approximately equal to $1/g_m$.

Special case (2)

If R_k is greater than $1/g_m$ and the whole of R_k is used to provide grid bias, the maximum output voltage is thereby reduced,

$$E_{km} = \frac{E_{bb} R_k}{r_p + (\mu + 1)R_k} \quad (4i)$$

Special case (3)

If R_k is made equal to $1/g_m$ the cathode follower works into a load equal to its own effective plate resistance (r_p). The value of peak output voltage is given by

$$E_{gm} = \frac{1}{2} E_{bb} / (\mu + 1)$$

and the optimum value of bias resistor R_2 is given by

$$R_2 = \frac{r_p \left(\frac{\mu + 1}{\mu} \right)}{\mu} \approx R_k \quad (4k)$$

so that the valve may be considered perfectly biased by the whole of its cathode resistor R_k .

Special case (4)

When the value of cathode resistance required to provide bias is small compared with $1/g_m$, the arrangement of Fig. 7.11 may be used in which $R_1 = R_k = 1/g_m$, and R_2 is calculated to provide the correct bias. Since R_1 is small compared with $1/g_m = r_p/\mu$, the maximum peak output voltage will be given approximately by

$$E_{km} \approx \frac{1}{2} E_{bb} R_1 / r_p \quad (4l)$$

Special case (5)

If R_k is small compared with $1/g_m$ and R_k alone used to provide bias, the bias will not be optimum and the maximum peak output voltage will be given by

$$E_{km} = \frac{\mu R_k^2 E_{bb}}{r_p [r_p + (\mu + 1) R_k]} = \frac{\mu n^2 E_{bb}}{(\mu + 1)n + 1} \quad (4m)$$

where R_k is neglected in comparison with r_p and $n = R_k/r_p$.

The ratio of the output voltage with correct bias (eqn. 4l) and that with self bias from cathode resistor (eqn. 4m) is given by

$$\text{Ratio} = \frac{2}{1 + 1/\mu n} \quad (4n)$$

(F1) The "looking-backwards" output terminal impedance (R_o')

The impedance, seen when looking backwards from the output terminals of Fig. 7.7 into the amplifier, is equal to r_p' in parallel with R_k . This corresponds to the plate-loaded case where we have to consider r_p and R_L in parallel.

$$R_o' = \frac{r_p' R_k}{r_p' + R_k} = \frac{R_k}{(r_p + R_k)/r_p + g_m R_k} = \frac{1}{g_m + 1/R_k + 1/r_p} \quad (5a)$$

$$\text{Therefore } R_o' = \frac{r_p R_k}{(\mu + 1) R_k + r_p} \quad (5b)$$

$$\text{If } r_p \gg R_k, R_o' \approx \frac{R_k}{1 + g_m R_k} \quad (6)$$

In special cases, where a very low value of R_o' is required, it may be convenient to obtain it by decreasing the value of R_k , even though this results in a serious reduction in maximum power output. For example, with type 6V6 (triode connection) under the conditions given above, where $r_p' = 226$ ohms,

when $R_k = 2400, 1000, 500, 200, 100, 50$ ohms.

then $R_o' = 206, 184, 156, 105, 69, 41$ ohms.

Charts :

R_o' (approx.) but with correction factor to give exact value—Ref. C22.

(F2) Resistance-capacitance coupled cathode follower

An alternative form of load is illustrated in Fig. 7.8 where R_k is the d.c. load resistance, C_c the coupling condenser, and R_p the a.c. shunt load resistance. In cal-

FIG. 7-8

Fig. 7.8. Cathode follower with d.c. load resistance R_k , capacitance coupled to a shunt load resistance R_p .

culations regarding grid bias, the resistance of R_k should be used ; in calculations regarding gain the resultant $R = R_k R_p / (R_k + R_p)$ should be used. As for the

similar case with plate-loading, it is usually desirable to have R_o considerably greater than R_k . R_o may take the form of a volume control.

Alternatively, R_k may be selected to suit the grid bias, while R_o is then calculated to provide the desired total a.c. load.

When the circuit of Fig. 7.8 is used as a power amplifier stage, it may be shown (Ref. C32) that maximum power is dissipated in R_o when $R_o = r_p$ and $R_k = \sqrt{2}r_p$, and that when these conditions are fulfilled the power dissipated in R_o is given by

$$P_{max} = E_1^2/93r_p$$

where E_1 = plate supply voltage E_{bb} less the voltage where the tangent to the $E_c = 0$ characteristic cuts the axis (point B in Fig. 7.8A)

and r_p = plate resistance of valve at junction of d.c. loadline with $E_c = 0$ characteristic (point D in Fig. 7.8A).

If in Fig. 7.8 the load impedance is removed to a distance and the leads between the cathode follower and the output terminals are lengthened, the "link" between the amplifier and the output may be used as a low impedance loaded a-f line, although it is loaded unequally at the two ends.

The term "link" is used to describe a line which is so short that its characteristics at the frequency of operation may be neglected in comparison with the loading. It should be carefully distinguished from a "transmission line," which has a characteristic impedance determined by the self inductance and capacitance per unit length and which, for the suppression of standing waves, requires to be terminated by an impedance equal to the characteristic impedance.

Fig. 7.8A. Loadlines of circuit Fig. 7.8 used as a power amplifier.

(G) Transformer coupled cathode follower

With the resistance-coupled case of Fig. 7.7 the plate supply voltage must be higher than the plate-to-cathode voltage and the whole of the power output plus the d.c. losses are dissipated in the resistance R_k . It is possible to replace R_k by the primary of a transformer, and the secondary of the transformer may then be loaded, e.g. by driving the voice coil of a loudspeaker or other electrical network (Fig. 7.9). In this case the full supply voltage, except for the small resistance loss in the transformer primary, is applied between plate and cathode.

Fig. 7.9. Cathode follower having the primary of a transformer in its cathode circuit, the secondary of the transformer being loaded.

The maximum power output with the same load resistance as for plate loading will be approximately the same. The distortion and the output resistance will, however, be very much lower than for plate loading, and the damping on the loudspeaker will be greater.

A special case of some importance is when V_1 is the driver valve of a Class B power amplifier (see Chapter 13 Sect. 7).

The optimum load resistance may best be calculated graphically (see Sect. 5).

The resistance of the transformer primary will provide at least part of the voltage for grid bias; the balance may be supplied by a suitable resistance (shunted by the

usual by-pass capacitance) between the cathode and the upper transformer primary terminal.

Alternatively, the primary of the transformer may be connected in place of R_g in Fig. 7.8, and C_g may be adjusted to tune the primary to a suitable low frequency to extend the frequency band to lower frequencies or to give bass boost (Ref. C14).

(H) Grid circuit arrangements and their effect on input resistance and R_o'

If the voltage drop in R_k is greater than the desired grid bias, then a convenient arrangement is to return the grid resistor (R_g) to a tapping point (X) on the cathode load resistor, the position of X being adjusted for optimum operating conditions (Fig. 7.10); the bias will be

$$E_{c1} = R_2 I_b \quad (7)$$

where E_{c1} is the bias in volts, R_2 is expressed in ohms and I_b the plate current in amperes. The total load resistance is $(R_1 + R_2)$ which corresponds to R_k in Fig. 7.7. The correct value of C should always be selected on the basis of the input resistance (R_i') and not on the basis of R_g .

FIG. 7.10

FIG. 7.11

FIG. 7.12

Fig. 7.10. Cathode follower with grid bias supplied by a tapping point (X) on the load resistance.

Fig. 7.11. Cathode follower with separate resistances for bias (R_2 by-passed by C_2) and load (R_1).

Fig. 7.12. Cathode follower with alternative form of grid bias circuit.

The circuit of Fig. 7.10 does not apply the full degree of feedback (as in Fig. 7.8) unless the output resistance of the preceding stage is very much smaller than R_g . In other cases the feedback is reduced by a factor $R_o/(R_g + R_o)$ where $R_o = r_p R_L/(r_p + R_L)$ for the preceding stage.

The input resistance (R_i') due to the grid resistor (R_g in Fig. 7.10) is greater than R_g because the voltage across R_g is less than E_i .

$$\text{Thus } R_i' = E_i/i$$

where E_i = the input voltage

and i = the current through R_g (Fig. 7.10).

$$\text{Now } i = (E_i - E_x)/R_g$$

$$\text{and } E_x = A'E_i R_1/(R_1 + R_2).$$

$$\text{Therefore } R_i' = \frac{E_i}{i} = \frac{E_i R_g}{E_i - E_x} = \frac{E_i R_g}{E_i [1 - A' R_1/(R_1 + R_2)]}$$

$$\text{Therefore } R_i' = \frac{R_g}{1 - A' R_1/(R_1 + R_2)} \quad (8)$$

Special cases :

$$\text{If } R_2 = 0, \text{ i.e. } R_g \text{ returned to cathode : } R_i' = R_g/(1 - A') \quad (9a)$$

$$\text{If } R_1 = 0, \text{ i.e. } R_g \text{ returned to earth : } R_i' = R_g \quad (9b)$$

As a practical example take type 6J7 (triode connection) with the same conditions as previously (Example 1). The cathode load resistance ($R_1 + R_2$) is therefore 20 000 ohms. The cathode current (from the published data) is 6.5 mA while the grid bias is -8 volts. The resistance of R_2 is therefore 1230 ohms and R_1 is 18 770 ohms. If R_g is taken as 1 megohm the input resistance will be

$$R_i' = \frac{1}{1 - 0.93 \times 18\,770/20\,000} = \frac{20\,000}{20\,000 - 17\,500} = 8 \text{ megohms.}$$

The "looking-backwards" output terminal impedance with the circuit of Fig. 7.10 becomes (Ref. C28)

$$R_o' = \frac{1}{g_m \left[1 - \frac{R_s}{R_s + R_o} \cdot \frac{R_1}{R_1 + R_2} \right] + \frac{1}{R_1 + R_2} + \frac{1}{r_p}} \quad (10)$$

where R_s = source impedance of input voltage.

[Compare eqn. (10) with eqn. (5a) which applies to the circuit of Fig. 7.7.]

If R_s is not greater than one fifth of R_o , the effect on the output terminal impedance will usually be negligible.

If R_2 in Fig. 7.11 is by-passed, the a.c. load is lower than the static load resistance, which is usually undesirable unless R_2 is very much smaller than R_k . For example, if R_1 is at least 10 times the value of R_2 , the effect is usually so small as to be negligible. The input resistance is

$$R_i' = R_o / (1 - A') \text{ which is the same as (9a).}$$

The same remarks apply as for Fig. 7.10 with regard to the output resistance of the preceding stage.

An alternative circuit is shown in Fig. 7.12 in which the reactance of C_{11} , at the lowest frequency to be amplified, should be small compared with the resistance of R . The input resistance is approximately equal to R_o , provided that $(R + R_1)$ is much larger than the reactance of C_1 . With this circuit, the full degree of feedback is obtained irrespective of the output resistance of the preceding stage.

Another method of securing the correct grid bias voltage is to connect a positive grid bias to counteract the too-great negative bias due to R_k , either at the point D in Fig. 7.7 or at the low potential end of the grid resistor R_g . One method of obtaining the negative bias without requiring a separate bias voltage source is shown in Fig. 7.13 where R_3 and R_o form a voltage divider across the plate voltage source. The input resistance here is equal to R_o and R_3 in parallel.

Direct coupling to a cathode-follower is shown in Fig. 7.14. If the first valve has low plate resistance, it would be practicable to drive the cathode follower into the grid current region. The voltage drop in R_{L1} must equal the grid-plate voltage of the cathode follower.

FIG. 7-13

FIG. 7-14

FIG. 7-15

Fig. 7.13. Cathode follower with positive grid bias from voltage divider across $B+$, in order to counteract the too-great negative bias from R_k .

Fig. 7.14. Direct coupling to the grid of a cathode follower.

Fig. 7.15. Triode cathode follower showing capacitances.

(I) Input capacitance (purely resistive load)

The capacitance from grid to plate (C_{gp}) is effectively across the input (Fig. 7.15). The effect of the capacitance from grid to cathode is reduced by the ratio of the voltage from grid to cathode to the voltage from grid to earth. Thus

$$C_i' = C_{gp} + (1 - A')C_{gk} \quad (11)$$

$$\text{or } C_i' = C_{gp} + C_{gk}/(1 + A) \quad (12)$$

where A has the same meaning as with plate loading, being the stage gain without feedback, and A' is the actual stage gain, being always less than 1 (eqns. 1a and 1b). Note the reversed Miller Effect whereby the C_{gk} is reduced by the factor $1/(1 + A)$.

In a typical case, using type 6J7-GT (triode connection):—

$$A' = 0.93; C_{gp} = 1.8 \mu\text{F}; \text{ and } C_{gk} = 2.6 \mu\text{F}.$$

$$C_i' = 1.8 + 0.07 \times 2.6 = 1.8 + 0.18 = 1.98 \mu\text{F}$$

This may be compared with an input capacitance of $22.4 \mu\text{F}$ under equivalent plate loaded conditions.

(J) Output capacitance

The capacitance from plate to cathode (C_{pk}) and also the capacitance from heater

to cathode (C_{hk}) are across the output (Fig. 7.15). The voltage across the capacitance from grid to cathode (C_{gk}) is $(1 - A')e_i$ and the current through C_{gk} is, therefore, $(1 - A')e_i \cdot j\omega C_{gk}$. The current which would flow through C_{gk} if connected directly across R_k is $A'e_i \cdot j\omega C_{gk}$. Therefore, the effect of C_{gk} connected between grid and cathode is the same as that of a capacitance of $[(1 - A')/A'] C_{gk} = C_{gk}/A$ connected across R_k . It is assumed that the source of input voltage has a resistance and a reactance each negligibly small in comparison with the reactance of C_{gk} . With this assumption the effect of the capacitance from grid to plate (C_{gp}) is zero, since it merely shunts the input voltage.

Thus, the output capacitance (C_o') under the assumed conditions is given by

$$C_o' = C_{pk} + C_{hk} + C_{gk}/A \quad (13)$$

This capacitance is effectively shunted across R_o' (see eqn. 5).

In the case of type 6J7-GT (triode connection), $C_{pk} = 17.0 \mu\text{F}$, $C_{hk} = 10.5 \mu\text{F}$ (approx.), $C_{gk} = 2.6 \mu\text{F}$, and $A' = 0.93$ (see Example 1).

Therefore $C_o' = 17.0 + 10.5 + 2.6 (0.07/0.93) = 27.7 \mu\text{F}$.

This is effectively in shunt with the output resistance (R_o') of 47 ohms. In the plate-loaded case there would be a capacitance of $17.0 \mu\text{F}$ shunted across 6900 ohms.

In all practical cases, both for input and output capacitances, it is necessary to make allowances for stray capacitances in addition to the valve capacitances.

(K) Special considerations with pentodes

The discussion so far has been principally confined to triodes, or pentodes connected as triodes. It is readily seen that if a pentode is operated with the screen voltage equal to the plate voltage, without special precautions

FIG. 7.16

Fig. 7.16. Pentode cathode follower with screen by-passed to cathode.

to isolate the screen and plate, the result is equivalent to triode operation. The reason is that there is, in the cathode circuit, an impedance which is common to both plate and screen currents, so that the signal voltage drop across it affects the voltages of both plate and screen. Under these conditions the valve ceases to behave like a pentode.

If it is desired to obtain pentode operation, the voltage between screen and cathode must be maintained steady and free from signal frequency fluctuations. This may be done by connecting an impedance (either a voltage dropping resistor or a choke) between the plate and the screen, and by-passing the screen to the cathode by means of a sufficiently large capacitance (Fig. 7.16).

The screen dropping resistor R_{p2} is effectively in parallel with R_k so far as signal voltages are concerned. Unless R_{p2} is more than 20 times greater than R_k , allowance should be made for its effect.

If the by-pass condenser (C) is returned to earth instead of to the cathode the result is, again, effectively triode operation except that the screen may be operated at a

FIG. 7.17

Fig. 7.17. Voltage relationships in pentode cathode follower.

voltage lower by a fixed amount than that of the plate. For example, if the static voltage from cathode to plate is 200 volts, and from cathode to screen 100 volts, then the voltage from screen to plate is 100 volts (Fig. 7.17). But, when a signal voltage is being amplified, the cathode voltage has a signal-frequency component which may reach a peak value of, say, 120 volts (see diagram). This makes the cathode 20 volts more positive than the screen, or this may be expressed the other way around as the screen being 20 volts negative to the cathode. The result is

plate-current cut-off and severe distortion, which can only be avoided by a reduced output voltage. In the case of pentode operation, with the screen by-pass condenser returned to the cathode (Fig. 7.16) this type of overloading cannot occur.

When valves having high mutual conductance are connected as triodes, it may be found that parasitic oscillation occurs at a very high frequency. This may be prevented by connecting a 100 to 500 ohm non-inductive resistor in the link between plate and screen, using short leads.

(L) Voltage gain with pentodes

Owing to the very high values of μ with most pentodes, eqn. (2) may be taken as being almost exact:

$$A' = \frac{g_m R_k}{1 + g_m R_k} \quad (2)$$

where g_m = pentode mutual conductance under operating conditions in mhos.

In Example 1, the pentode g_m may be taken as being $(I_b/I_k) \times \text{triode } g_m$; i.e. $0.8 \times 1900 = 1520$ micromhos.

With $R_k = 20\,000$ ohms,

$$A' = \frac{1520 \times 20\,000 \times 10^{-6}}{1 + 1520 \times 20\,000 \times 10^{-6}} = 0.97.$$

Values of A' up to about 0.99 are practicable with pentodes, using higher values of load resistance.

(M) Input capacitance with pentodes, screen by-passed to cathode (Fig. 7.16)

The input capacitance with pentode operation is different from that with triode operation of the same valve. The capacitance from grid to plate may be neglected, and the total input capacitance is approximately given by

$$C_i' = (1 - A') \times \text{pentode input capacitance} \quad (14)$$

In the case of type 6J7-GT the pentode input capacitance is $4.6 \mu\text{F}$ and with a stage gain (A') of 0.97 the input capacitance will be $0.03 \times 4.6 = 0.14 \mu\text{F}$. This is less than one fourteenth the input capacitance of the same valve with triode connection under similar conditions (previously shown to be $1.98 \mu\text{F}$).

If the screen is by-passed to earth the input capacitance will be the same as for triode operation.

(N) Output capacitance with pentodes (screen by-passed to cathode)

With pentode operation the screen and suppressor are effectively at cathode potential at signal frequency (Fig. 7.16). The "pentode output capacitance" is the capacitance from the plate to all other electrodes except the signal grid and will therefore take the place of the plate-to-cathode capacitance in a triode (eqn. 13). The output capacitance is therefore given by

$$C_o' = \text{pentode output capacitance} + C_{hk} + (1/A') \times \text{pentode input capacitance} \quad (15)$$

In the case of type 6J7-GT with a stage gain of 0.97, the pentode output capacitance is $12 \mu\text{F}$, and the pentode input capacitance $4.6 \mu\text{F}$, so that C_o' is $12 + 10.5 + 0.14 = 22.6 \mu\text{F}$. This may be compared with $27.7 \mu\text{F}$ for triode operation under similar conditions.

(O) Circuit to avoid screen current through the load resistance

With the normal pentode cathode follower, the screen current passes through the load resistance with resulting complications (see also Sect. 5). One way of avoiding these is shown in Fig. 7.18 which produces results identical with those of the cathode follower. The input is applied between grid and plate, the load resistance is in the plate circuit, and the cathode bias resistor has the same value as for normal operation. It has the disadvantage that neither input terminal is earthed, and transformer input is necessary.

FIG. 7.18

Fig. 7.18. Alternative to the cathode follower, giving similar results, with input applied between grid and plate.

(P) Circuit to make the screen current constant

One other method of avoiding the troubles caused by the screen current involves the use of an additional valve to apply signal voltage of the correct value and phase to the screen, and thereby maintain the screen current constant (Ref. C25).

(Q) Screen-coupled cathode follower

The cathode of a cathode follower may be directly coupled to the screen of the following stage, this being particularly valuable in d.c. amplifiers. See Ref. C26, also Chapter 12 Sect. 9(vi).

(R) "Infinite impedance detector"

The circuit arrangement of the cathode follower is the same as for the so-called "infinite impedance detector" or "reflex detector," but in the latter case it is essential for the plate current to cut off for part of every r-f cycle.

For further information see Chapter 27 Sect. 1(ii)D.

(S) Amplification at all frequencies—complex load

It is impossible in practice to have a purely resistive load owing to the unavoidable effect of the interelectrode capacitances plus stray wiring capacitances.

When the load is a resistance in parallel with a capacitance, the input resistance (and conductance) may become negative, thus leading to oscillation under certain conditions. This may be prevented, where necessary, by the addition of a non-inductive grid-stopper of 100 to 2000 ohms resistance; in resistance-coupled a-f applications a grid stopper is unnecessary. When an inductance is coupled to the grid circuit (e.g. the secondary of an a-f transformer) it may be necessary to shunt it by means of a fairly low value of resistance to avoid instability.

When the load is inductive the input resistance and conductance are always positive.

The input reactance is always capacitive.

References C14, C20.

(T) Gain with capacitive load

When the load impedance is a resistance R_k (as in Fig. 7.16) shunted by a capacitance C_k , the gain is given approximately by (Ref. C6),

$$A' \approx \frac{g_m R_k}{1 + g_m R_k} \sqrt{\frac{1}{1 + \left(\frac{f/f_0}{1 + g_m R_k}\right)^2}} \quad \angle \theta \quad (16)$$

where $\mu \gg 20$

f = frequency at which the gain is calculated,

$$f_0 = 1/2\pi R_k C_k$$

and $\theta = \tan^{-1} - \left(\frac{f/f_0}{1 + g_m R_k} \right)$.

The expression within the square root sign in eqn. (16) is known as the **relative gain**, and has been plotted graphically (Ref. C6b, Data Sheet 39). The **phase angle** θ has also been plotted (Data Sheet 41).

References C6, C9; Reich (Ref. A30) pp. 166-168 equations 6-34 to 6-34F.

The transient performance under pulse conditions is given in Refs. J1, J5, J6.

(U) Input impedance with capacitive load

Input resistance

$$R_i' \approx \frac{(1 + g_m R_k)^2 + (f/f_0)^2}{\omega C_{gk} R_k g_m (f/f_0)} \quad \text{when } \mu \gg 1. \quad (17)$$

Input capacitance

$$C_i' \approx C_{gp} + C_{gk} \frac{1 + g_m R_k + (f/f_0)^2}{(1 + g_m R_k)^2 + (f/f_0)^2} \quad \text{when } \mu \gg 1 \quad (18)$$

References C6, C9, C20, J7; Sturley (Ref. C34) Vol. 2, pp. 119-120.

(V) Plate resistance with capacitive load

$$r_p' = r_p \left[1 + \frac{g_m R_k}{1 + j(f/f_0)} \cdot \frac{\mu + 1}{\mu} \right] \quad (19)$$

(W) Effect of impedance of input voltage source

This is covered partly by Lockhart (Ref. C6) and more completely by Jeffery (Ref. C9)

(X) Wide band amplifiers

The cathode follower is a valuable method of coupling in wide band amplifiers (Refs. C2, C10, C14).

(Y) Cut-off effect and overloading with capacitive load

When a cathode follower with a capacitive load has a quickly-changing voltage applied to its input, the plate current tends to cut off and positive grid current tends to flow even with input voltages less than those practicable with low frequency sine-wave input. At low input voltages it behaves quite normally, and the time constant of its load impedance (R_k and C_k in parallel) is

$$R_k C_k r_p' / (r_p' + R_k).$$

When the plate current has been cut off, the time constant becomes $R_k C_k$, which is more than μ times greater (it is assumed that R_k is not less than r_p), and the advantages of the cathode follower are lost. It is therefore essential to ensure that plate-current cut-off never occurs. This effect occurs with a rectangular waveform, a steep saw-tooth waveform or with a high frequency sinewave input.

References C13, C15, J3, J4, J5, J6, J9

(Z) Noise in cathode followers

A triode cathode follower has the same reflected noise voltage in the grid circuit, and the same reflected equivalent noise resistance as when used with plate loading. The high input resistance has the effect of improving the signal/noise ratio.

A pentode cathode follower always has a higher equivalent noise resistance than a triode, but the noise resistance is greater when the screen is by-passed to earth than to the cathode.

Refs. B1, B2, C6a (Part 3-A), J12.

(ii) The cathode-degenerative amplifier and phase splitter

With conventional plate loading, the whole load is in the plate circuit; with the cathode follower the whole load is in the cathode circuit. We now consider the case when part of the load is in the plate circuit and part in the cathode circuit.

Fig. 7.19 shows the general form of the cathode degenerative amplifier with plate load Z_L and cathode load Z_k . The output may be taken from K and earth, or from P and earth, or from both.

(A) Unbypassed cathode resistor

Fig. 7.20 is a particular case commonly known as the unbypassed cathode resistor.* Although not shown in the diagram, there are valve and stray capacitances which can only be neglected at low audio frequencies; this condition will be assumed as a first approach. Here R_L is the load resistance, R_k is the unbypassed cathode resistor and R_g the grid resistor. In this application R_k usually has a much lower resistance than R_L . If the signal current through the valve and through R_L is called I_p , then the signal voltage drop across R_k is $R_k I_p$, which is proportional to the signal current through the load; hence the current feedback. The formulae used below are taken from Sect. 1(iii), putting R_k in place of R_3 .

Gain (equation 23, Section 1):

$$A' = \frac{\mu R_L}{(\mu + 1)R_k + r_p + R_L} \quad (20a)$$

For pentodes

*For graphical treatment see Sect. 5(v) and (vi).

$$A' \approx \frac{g_m R_L}{g_m R_k + (r_p + R_L)/r_p} \quad (20b)$$

Ratio of gain with and without feedback

From equation (24a) Section 1,

$$\frac{A'}{A} = \frac{1}{1 + \mu R_k / (r_p + R_k + R_L)} \quad (21)$$

or as a rough approximation for triodes

$$A'/A = R_L / (R_L + \mu R_k) \quad (22)$$

An alternative exact form is

$$A'/A = \frac{1}{1 + g_m R_k r_p / (r_p + R_k + R_L)} \quad (23a)$$

or as a rough approximation for pentodes

$$A'/A \approx 1 / (1 + g_m R_k) \quad (23b)$$

From equations (24a) and (24b) of Section 1:

$$\frac{A'}{A} = \frac{1}{1 - \gamma A} = \frac{1}{1 - \frac{\mu \gamma R_L}{r_p + R_L(1 - \gamma)}} \quad (24)$$

where $-\gamma = R_k/R_L$.

Example (1): 6J5 with $\mu = 20$, $r_p = 20\,000$ ohms (under resistance-coupled conditions), $R_L = 100\,000$ ohms, $R_k = 2700$ ohms.

$$A'/A = 1 / [1 + 20 \times 2700 / (20\,000 + 2700 + 100\,000)] = 0.695.$$

Using the rough approximation, $A'/A \approx 0.65$.

Example (2): Pentode with $g_m = 2000$ micromhos and

$$R_k = 2000 \text{ ohms, } A'/A \approx 1 / (1 + 4) \approx 1/5.$$

With a pentode, the gain is approximately halved when $R_k = 1/g_m$ (see eqn. 23b).

Thus when $g_m = 2000$ micromhos, a value of $R_k = 500$ ohms will halve the gain and halve the distortion.

FIG. 7.19

FIG. 7.20

FIG. 7.21

Fig. 7.19. General circuit of a cathode-degenerative amplifier.

Fig. 7.20. Resistance coupled amplifier with unbypassed cathode bias resistor, giving cathode degeneration with current feedback.

Fig. 7.21. Resistance coupled pentode with unbypassed cathode bias resistor.

Input resistance: As the grid resistor R_g (Fig. 7.20) is returned to earth, the input resistance is R_g . If it had been returned to cathode, eqn. (30) Sect. 1 could then be applied, putting R_g in place of r_i :

Input resistance with R_g returned to cathode—

$$r_i' = R_g(1 + \mu R_k / R_L) = R_g[1 + \mu R_k / (R_L + R_k + r_p)] \quad (25)$$

Effective plate resistance (equation 25a, Sect. 1)

$$r_p' = r_p + \mu R_k \quad (26)$$

$$\text{and } r_p'/r_p = 1 + \mu R_k / r_p \quad (27)$$

With the arrangement of Fig. 7.20, the total load on the valve is $R_L + R_k$ and this is the value which should be used in drawing the loadlines on the characteristics. The value of R_k is, however, regarded as fixed, while R_L is regarded as capable of being varied—otherwise the “output resistance” would be meaningless. In practice,

R_L may be modified by the connection to point P of a coupling capacitance and following grid resistor, thus providing an a.c. shunt load.

If the valve is a pentode, the suppressor is normally connected to the cathode, although it may be connected to earth if the voltage drop across R_k is very small; the screen should be by-passed to the cathode (Fig. 7.21). In calculating the grid bias, allowance should be made for the d.c. screen current through R_k .

If a less degree of feedback is desired, portion of R_k may be by-passed. In Fig. 7.22, the value of R_k for calculations of gain, r_i' and r_o' should be R_2 , but for grid bias should be $(R_1 + R_2)$. Alternatively, R_2 could be by-passed, instead of R_1 .

FIG. 7.22

FIG. 7.23

FIG. 7.24

Fig. 7.22. Cathode degenerative amplifier with a small degree of current feedback.

Fig. 7.23. Cathode degenerative amplifier with a large degree of current feedback.

Fig. 7.24. Cathode degenerative amplifier with an alternative method of obtaining grid bias.

If a higher degree of feedback is desired there are several alternatives. In Fig. 7.23 $(R_1 + R_2) = R_k$ for signal frequencies, but only R_2 is effective in producing grid bias. C_1 should have a reactance much lower than $(R_3 + R_1)$. As a slight modification, C_1 may be returned to any tapping point along R_1 and R_2 , to give any desired degree of feedback between zero and maximum. An alternative modification is to by-pass R_2 , and to return C_1 to any tapping point along R_1 . Finally, the arrangement of Fig. 7.24 provides a positive voltage from the voltage divider R_4 , R_5 which may be adjusted to give the correct bias voltage from grid to cathode.

When R_L and R_k are not purely resistive, they may be replaced by Z_L and Z_k in the expressions for gain which then become vectors.

Current feedback is undesirable in transformer loaded amplifiers for it tends to stabilize the output transformer's magnetizing current (i.e. make it sinusoidal) and thus produce a distorted output voltage.

FIG. 7.25

Fig. 7.25. Conventional phase splitter.

(B) Phase splitter

If R_k is made equal to R_L , we have the well known "phase splitter" (Fig. 7.25), in which the output from P to earth is equal and opposite in phase to that from K to earth. Obviously $(R_1 + R_2) = R_k = R_L$, and the same signal current (I_p) passes through R_L , r_p , R_2 and R_1 . The grid resistor R_g is returned to a point on R_k to give the desired grid bias ($E_c = -R_2 I_b$).

The gain to either output channel is then

$$A' = \frac{\mu R_L}{(\mu + 2)R_L + r_p} \quad (28)$$

which is always less than 1. In a typical example where $\mu = 20$ and $R_L = 4r_p$, $A' = 0.9$.

The input resistance is

$$R_g' = \frac{R_g}{1 - A'R_1/(R_1 + R_2)} \quad (29)$$

If $A' = 0.9$ and $R_1 = 9R_2$, then $r_i' = 5.25R_g$.

If R_g is returned to earth, or to a voltage divider, or to a separate bias supply, the input resistance is R_g .

If R_g is returned to cathode, or if R_2 is by-passed, then $r_i' = R_g/(1 - A') \approx 10R_g$.

If R_2 is by-passed, then R_1 must be increased to equal R_L and channel K should be taken from point X. If channel K is taken from point X_1 and $R_1 = R_L$, then the by-passing of R_2 is unimportant, except that the maximum output voltage will be reduced slightly; this is of greater importance with low μ valves.

The effective output resistance is different for the two output channels, since P operates with current feedback and K with voltage feedback.

$$\text{Channel P: } r_p' = (\mu - 1)R_k \text{ where } R_k = R_L \quad (30)$$

(from equation 25a, Sect. 1)

$$\text{Channel K: } r_p' = (r_p + R_L)/(\mu + 1) \quad (31)$$

(from equation 3)

but this does not affect the balance at either low or high frequencies when the total effective impedance of channel P is equal to that of channel K. The same signal plate current which flows through one impedance Z_p also flows through the other impedance Z_K , and if $Z_p = Z_K$ then the two output voltages are equal. The ratio of the output voltages is $R_L : R_k$ at low frequencies and $Z_p : Z_K$ at any high frequency. The capacitive component of Z_p is the sum of the input capacitance of the following stage, wiring and stray capacitances, and the output capacitance of P channel (eqn. 33), and similarly with Z_K (eqn. 34). The output capacitances of the phase splitter normally differ by only 1 or 2 μF , having a negligible effect on the balance at 10 000 c/s—see also pages 522-523.

Input capacitance (Fig. 7.25)

$$C_i' = C_{gk}/(1 - A') + C_{gp}(1 + A') \quad (32)$$

Output capacitance

$$\text{P channel: } C_o' = 2C_{pk} + C_{gp}(1 + 1/A') \quad (33)$$

$$\text{K channel: } C_o' = 2C_{pk} + C_{gk}(1/A' - 1) + C_{hk} \quad (34)$$

The equivalent source impedance that determines the high frequency attenuation for each channel due to shunt capacitance is given by

$$R_0 = \frac{r_p R_L}{r_p + R_L (\mu + 2)} \quad (34a)$$

and is of the order of 1000 ohms. Hence the excellent high frequency response characteristic (Ref. A33).

(C) Tone control with cathode degenerative amplifier

If R_k (Fig. 7.20) is shunted by a capacitor C_k , it will cause a rise in gain which will reach the maximum of a normal non-degenerative amplifier at frequencies where the reactance of C_k is small compared with R_k . C_k may also be connected across portion of R_k .

If R_k is shunted by an inductor L_k , it will cause a similar rise of gain at low frequencies.

(D) Degenerative cathode impedance ($R_k + L_k$)

A degenerative cathode impedance with R_k in series with L_k may be used with r-f or i-f amplifiers.

(F) Other forms of cathode degenerative amplifiers

Cathode-coupling is described in Section 2(viii).

A cathode-degenerative amplifier may be used as the first or second stage of an amplifier having an overall feedback loop, to provide improved stability and a flatter frequency response characteristic—see Sect. 3(v)E and 3(vii)C.

(iii) Voltage feedback from secondary of output transformer

Voltage feedback* may be taken from the secondary of the output transformer and applied to the grid or any other suitable electrode in the power amplifier valve or any earlier stage. Fig. 7.26 shows one form with feedback to the grid of the power amplifier valve. This is limited to transformer input, and there is a further limitation

*For graphical treatment see Sect. 5(iii) and (iv).

in that the voltage across the voice coil may not be great enough to provide sufficient degeneration. It is important to avoid accidental reversal of the secondary terminals. This, and all its modifications, may be treated as pure voltage feedback following the formulae of Sect. 1, at least in the middle frequency range where β is equal to T_2/T_1 , the transformer turns or voltage ratio. It has the properties of maintaining constant the voltage across the secondary, thereby avoiding the effects of transformer leakage inductance at high frequencies, and of reducing the transformer distortion. Unfortunately, at very low and very high audio frequencies, the phase angle introduced by the output transformer tends to cause instability, the tendency being more pronounced as the feedback is applied over 2 or 3 stages. This subject is treated in detail in Section 3.

Fig. 7.26. Voltage feedback from secondary of output transformer, over one stage.

FIG. 7.26

The push-pull form is merely a mirror image of the single-ended variety, and involves two separate secondary windings on the input transformer, and a centre-tap on the secondary of the output transformer, which is earthed.

In either case, if the feedback voltage is greater than desired, the connection may be taken from a voltage divider across the voice coil (or each half of the transformer secondary).

FIG. 7.27

Fig. 7.27. Voltage feedback from secondary of output transformer to cathode of preceding stage.

FIG. 7.28

Fig. 7.28. Voltage feedback from secondary of output transformer to grid of preceding stage.

A form suitable for feedback over two stages is shown in Fig. 7.27 where the feedback voltage is reduced by the voltage divider R_1R_2 and applied to the cathode of V_1 . The voltage divider total resistance ($R_1 + R_2$) should be at least 20 times the voice coil impedance, while R_1 should preferably be less than one tenth of R_3 , otherwise there will be an appreciable amount of negative current feedback* in V_1 . Here

A = voltage gain from grid of V_1 to plate of V_2 ,

$$\beta = \left(\frac{R_1}{R_1 + R_2} \right) \left(\frac{T_2}{T_1} \right) \quad (35)$$

and $r_i' = R_i$ at mid frequencies

$$(36)$$

Portion of the plate current of V_1 will flow through the secondary winding. It is sometimes found that a very small condenser C connected from the plate of V_2 to the cathode circuit of V_1 reduces the tendency to instability.

A modified form providing feedback to the grid circuit of V_1 is shown in Fig. 7.28 (note the reversed connections to the secondary of the output transformer). This

*In practice, this may be desirable.

avoids d.c. through the secondary winding, but the impedance of the preceding stage (R_0) affects the value of β , A being unchanged,

$$\beta = \left(\frac{R_1}{R_1 + R_2} \right) \left(\frac{T_2}{T_1} \right) \left(\frac{R_0}{R_0 + R_4} \right). \quad (37a)$$

In this case the input resistance is decreased because the feedback voltage is applied in shunt from grid to cathode,

$$r_i' = R_1 / (1 - \beta A). \quad (37b)$$

This principle is also incorporated in Fig. 28.3 where feedback is taken from the secondary to a tapping on the volume control.

A further modification, in which the amount of feedback decreases as the volume control is increased, is described in Chapter 35 (Fig. 35.3).

See Sect. 2(vi) below for an analysis of a two stage amplifier with feedback from the secondary of the output transformer.

(iv) Voltage feedback from plate—transformer-input

A typical power output stage with negative voltage feedback from the plate to the bottom end of the secondary of the input transformer is shown in Fig. 7.29. The reactance of C is normally small compared with the total resistance of the voltage divider ($R_1 + R_2$). The condenser C is placed in this position instead of between R_2 and plate since in the latter position the circuit may oscillate owing to the capacitance of C to grid. If there is a tendency to oscillate due to the leakage inductance of the transformer, a small condenser or a resistance, or both, may be connected across the input transformer secondary.

Fig. 7.29. Voltage feedback from the plate to the grid circuit, using transformer-coupled input.

This arrangement reduces the amplitude distortion resulting from saturation of the output transformer core at low frequencies, and improves the low-frequency response. It does not, however, counteract the effect of leakage reactance at high frequencies.

A = voltage gain of valve from grid to plate

$$\beta = R_1 / (R_1 + R_2)$$

and r_i' is extremely high, being unchanged by the feedback (valve input impedance alone).

The same method may be applied to a push-pull stage, but a transformer is required having two separate secondaries, and each valve must have its own feedback network. This circuit is not suitable for use with resistance coupling.

(v) Voltage feedback from plate—r.c.c. input

If it is desired to employ negative feedback from the plate to a resistance-capacitance input coupling, it is impossible to apply the feedback voltage in series opposition to the signal voltage. The only manner of applying it is, so to speak, in shunt with the input signal.

The simplest circuit is Fig. 7.30 in which V_1 is r.c. coupled to V_2 , and a feedback path $R_1 C_1$ is provided from plate to grid of V_2 . For normal applications C_1 is merely a blocking condenser to isolate grid and plate for d.c. The resistance R_1 acts as a shunt path for signal frequencies in much the same way as the Miller Effect; the circuit behaves as though an additional shunt resistance equal to $R_1 / (A_2 + 1)$ were connected from grid to earth, A_2 being the numerical voltage gain of V_2 . This decreased input resistance causes a reduction in overall amplification. The amplification of V_2 is not affected, but V_1 now has a heavy a.c. shunt load, leading to increased distortion and possible overloading. As an example, for the gain to be reduced to

half, the additional a.c. shunt resistance across R_p will be equal to the total resistance of r_{p1} , R_L and R_p in parallel. A larger than normal value of coupling condenser (C) will obviously be required.

Fig. 7.30. Voltage feedback from plate to grid, with resistance capacitance coupling. The feedback makes the a.c. shunt load on V_1 considerably less than R_p .

FIG. 7.30

As a modification of Fig. 7.30, R_1 may be made zero and C_1 may have a capacitance of about 10 to 100 μF to provide degeneration principally at high audio frequencies. This has been used very successfully in small receivers with very little margin of gain, but is only fully effective when no plate by-pass capacitor is used.

An improved circuit is Fig. 7.31 (Refs. E1, E3) in which R_1 and R_2 form a voltage divider across the primary of the output transformer, R_L being connected to the junction (X). If $(R_1 + R_2)$ is at least 10 times the load resistance of V_2 , the divider will have little effect on V_2 . It is obvious that the degree of feedback can be adjusted from zero to maximum by moving the tapping point X on the voltage divider from the B+ end to the plate end. If $R_s + R_L \gg R_1$, where $R_s = r_{p1}R_p/(r_{p1} + R_p)$,

$$\text{then } \beta \approx - \frac{R_s}{R_s + R_L} \cdot \frac{R_1}{R_1 + R_2} \quad (38)$$

An electrically equivalent circuit is Fig. 7.32 (Ref. E2) in which the two resistances R_3 and R_4 take the place of the three resistances R_L , R_1 and R_2 of Fig. 7.31. For identical operating conditions:

$$R_s = \frac{(R_1 + R_2)R_L}{R_2} \text{ and } R_4 = \frac{R_s R_L}{R_s - R_L} \quad (39)$$

The value of β in Fig. 7.32 is given by

$$\beta = - \frac{R}{R_4 + R} \text{ where } \frac{1}{R} = \frac{1}{r_{p1}} + \frac{1}{R_g} + \frac{1}{R_3} \quad (40)$$

FIG. 7.31

FIG. 7.32

Fig. 7.31. Voltage feedback applied in series with the load resistor. The reduction in effective resistance occurs in the load resistor itself.

Fig. 7.32. Electrically equivalent circuit to Fig. 7.31, using one less resistor.

Both these circuits (Fig. 7.31 and 7.32) have the effect of reducing the effective load into which V_1 works. This has the merit of extending the response to higher audio frequencies. In Fig. 7.31 the effective value of R_L becomes

$R_L' = R_L / (|\beta| A_2 + 1)$ where $|\beta| = R_1 / (R_1 + R_2)$ and A_2 is the numerical voltage gain of V_2 . For example if $|\beta| = 0.1$ and $A_2 = 17$, the effective load resistance changes from R_L without feedback to $0.37 R_L$ with feedback. The load R_L' into which V_1 works is, however, not constant because A_2 varies due to distortion. This circuit is usually limited to values of $|\beta|$ not greater than say 0.05 to 0.1 for typical applications.

A similar effect occurs with the equivalent circuit Fig. 7.32 in which the feedback causes the effective value of R_4 to change to $R_4 / (A_2 + 1)$. In both circuits V_1 is preferably a pentode, although a high- μ triode may be used with less effectiveness.

Mezger (Ref. E4) has shown that it is equally valid to regard the plate resistance of V_1 (and consequently its amplification factor) as being reduced by feedback, leaving the external resistors unchanged.

(vi) Voltage feedback over two stages

Voltage feedback over two stages permits a wide choice of circuits, without the limitations which frequently arise with a single stage.

(A) One of the deservedly most popular circuits is Fig. 7.33 in which feedback is taken from the plate of V_2 to the cathode of V_1 . The most serious limitation to its use is that it cannot be applied without complications* to combined second detector and amplifier valves of the conventional type. It actually involves two types of feedback—the primary voltage feedback, and the subsidiary current feedback caused by the unbypassed cathode resistor in V_1 .

This is a form of Duerdoh's multiple feedback—see Sect. 3(v)E—and the two feedback voltages must be added together to determine the performance. The subsidiary feedback increases the stability by reducing the slope of the βA characteristic over a wide range of very low and a wide range of very high frequencies.

FIG. 7.33

FIG. 7.34

Fig. 7.33. Amplifier with voltage feedback from the plate of V_2 to the cathode of V_1 , also incidentally incorporating negative current feedback due to the unbypassed resistor R_{k1} .

Fig. 7.34. Simplified a.c. equivalent of Fig. 7.33 for calculations.

The following theoretical treatment† is based on the simplified a.c. diagram Fig. 7.34. Here V_1 has constants μ_1, g_{m1}, r_{p1} while V_2 has μ_2, g_{m2} and r_{p2} . Resistor R represents R_{L1} and R_{p2} in parallel. It is assumed that, unless otherwise specified, the impedance of the input voltage source (R_s) is zero.

The amplification of stage V_1 without negative current feedback is defined as A_1 where

$$A_1 = E_{g2}/E_{g1} = \mu_1 R / (R + R_k + r_{p1}) \quad (41a)$$

The amplification of stage V_2 is given by

$$A_2 = E_0/E_{g2} = \mu_2 R_{L2} / (R_{L2} + r_{p2}) \quad (41b)$$

$$\text{Also } \beta \approx R_k / (R_f + R_k) \quad (41c)$$

$$\text{Now } E_0 = A_1 A_2 E_{g1} \quad (41d)$$

$$E_i' = E_{g1} + E_k = E_{g1} + R_k I_k \quad (41e)$$

$$\text{and } I_k = [\mu_1 E_{g1} / (R + R_k + r_{p1})] + \beta E_0 / R_k \quad (41f)$$

$$= E_{g1} [\mu_1 / (R + R_k + r_{p1}) + \beta A_1 A_2 / R_k] \quad (41g)$$

(neglecting $E_i' / (R_{g1} + R_k)$ as being very small).

Applying these values in equation (41e)

$$E_i' = E_{g1} \left[1 + \frac{\mu_1 R_k}{R + R_k + r_{p1}} + \beta A_1 A_2 \right] \quad (41h)$$

$$\text{Also } E_0 = A_1 A_2 E_{g1} = \frac{\mu_1 R}{R + R_k + r_{p1}} \cdot A_2 E_{g1}$$

*See Fig. 35.3 for one possible arrangement.

†The Editor is indebted to Mr. E. Watkinson for this method. This method assumes that $(r_{p1} + R)$ is large compared with R_k , and that R_f is large compared with R_{L2} .

$$\begin{aligned}
 &= \left(\frac{\mu_1 R}{R + R_k + r_{p1}} \right) \left(\frac{E_i'}{1 + \beta A_1 A_2 + \mu_1 R_k / (R + R_k + r_{p1})} \right) A_2 \\
 &= \left(\frac{\mu_1 R}{R + R_k + r_{p1}} \right) \left(\frac{A_2 E_i' (R + R_k + r_{p1})}{R + R_k + r_{p1} + \mu_1 R_k + \beta A_1 A_2 (R + R_k + r_{p1})} \right) \\
 &= E_i' \left(\frac{A_2 \mu_1 R}{R + (\mu_1 + 1) R_k + r_{p1} + \beta A_1 A_2 (R + R_k + r_{p1})} \right)
 \end{aligned}$$

$$\text{Therefore } E_o = E_i' \frac{A_2 \mu_1 R}{\left[R_k \left(\frac{1 + \mu_1 + \beta A_1 A_2}{1 + \beta A_1 A_2} \right) + R + r_{p1} \right] [1 + \beta A_1 A_2]} \quad (41i)$$

Also when $R_k = 0$ there is no current feedback :

$$E_o = E_i' \frac{A_2 \mu_1 R}{R + r_{p1}} \quad (41j)$$

The overall amplification with feedback is given by

$$A' = E_o / E_i' \quad (41k)$$

while that without feedback is given by

$$A = E_o / E_i = A_2 \mu_1 R / (R + r_{p1}) \quad (41l)$$

$$\text{Therefore } \frac{A'}{A} = \left[\frac{A_2 \mu_1 R}{\left[R_k \left(\frac{1 + \mu_1 + \beta A_1 A_2}{1 + \beta A_1 A_2} \right) + R + r_{p1} \right] [1 + \beta A_1 A_2]} \right] \left(\frac{R + r_{p1}}{A_2 \mu_1 R} \right)$$

$$\text{Therefore } \frac{A'}{A} = \frac{R + r_{p1}}{\left[R_k \left(\frac{1 + \mu_1 + \beta A_1 A_2}{1 + \beta A_1 A_2} \right) + R + r_{p1} \right] [1 + \beta A_1 A_2]} \quad (41m)$$

Output impedance

The effect of the unbypassed cathode resistor depends on the resistance of the source (R_s).

$$\text{Let } \delta = R_s / (R_s + R_p) \quad (42a)$$

Let voltage E_o be applied across R_{L2} from an infinite impedance source with no input voltage applied to the amplifier.

$$\text{Then } I_o = \frac{E_o}{R_{L2}} + \frac{E_o}{r_{p2}} + \frac{E_o}{R_f + R_k} + \frac{E_o \beta \delta A_1 \mu_2}{r_{p2} + R_{L2}} \quad (42b)$$

The final term in eqn. (42b) is the effect of the voltage E_o , a fraction of which is fed back across R_k , and amplified by V_1 and applied to the grid of V_2 . The effect in the plate circuit of V_2 is the same as though a voltage $E_o \beta \delta A_1 \mu_2$ were applied to a series connection of r_{p2} and R_{L2} .

Thus the "looking backwards" output terminal impedance is given by

$$R_o' = \frac{E_o}{I_o} = \frac{1}{\frac{1}{R_{L2}} + \frac{1}{r_{p2}} + \frac{1}{R_f + R_k} + \frac{\beta \delta A_1 \mu_2}{r_{p2} + R_{L2}}} \quad (42c)$$

i.e. the effect of the feedback is to add another impedance,

$$\frac{r_{p2} + R_{L2}}{\beta \delta A_1 \mu_2},$$

in parallel with the output, as shown in Fig. 7.41.

Input impedance

$$R_i' = \frac{E_i'}{I_i'} = \frac{E_{o1} \left[1 + \frac{\mu_1 R_k}{R + R_k + r_{p1}} + \beta A_1 A_2 \right]}{E_{o1} / R_{o1}} \quad (42d)$$

$$\text{Therefore } R_i' = R_{o1} \left[1 + \frac{\mu_1 R_k}{R + R_k + r_{p1}} + \beta A_1 A_2 \right] \quad (42e)$$

$$\text{Therefore } \frac{R_i'}{R_i} = 1 + \frac{\mu_1 R_k}{R + R_k + r_{p1}} + \beta A_1 A_2 \quad (42f)$$

where R_i is defined as the input resistance when $R_k = 0$.

Conclusions

Eqn. (41m) shows that the effect of feedback in reducing gain in this circuit (Figs. 7.33 and 7.34) is not given simply by the product of the current feedback gain reduction and the voltage feedback gain reduction, each considered separately.

Eqn. (41h) indicates that the two feedback voltages are effectively added so far as their effect on gain is concerned. This is in line with Duerdorth's multiple feedback theory in Sect. 3(v)E.

Eqn. (42c) shows that the effective plate resistance of V_2 differs from that of an equivalent amplifier without current feedback only on account of δ . When the source impedance is zero, δ has the value unity, and the effective plate resistance of V_2 is identical with that of an equivalent amplifier with voltage feedback only.

It is obvious that current feedback in V_1 cannot directly affect the plate resistance of V_2 . The only indirect effect (through δ) is the result of partial application of the feedback voltage to the grid of V_1 , which must also affect the gain. In other words, the impedance of the input voltage source affects the gain, the effective plate resistance and the output resistance R_o' .

If the source is reactive, some non-linear frequency characteristic will occur—for example, if the source is a crystal pickup there will be some measure of bass boosting.

The circuit of Fig. 7.33 tends to produce peaks at low and high frequencies in the response characteristic unless the feedback factor is low. An analysis of the peaks has been made by Everest and Johnston (Ref. H5) based on the ideal condition of zero-impedance screen circuits and unbypassed cathode resistors; it also omits any complications arising from an output transformer. Methods for reducing or eliminating these peaks are described in Sect. 3(vi) and (vii).

The condenser C_1 in the feedback network of Fig. 7.33 is normally only a blocking condenser; it may, however, be designed to produce a fixed degree of bass boost. Alternatively, C_1 may remain as a blocking condenser and a second condenser inserted at point X to provide bass boosting; the latter may be shunted by a variable resistance to form a continuously variable tone control (see Chapter 15 Sect. 2 and Fig. 15.11).

It will be demonstrated in Sect. 3 that feedback over two stages of r.c. coupling is normally stable; this does not necessarily hold if cathode or screen by-pass condensers are used or if an iron-cored transformer forms any part of the feedback loop.*

(B) Feedback from secondary of output transformer

See Sect. 2(iii) and Figs. 7.27 and 7.28 for the general description of such an amplifier.

An illustration of the effects of negative feedback on a simple 2 stage a-f amplifier can be obtained by calculating† the low frequency response of the circuit of Fig. 7.35. In this simplified circuit batteries are used as voltage sources to minimize calculation, but the effect of cathode by-passes (or of screen by-passes) could be covered without difficulty by using Figs. 12.11 A and B and 12.3 A and C.

The values of components used in interstage couplings have also been chosen for simplicity. Referring to Table 42 in Chapter 38 it will be seen that the reactance of a $0.01 \mu\text{F}$ condenser (the coupling between the 6AV6 and 6AQ5) at 50 c/s is 318 000 ohms. It is assumed that the series impedance of R_7 , and the parallel combination of R_8 and the 6AV6 plate resistance [see Chapter 12 Sect. 2(xiii) Eqn. 15] is also 318 000 ohms, so that at 50 c/s the reactance and resistance of the interstage coupling network are equal.

*The feedback loop is the complete path, commencing from the point to which the feedback is returned, through the amplifier to the point from where the feedback is taken, back through the feedback network to the starting point.

†The Editor is indebted to Mr. E. Watkinson for the calculation of this example.

Similarly the reactance of the output transformer primary at 50 c/s is equal to the plate resistance of the 6AQ5 in parallel with the reflected load and winding resistances (coupling 3).

Fig. 7.35. Simple feedback amplifier in which setting of volume control alters feedback.

Movement of the input volume control is assumed to have no effect on the frequency ($12\frac{1}{2}$ c/s) at which the reactance of the input condenser is equal to the resistance in series with it, say 2.55 megohms (coupling 1).

The amplification factor, μ , of the 6AV6 is 100 and its plate resistance, r_p , 80 000 ohms, so the mid-frequency 6AV6 gain, A_1 [see Chapter 12 Sect. 2(vii)] is

$$A_1 = \frac{100 \times 73\,000}{80\,000 + 73\,000} = 48$$

where 73 000 ohms is the value of R_s and R_r in parallel.

The 6AQ5 μ is 210 and its r_p 52 000 ohms so that the 6AQ5 gain

$$A_2 = \frac{210 \times 5000}{52\,000 + 5000} = 18.4.$$

The output transformer impedance ratio is 5000/1.7 so that its gain

$$A_3 = \sqrt{1.7/5000} = 1/54.$$

Total gain from 6AV6 grid to voice coil:

$$A = A_1 \times A_2 \times A_3 = 48 \times 18.4/54 = 16 \text{ times} = 24.1 \text{ dbvg.}^*$$

When the volume control is turned to its minimum setting, one half of the output voltage is applied to the amplifier input, i.e. $\beta = -\frac{1}{2}$ and the factor

$$\frac{1}{1 - \beta A} = \frac{1}{1 + 16 \times \frac{1}{2}} = 9.$$

As the volume control is turned up, a smaller amount of the negative feedback voltage is applied to the 6AV6 control grid, and when the control is 50 000 ohms from its maximum setting only one quarter of the previously used feedback voltage is effective (ignoring the shunting effect of R_s). In this case

$$\frac{1}{1 - \beta A} = \frac{1}{3}.$$

The low frequency response curves will be calculated for each of these volume control settings, but it is first necessary to obtain the response of the amplifier without feedback. This is done in Table 1. Lines 1 and 2 of Table 1 are obtained from Figs. 12.9A and B with $12\frac{1}{2}$ c/s taken as the frequency for 70.7 per cent. voltage gain (when the reactance is numerically equal to the resistance) in line 1, and 50 c/s in line 2. Thus for the 25 c/s response in line 1

Actual frequency

$$\frac{\text{Frequency for 70.7 per cent. frequency response}}{\text{Actual frequency}} = 2$$

so that attenuation = 1 db and phase shift = 27° , and so on for each of the other frequencies in the two lines.

Line 3 is obtained by adding twice the attenuation and phase shift of line 2 (because there are two 50 c/s couplings) to line 1.

Line 4 is the result of adding the mid-frequency gain of the amplifier (24.1 db) to the attenuation and phase shift at each of the tabulated frequencies. This gives the frequency response as plotted at A in Fig. 7.36.

In line 5 the gain A is expressed numerically, giving the actual gain at each frequency.

*Gain expressed in decibels of voltage gain—see Chapter 19 Sect. 1(vi)A.

Table 2 sets out the calculations necessary to obtain the modification of the frequency response by the application of feedback when $\beta = -\frac{1}{2}$. Line 1 results from converting the attenuation expressed in db in line 3 of Table 1 to fractions, and line 2 is obtained by multiplying the mid-frequency gain, the attenuation and phase (for the frequency concerned) by β . The result is βA which is plotted in Fig. 7.37.

Fig. 7.36. Frequency response of amplifier of Fig. 7.35 with zero feedback and two selected values of feedback.

For the method of plotting this curve and for its significance see Sect. 3 of this Chapter. It should be noted that once the βA curve has been obtained the effects of feedback on the gain and phase shift of the amplifier can readily be obtained graphically as discussed below. Lines 3 to 9 of Table 2 are the mathematical equivalents of the measurements mentioned below (1 and 5) which give the degree of degeneration or regeneration and the phase shift with feedback between output and input voltages at a given frequency.

Fig. 7.37. Polar diagram for two selected values of feedback.

TABLE 1.

	Mid-frequency	200 c/s	100 c/s	50 c/s	37½ c/s	25 c/s	20 c/s	18½ c/s	16 c/s	12½ c/s

(2) Coupling 2 or 3 Attenuation (db)	0 ∠ 0°	0.3 ∠ 14°	1.0 ∠ 27°	3.0 ∠ 45°	4.5 ∠ 53°	7.0 ∠ 63°	8.5 ∠ 68°	9.1 ∠ 69.5°	10.3 ∠ 72°	12.3 ∠ 76°
(3) Couplings 1 + 2 + 3. Attenuation (db)	0 ∠ 0°	0.6 ∠ 32°	2.1 ∠ 61°	6.3 ∠ 104°	9.5 ∠ 124°	15.0 ∠ 153°	18.4 ∠ 168°	19.7 ∠ 173°	22.7 ∠ 182°	27.6 ∠ 197°
(4) Gain $A = A_1 \times A_2 \times A_3$ (db)	24.1 ∠ 0°	23.5 ∠ 32°	22.0 ∠ 61°	17.8 ∠ 104°	14.6 ∠ 124°	9.1 ∠ 153°	5.7 ∠ 168°	4.4 ∠ 173°	1.4 ∠ 182°	-3.5 ∠ 197°
(5) Gain A	16 ∠ 0°	14.9 ∠ 32°	12.6 ∠ 61°	7.7 ∠ 104°	5.3 ∠ 124°	2.9 ∠ 153°	1.9 ∠ 168°	1.66 ∠ 173°	1.17 ∠ 182°	0.67 ∠ 197°

Lines 3 and 4 are the values for the sine and cosine of the angle of phase shift [see Chapter 38 Table 72 for magnitude; Chapter 6, Sect. 3(iii) for sign]. Line 5 expresses $1 - \beta A$ in the form $a + jb$. Multiplying the magnitude of βA in line 2 by the sine of the associated angle gives the j term and multiplying by the cosine and adding 1 (because of the 1 in $1 - \beta A$) gives the real term. For example, at 100 c/s, $1 + 6.3 \times 0.4848 = 4.05$ and $6.3 \times 0.8746 = 5.5$ so that $1 - \beta A = 4.05 + j 5.5$.

Lines 6 and 7 convert $1 - \beta A$ to polar co-ordinates again (the change to rectangular co-ordinates was necessary to add 1 to βA), line 6 being expressed in the form of the square root of the sum of the squares of the two terms in line 5 at the angle whose tangent is the imaginary term divided by the real term, e.g. at 100 c/s the angle is $\tan^{-1} 5.5/4.05 = \tan^{-1} 1.36 = 54^\circ$ to the nearest degree. Where negative terms occur the appropriate quadrant is determined from the knowledge of the sign of the sine, cosine and tangent, all of which are known at this stage.

Line 8 is the reciprocal of line 7, so that magnitudes are divided into unity, and angles are reversed in sign. In line 9 the magnitudes are expressed in db, and in line 10 the original gain A at each frequency is multiplied by $1/(1 - \beta A)$ to give the response of the amplifier with feedback. Since lines 9 and 4 are both expressed in db, the multiplication is carried out by adding the values in decibels. Line 10 is plotted in curve C of Fig. 7.36.

Table 3 gives similar calculations when $\beta = -1/8$ and the result is plotted in curve B of Fig. 7.36, while the smaller βA polar diagram is also plotted in Fig. 7.37.

Several interesting aspects which are common to all feedback amplifiers are brought out by these calculations and curves.

(1) The degree of degeneration (or regeneration) at any frequency marked on the polar diagram Fig. 7.37 can be obtained by measuring the distance at the appropriate frequency from the curve to the point 1,0. The same scale is used for the measurement as for plotting βA and the distance gives the amount of degeneration, e.g. the 50 c/s point on the $\beta A = -8$ curve is 3.66 βA units from 1,0, so gain reduction = 3.66 times = 11.3 db (compare 11.4 db Table 2 line 9). Again at 20 c/s, distance = 0.2 units so gain reduction = 0.2 times, i.e. gain increase = 5 times = 14 db (compare 14.1 db Table 2 line 9).

It follows that at whatever frequency the βA curve crosses the circle with centre 1,0 and radius 1, the gain of the amplifier is unchanged by feedback. For example, with $\beta A = -8$, the locus cuts the circle with radius 1 unit at a frequency of 28 c/s, which is therefore the frequency at which the gain of the amplifier is unchanged by feedback.

The same result may be obtained from Fig. 7.36 where the intersection of curves $\beta A = 0$ and $\beta A = -8$ is at 28 c/s. At lower frequencies the feedback is positive.

(2) When $\beta A = -8$ the low frequency peak is relatively much larger than when $\beta A = -2$ (14 db when $\beta A = -8$ and $2\frac{1}{2}$ db when $\beta A = -2$) and it occurs at a lower frequency. The reason can be seen from the polar diagram. When βA is large the curve is increased in size so that lower frequencies on the curve come closer to the 1,0 point.

(3) When $\beta A = -8$, the angle of βA varies from 0° to 197° but the angle of $1 - \beta A$ varies from 0° to 113° to -8° (Table 2). The reason can be seen from the polar diagram. Note the rapid $1 - \beta A$ phase shift near the regenerative peak and the reason from the polar diagram.

(4) From the calculations it will be seen that, close to the mid-frequency, phase shift correction is approximately equal to $1/(1 - \beta A)$ e.g. when $\beta A = -8$ at 200 c/s in Table 2, a phase shift of 32° is reduced to 4° .

(5) Although the feedback is regenerative as soon as the βA curve cuts the circle with centre 1,0 and radius 1, there is phase correction until the βA curve cuts the horizontal axis (between $18\frac{1}{2}$ and 16 c/s when $\beta A = -8$).

voltage E_0 ($= 16$ at the mid-frequency). Similarly the βA_0 curve represents the feedback voltage, and the vector sum of the grid to cathode voltage and the feedback voltage gives the required input voltage with feedback, i.e. $E_0 + \beta E_0 = E'_0$.

Thus at the mid-frequency, 1 volt of input gives 16 volts of output without feedback, but 9 volts of input are required for the same output voltage with feedback. Since there is no phase shift, there is no phase correction.

However at 250 c/s a phase shift of 23° has occurred and E_0 has the magnitude and phase shown in the diagram. E'_0 is still the vector sum of E_0 and βE_0 as shown on the diagram, and the phase angle between feedback input voltage E'_0 and output voltage E_0 is only about 3° .

This checks as closely as the angles can be measured with Eqn. (51) Sect. 3(viii) of this chapter, taking into account the fact that E_0 has a smaller value at 250 c/s than at the mid-frequency.

At 50 c/s a phase shift of 106° between the voltage between grid and cathode of the first valve and the output voltage is reduced to about 17° between input voltage with feedback and output voltage, which is also in agreement with eqn. (12).

As the phase shift in the amplifier proper approaches 180° , phase shift reduction from inverse feedback becomes smaller, disappearing at 180° and becoming an increase at greater angles. This can be visualized from Fig. 7.38 or demonstrated on a polar diagram on which the βA curve cuts the X axis between 0 and 1 and returns to zero after passing through angles greater than 180° .

(C) Feedback from plate, with transformer coupling

The circuit is conventional, but there is danger of instability. See Sect. 3.

(D) Multiple feedback

The theory of multiple feedback for the purpose of improving stability is covered in Sect. 3(v)E. Fig. 7.33 is an example of dual feedback, with a principal feedback loop and subsidiary feedback through the unbypassed cathode resistor in the circuit

Fig. 7.39. Amplifier with interconnected positive and negative feedback loops in which the negative loop is completely contained within the positive.

Fig. 7.40. Amplifier with interconnected feedback loops in which the loops overlap.

of V_1 . In the case of a 3 stage amplifier, the unbypassed cathode resistor could be in the first or second stage. It is highly desirable, in general, for some such form of subsidiary feedback to be used. It is normally desirable that the degeneration due to the subsidiary feedback should not exceed say 10 per cent. of that due to the principal feedback loop, since the subsidiary feedback increases the distortion in the final stage. For further details and more complicated circuits see Sect. 3(v)E.

There are two general cases of interconnected feedback loops, the first in which one loop is completely contained within the other (Fig. 7.39) and the second in which the loops overlap as in Fig. 7.40. In each of the circuits the gain of the valves V_1 , V_2 and V_3 is A_1 , A_2 and A_3 respectively, and the size of the resistors R is such as to introduce negligible current feedback.

For the circuit of 7.39 the gain reduction factor is

$$\frac{1}{1 - \alpha A_1 A_2 A_3 - \beta A_2 A_3}$$

(with α subject to the same convention as β) and the effective plate resistance of V_3 becomes

$$r_{p3}' = \frac{r_{p3}}{1 - \alpha A_1 A_2 A_3 - \beta A_2 A_3}$$

For the circuit of 7.40 the gain reduction factor is

$$\frac{1}{1 - \alpha A_1 A_2 - \beta A_2 A_3}$$

and the effective plate resistance of V_3 becomes

$$\frac{r_{p3}}{1 - \frac{\beta A_2 A_3}{1 - \alpha A_1 A_2}}$$

(vii) Voltage feedback over three stages

When the feedback is taken over three stages, there is a strong likelihood of experiencing instability at extremely low and high audio (or ultrasonic) frequencies (see Sect. 3). There are several popular circuits :

FIG. 7.42

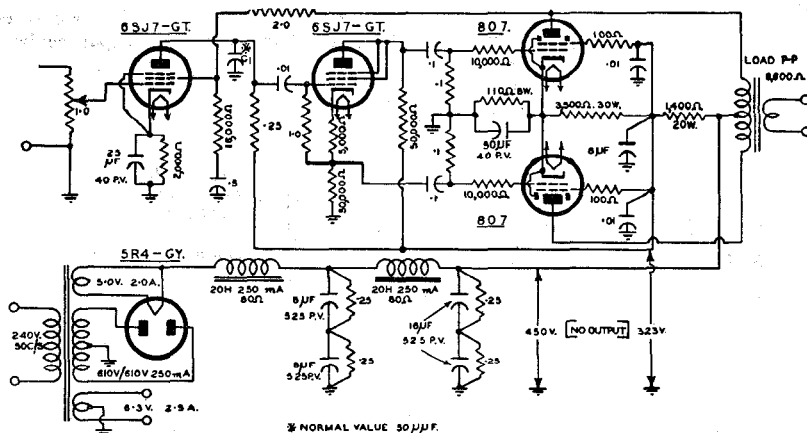

Fig. 7.42. 30 watt push-pull amplifier with voltage feedback from one output plate to the screen of the first stage. Stability is ensured by adjustment of condenser C_1 .

(A) Feedback from plate of V_3 to screen of V_1 (Fig. 7.42)

This circuit is very satisfactory for push-pull amplifiers. As the feedback is taken from one plate only, the output transformer should have very tight coupling between the two halves of the primary (i.e. very low leakage reactance). The amplifier and feedback network have been designed to give a flat response over a wide band of frequencies, with the intention of introducing additional attenuation at one point only. No instability has been experienced, and practically no rise in response, at low audio frequencies. On a resistive load, the high frequency response has a slight peak at about 40 000 c/s, while on a loudspeaker load the peak is much larger and occurs at a lower frequency. Attenuation is provided by the condenser C_1 from the plate of

the first valve to earth, with the results on frequency response shown in Fig. 7.43, for resistive loading.

Fig. 7.43. Frequency response curves for amplifier of Fig. 7.42 on resistive load with several values of C_1 .

In the absence of C_1 and on a loudspeaker load, parasitic oscillations may occur at a fairly high output level. These are largely independent of the input signal frequency but are found to occupy a small part of the cycle, with a parasitic frequency in the region of 30 000 to 40 000 c/s. The effect on music is not very apparent, but a single input frequency shows a slight "breaking up" effect when the parasitics appear. The best check is by the use of a C.R.O.

The feedback is equivalent to overall voltage feedback, and follows the usual formulae, except that it is necessary to allow for μ_{o1o2} of the first valve in the calculations for β and A . In this case :

$$\beta = 16\,000 / (16\,000 + 2\,000\,000) = 0.008$$

$$A = \text{amplification from first grid to final plate divided by } \mu_{o1o2} \\ = 2730 / 20 = 136.5$$

Calculated gain reduction 1/2.1

Measured gain reduction 1/2.2

Input voltage for 30 watts output = 0.2 volt r.m.s.

Distortion at 30 watts output : $H_2 = 0.7\%$, $H_3 = 0.9\%$, $H_4 = 0.1\%$, $H_5 = 0.2\%$. Total 1.16% r.m.s.

Intermodulation distortion (Amplifier A513) :

Conditions of test—input frequencies 60 c/s and 2000 c/s (voltage ratio 4:1)

Power output (r.m.s.)*	4	10	14	20	24 watts
Equivalent power**	5.9	14.7	20.6	29.4	35.4 watts
Intermodulation	2.9	7.7	10	17.5	42%

*r.m.s. sum of two output frequencies

**r.m.s. sum $\times 25/17$ to give the single frequency power having the same peak voltage swing (see Chapter 14 Sect. 3).

Any further increase in the degree of feedback is likely to prove difficult (see Section 3).

When a circuit is used which applies negative feedback to the screen of a pentode, the input capacitance is increased by

$$\mu_i C_{o1o2} |\beta| A$$

where μ_i is the "triode amplification factor"

C_{o1o2} is the capacitance from control grid to screen

$|\beta|$ is numerical value of β

and A is voltage gain from grid to the point from which the feedback is returned.

(B) Feedback from secondary of output transformer

This introduces additional phase shift in the amplifier and requires very careful design of the output transformer for all but small degrees of feedback. The feedback voltage is usually taken to the cathode of the first valve, but if there is transformer input to the first stage then it may be returned to the transformer secondary (as Fig. 7.26). This method may be applied equally to both single-ended and push-pull amplifiers.

Fig. 7.44 is the circuit of such an amplifier using push-pull triodes, with extraordinarily low distortion. It is based on the design of Williamson (Refs. F4, F6). The first triode (V_1) is direct-coupled to the grid of a phase splitter (V_2) which in turn is r.c. coupled to push-pull triodes (V_3 and V_4) and thence to the output stage. No by-pass condensers are used and the only reactances to cause phase shift at low frequencies are the grid coupling condensers in two stages. The circuit has a number of refinements which are described in the references.

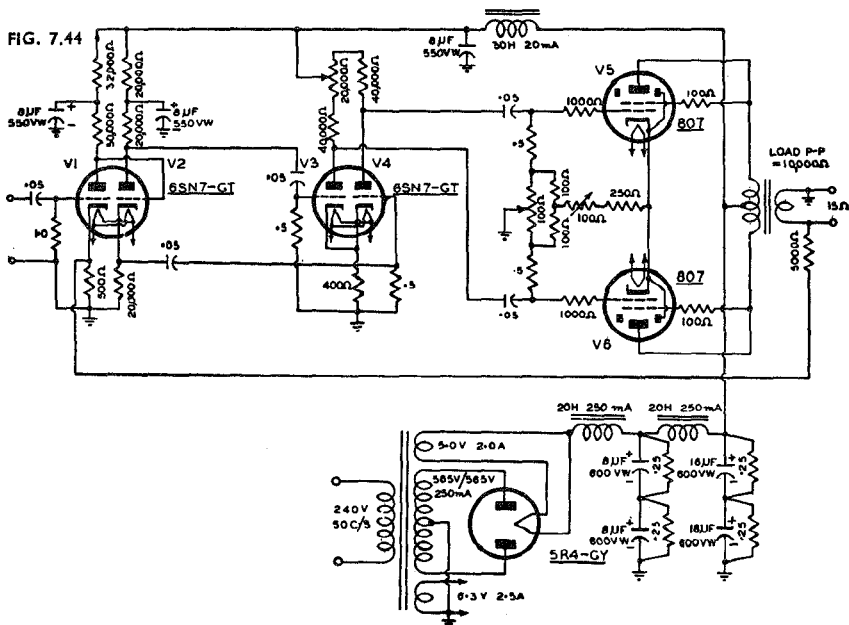

Fig. 7.44. Amplifier employing voltage feedback from the secondary of the output transformer, with push-pull triodes. The amplifier is virtually distortionless up to an output of 11 watts, and has a smooth overload up to 16 watts.

The original version used type L63 valves in place of each half of the 6SN7-GT, and type KT66 as triodes in the output stage. The circuit shown (A515) gives almost identical results, but type 807 valves are used in place of type KT66.

The specifications laid down by Williamson for the **output transformer** are as follows :

Primary load impedance	10 000 ohms, centre-tapped
Primary inductance	100 henrys, min.
Leakage inductance, series (whole prim. to whole sec.)	30 millihenrys, max.
Primary resistance	250 ohms, approx.

Commercial transformers wound to the original winding data supplied by Williamson perform quite satisfactorily, although some difficulty may be experienced where the winding structure differs from that recommended. This is brought about by the increase in interwinding capacitances which may result.

Several manufacturers have recently marketed some wide range output transformers which are a considerable improvement on that specified above.

In one particular transformer, the Partridge CFB, the series leakage inductance, the winding resistances and weight have been reduced by a third, but the power handling capabilities have been increased four times. The core distortion at a level

of 16 watts has been reduced ten times and the important leakage inductance existing between the halves of the primary has been decreased thirty times.

These improvements mean that this transformer, when used in the original Williamson circuit, will give a greater stability margin or alternatively will permit the use of a greater amount of feedback.

Distortion will be appreciably reduced in any amplifier by the use of a well designed transformer of such a type.

Distortion with amplifier A515

Power Output	H_2	H_3	H_4	H_5	Total r.m.s.
11 watts	0.01	0.04	0.01	0.015	0.045%
14 watts	0.075	0.35	0.01	0.26	0.44%
16 watts	0.04	0.92	0.11	0.45	(overload)

The smooth overload is a particularly valuable feature.

Intermodulation distortion

Conditions of test—input frequencies 60 c/s and 2000 c/s ; higher frequency 12 db lower than 60 c/s level.

Power output (r.m.s.)*	4	6	8	10	12 watts
Equivalent power**	5.9	8.8	11.8	14.7	17.6 watts
Intermodulation	0.17	0.27	0.72	3.7	8.8%

*r.m.s. sum of two output frequencies

**r.m.s. sum $\times 25/17$ to give the single frequency power having the same peak voltage swing (see Chapter 14 Sect. 3).

Note :

In the circuit of Fig. 7.44, a capacitance may be inserted in series with the 5000 ohm resistor in the feedback circuit to provide bass boosting for equalizing purposes in record reproduction ; see Chapter 15 Sect. 9(ii)B.

A modification of this circuit, which provides for bass boosting, is given in Fig. 15.58A.

A new version of the Williamson amplifier, together with pre-amplifier and tone control (Ref. F9) is given in Figs. 17.35B,C,D,E,F,G. See also Chapter 13 Refs. F4, F5, H15.

Modified forms of the Williamson amplifier are given in Refs. F6, F8 and Chapter 13 Refs. H5, H6, H8, H10, H12.

(C) Bridge circuits

Amplifiers can be designed with bridge circuits in both input and output circuits, which prevent any modification of the input and output impedances and which also eliminate any phase shift round the feedback loop caused by reactances introduced through the input or output circuits (Refs. A1, A2, A11).

(viii) Cathode-coupled phase inverters and amplifiers

(A) Cathode coupled phase inverters

The fundamental circuit is Fig. 7.45 and requires two triode units with both cathodes linked, a common cathode resistor R_k and separate plate resistors R_{L1} and R_{L2} . Three tapings are required on the battery or potential divider across the B supply. The input voltage is applied between the two grids (Ref. G1).

If both V_1 and V_2 have identical characteristics and $R_{L1} = R_{L2} = R_L$, it may be shown (Ref. C7) that

$$E_{AB} = \mu E_s R_L / (R_L + r_p) \quad (43)$$

where E_s = signal input voltage applied between the two grids
and E_{AB} = signal output voltage between points A and B.

Similarly, where E_A and E_B are the voltages from these points to earth,

$$E_A = \frac{1}{2} \left(\frac{\mu E_s R_L}{R_L + r_p} \right) \left(1 + \frac{R_L + r_p}{R_L + r_p + 2(\mu + 1)R_k} \right) \quad (44)$$

$$\text{and } E_B = -\frac{1}{2} \left(\frac{\mu E_s R_L}{R_L + r_p} \right) \left(1 - \frac{R_L + r_p}{R_L + r_p + 2(\mu + 1)R_k} \right) \quad (45)$$

The two voltages thus differ by a small amount, which can be reduced by using a large value of R_k and/or by using high μ valves. If the remaining out-of-balance is still serious, it may be eliminated entirely by making R_{L1} slightly smaller than R_{L2} so as to give exact balance.

FIG. 7.45

Fig. 7.45. Fundamental circuit of a cathode coupled phase inverter.

FIG. 7.46

Fig. 7.46. Fundamental circuit of a cathode-coupled amplifier.

One stage of a cathode-coupled phase inverter may be coupled to a second (Ref. C7) and the output of the latter will be almost exactly balanced.

The same principle may be applied to the power output stage (Ref. G6).

The circuit of Fig. 7.46 may also be used as a phase-inverter.

See also Chapter 12, Sect. 6(vi).

(B) Cathode-coupled amplifiers

The fundamental circuit of a cathode-coupled amplifier is shown in Fig. 7.46 in which V_1 and V_2 are twin triodes with a common cathode resistor R_k . The output may be taken from either A or B, A being 180° out of phase with the input, while B is in phase with the input voltage.

Output from A : Gain $A_1' = \frac{\mu R_{L1}}{r_p + R_{L1} + r_p R_k (\mu + 1) / [r_p + R_k (\mu + 1)]}$ (46)

(Note : R_{L2} may be shorted-out.)

The plate resistance is increased by r_p and $R_k(\mu + 1)$ in parallel. The minimum value of A' is half the gain without feedback (when $R_k = 0$). (Ref. G2).

Output from B : (Note : R_{L1} may be shorted out) (Refs. G2, G4)

Gain $A_2' = - \frac{\mu R_{L2}}{2r_p + R_{L2} + r_p(r_p + R_{L2})/R_k(\mu + 1)}$ (47)

If $\mu R_k \gg r_p$, then $A_2' \approx - \mu R_{L2} / (2r_p + R_{L2})$ (48)

In reality, the values of μ and r_p are not constant and not equal for the two units in the twin triode. A rigorous analysis (Ref. G17) provides a straight forward method for the accurate derivation of the amplification when the output is taken from B.

Outputs from A and B (special case of phase inverter).

The gain is somewhat less than with Fig. 7.45, but the circuit is often more convenient.

There are many applications of this circuit which are described in References (G) also C7, D6 and J2 ; see also Chapter 12 Sect. 9(iii).

(ix) Hum

The hum in a practical amplifier is not always reduced by the factor $1/(1 - \beta A)$ as in eqn. (12), Sect. 1 but sometimes is decreased according to a different law, and sometimes is even increased by the application of feedback. All hum arising from sources within the amplifier and which is independent of the signal level, may be represented by an equivalent hum voltage in series with the input voltage ; this is reduced in all cases by the factor $1/(1 - \beta A)$.

(A) **Hum originating in the grid circuit** of a single stage amplifier will be reduced by $1/(1 - \beta A)$.

(B) **Hum caused by heater-cathode leakage** is reduced by $1/(1 - \beta A)$ with

voltage feedback. With feedback from an unbypassed cathode resistor, however, the cathode-to-earth impedance is often very high, and the hum is thereby increased.

With the circuit of Fig. 7.20 the hum voltage in the output is

$$\frac{\frac{1}{2}E_h R_k}{R_k + R_{hk}} \cdot \frac{\mu R_L}{(\mu + 1)R_k + r_p + R_L} \quad (49)$$

where E_h = heater voltage (r.m.s.)

and R_{hk} = leakage resistance from heater to cathode.

(C) Hum originating in the plate supply voltage

[The examples below are based on the following power amplifier valves under typical operating conditions :

Type	Triode	Pentode
μ	2A3	6V6-GT
μ (triode connection of pentode)	4.2	215
r_p		9.6
R_L	800	52 000 ohms
A	2500	5000 ohms
	3.2	18.8 times

Voltage feedback is taken as 20% (i.e. $\beta = -0.2$).

Current feedback is based on $R_k = 250$ ohms.]

Case (1) Transformer-coupled output with voltage feedback from the secondary (Fig. 7.26)

In this case the hum is multiplied by the factor $1/(1 - \beta A)$ [= 0.61 for type 2A3 and 0.21 for type 6V6-GT]. The result is that the feedback reduces the hum slightly in the case of a triode and very considerably in the case of a pentode. If a hum-bucking coil is used, the number of turns will require readjustment for negative feedback.

Case (2) Transformer-coupled output with voltage feedback from the plate (Fig. 7.29)

In this case the feedback voltage is a fraction of the output voltage plus the hum voltage across the condenser C_2 .

If V_1 is a **triode**, the hum voltage **without feedback** is

$$E_{h0} = E_h R_L / (R_L + r_p) \quad (50)$$

[Example: $E_{h0} = 0.76E_h$ for type 2A3.]

while the hum voltage **with feedback** is

$$E_{h0}' = E_h R_L / (R_L + r_p') \quad (51)$$

[Example: $E_{h0}' = 0.85E_h$ for type 2A3.]

where E_{h0} = hum voltage output without feedback

E_{h0}' = hum voltage output with feedback

and E_h = hum voltage across condenser C_2 .

Since $r_p' = r_p / (1 - \beta\mu)$ is less than r_p , the hum with feedback is greater than the hum without feedback :

$$\frac{E_{h0}'}{E_{h0}} = \frac{R_L + r_p}{R_L + r_p'} = \frac{1 - \beta\mu}{1 - \beta A} \quad (52)$$

[Example: $E_{h0}'/E_{h0} = 1.12$ for type 2A3.]

If V_1 is a **pentode**, the hum voltage **without feedback** is

$$E_{h0} = E_h [R_L / (R_L + r_p) + R_L \mu_{v2p} / (R_L + r_p)] \quad (53)$$

[Example: $E_{h0} = (0.09 + 1.96)E_h = 2.05E_h$ for type 6V6-GT.]

while the hum voltage **with feedback** is

$$E_{h0}' = E_h [R_L / (R_L + r_p') + R_L \mu_{v2p} / (R_L + r_p - \beta\mu R_L)] \quad (54)$$

[Example: $E_{h0}' = (0.81 + 0.41)E_h = 1.22E_h$ for type 6V6-GT.]

where μ_{v2p} = mu factor from screen to plate without feedback

$\approx \mu_{v1p} / \mu_{v1v2} = 215/9.6 = 22.4$ for type 6V6-GT.]

It will be noticed that the screen and plate effects are additive ; it is only with parallel feed (see Case 3 below) that they oppose one another. The "screen" component of E_{h0}' is equal to that without feedback multiplied by $1/(1 - \beta A)$. This is not a good circuit for low hum, either with or without feedback ; these remarks also apply to Figs. 7.30, 7.31, 7.32, 7.33 and 7.42.

If the screen is perfectly filtered, the second term in eqn. (54) becomes zero. [Example : $E_{h0}' = 0.81E_h$ for type 6V6-GT.] The effect of feedback on the hum is then given by eqn. (52) with the substitution of the correct values of μ and A [Example : $E_{h0}'/E_{h0} = 9.2$ for type 6V6-GT].

Case (3) Parallel feed with voltage feedback (Fig. 7.47).

When V_1 is a triode, this is an excellent circuit for low hum, both with and without feedback, provided that L_1 has a reactance, at the hum frequency (i.e. twice supply frequency for full wave rectification) at least several times the impedance of r_p and R_L in parallel.

When V_1 is a pentode, the hum due to the plate circuit is low but that due to the screen is high. Screen filtering (L_2C_2) is required for low total hum ; this is improved by feedback so that the screen filtering may be omitted in some applications.

Without feedback, when V_1 is a triode, the hum voltage is applied to a voltage divider with ωL_1 in one arm and R in the other, where $R = r_p R_L / (r_p + R_L)$. For ease in calculation it may be expressed in the form

$$E_{h0} = \cos \theta E_h \text{ where } \theta = \tan^{-1} \omega L_1 / R \quad (55)$$

[If $\omega L_1 = 25\,000$ ohms, and $R = 606$ ohms as for type 2A3,

then $\theta = \tan^{-1} 41.2 = 88.6^\circ$. Thus

$\cos \theta = 0.024$ and $E_{h0} = 0.024E_h$.]

With feedback, $E_{h0}' = E_{h0} / (1 - \beta A)$ (56)

[Example : $E_{h0}' = 0.024 / 1.64 = 0.015$ for type 2A3].

When V_1 is a pentode **without feedback**

$$E_{h0} \approx E_h [\cos \theta - R_L \mu_{azp} / (R_L + r_p)] \quad (57)$$

where $\theta = \tan^{-1} \omega L_1 / R$ as for the triode case

and $R = r_p R_L / (r_p + R_L)$.

The second term in eqn. (57) is only approximate, since it is assumed that the shunting effect of ωL_1 on R_L has no effect on the gain ; this is very nearly true when ωL_1 is at least equal to $10R_L$.

[Example : If $\omega L_1 = 25\,000$ ohms, and $R = 4560$ ohms as for type 6V6-GT, then $\theta = \tan^{-1} 5.48 = 79.7^\circ$. Thus $\cos \theta = 0.179$ and $E_{h0} = (0.179 - 1.96)E_h = -1.78E_h$. With screen filtering, this would be considerably improved.]

With feedback, $E_{h0}' = E_{h0} / (1 - \beta A)$. (58)

[Example : $E_{h0}' = (-1.78/4.8)E_h = -0.37E_h$ for type 6V6-GT.]

If L_1 is replaced by a resistor R , the necessary substitution for $j\omega L$ may be made in the equations for hum. Similarly, the transformer-coupled load (R_L) may be replaced by a following grid resistor R_g .

FIG. 7.47

Fig. 7.47. Circuit of an amplifier with parallel-fed transformer output and negative feedback supplied from the plate.

FIG. 7.48

Fig. 7.48. Cathode follower with parallel feed.

With this type of amplifier, hum balancing arrangements inside the amplifier are unaffected by the feedback. An adjustment of the hum bucking coil (if used) in the loudspeaker will be necessary. Any type of feedback circuit may be used, either from the plate, or from the primary or secondary of the output transformer.

Case (4) Cathode follower with parallel feed (Fig. 7.48)

In this case the plate resistance is reduced by the factor $1/(\mu + 1)$, and the hum output voltage is decreased by the factor $1/(\mu + 1)$. If a pentode is used, the screen

capacitance by-pass to cathode (C in Fig. 7.16) may be adjusted to neutralize hum (Ref. C14).

Case (5) Transformer-coupled output with feedback from an unbypassed cathode resistor (Fig. 7.49)

The hum arising from the plate and screen circuits is the same as for Case (2) except that r_p' is now greater than r_p (Eqn. 51): $r_p' = r_p + (\mu + 1)R_k$. With a triode the hum is less with current feedback than without feedback. [Example type 2A3: $E_{h0}' = 0.54E_h$]. With a pentode the total hum from plate and screen is always decreased by current feedback

$$E_{h0}' = E_h \left[\frac{R_L}{R_L + r_p + R_k(\mu + 1)} + \frac{\mu_{02} R_L}{R_L + r_p + (\mu + \mu_{02}) R_k} \right] \quad (59)$$

where the first term is for the plate, and the second for the screen circuit.

[Example: $E_{h0}' = (0.04 + 0.97)E_h = 1.01E_h$ for type 6V6-GT.]

FIG. 7.49

Fig. 7.49. Transformer-coupled output with feedback from an unbypassed cathode resistor.

FIG. 7.50

Fig. 7.50. Parallel-fed transformer-coupled output with feedback from an unbypassed cathode resistor.

Case (6) Parallel feed, with feedback from an unbypassed cathode resistor (Fig. 7.50)

With a pentode, the "plate" hum is increased by feedback from an unbypassed cathode resistor, while the "screen" hum is the same as for transformer-coupling (Eqn. 59) except for the sign.

$$E_{h0}' \approx E_h \left[\frac{r_p + R_k(\mu + 1)}{R_L + r_p + R_k(\mu + 1)} - \frac{\mu_{02} R_L}{R_L + r_p + (\mu + \mu_{02}) R_k} \right] \quad (60)$$

The first term also applies to a triode. The approximation is from regarding R_k as the load, instead of R_k in parallel with ωL .

[Example of triode: $E_{h0}' = 0.46E_h$ for type 2A3.

Example of pentode: $E_{h0}' = (0.95 - 0.97)E_h = -0.02E_h$.

This gives almost exact hum neutralization.]

References to hum: B3, B4, B5, B7.

Summary—hum originating in the plate and screen supply voltages

With triodes, the output hum voltage is always less than the hum voltage from the plate supply. In the examples given above, it varies from 46% to 85% of the plate supply hum voltage with one exception. The exception is transformer-coupled output with parallel-feed, feedback being taken from the plate, for which the output hum is only 1.5% of the plate supply hum voltage (Case 3).

With pentodes or beam power amplifiers the output hum may exceed the plate supply hum voltage, owing to the effect of the screen. This occurs with Case (2) which is the conventional transformer-coupled output both without feedback and with voltage feedback from the plate. The only circuit giving very low output hum is Case (6) which applies to transformer-coupled output with parallel feed and with feedback from an unbypassed cathode resistor. The second best is Case (1) with feedback from the secondary, while the third best is Case (3) with parallel feed, having feedback from the plate.

The examples given above have been tabulated for ease in comparison, including some cases also without feedback, and some with the screen circuit perfectly filtered.

Case	Fig.	Relative hum voltage with		Conditions
		2A3	6V6-GT	
1.	7.26	0.61	0.21	with feedback
2.	7.29	0.76	2.05	without feedback
		0.85	1.22	with feedback
		—	0.09	without feedback and with screen perfectly filtered
		—	0.81	with feedback and with screen perfectly filtered
3.	7.47	0.024*	1.78	without feedback
		0.015*	0.37	with feedback
		—	0.179	without feedback but with screen perfectly filtered

5.	7.49	0.54	1.01	with feedback
6.	7.50	0.46	0.02*	with feedback

*Very low output hum.

(x) Some special features of feedback amplifiers

(A) It is important to ensure that the frequency range of the input signal applied to a feedback amplifier does not extend in either direction beyond the "flat" frequency range of the amplifier. The reason for this is explained below.

The voltage applied to the grid of the first valve in a multi-stage amplifier with overall feedback is equal to the difference between the input signal and the feedback voltage. For example, assuming 20 db of feedback, the signal voltage may be 1 volt, the fed-back voltage 0.9 volt and the voltage applied to the first stage will then be $1 - 0.9 = 0.1$ volt. At some frequency well outside the "flat" frequency range of the amplifier, where the amplifier output is 20 db down, the fed-back voltage will be 0.09 volt for a 1 volt signal, leaving a difference of 0.91 volt applied to the grid of the first valve—i.e. nine times its normal input. This may not overload the first stage, but it will probably overload the subsequent stages and cause serious distortion, even though the frequency is itself inaudible.

Even at a frequency which is only 1 db down, the signal voltage may be 1 volt, the fed-back voltage will then be 0.8 volt and the difference of 0.2 volt will be applied to the grid of the first valve; twice normal. It is therefore essential to restrict the input range of frequencies, and it is also advisable to place the coupling having the highest attenuation as close as possible to the input of the amplifier (Ref. F7).

(B) Damping on transients

See Sect. 3(v) including "Design Tests."

(C) Overload test

See Sect. 3(v) "Design Tests."

(xi) Combined positive and negative feedback

The principle of combined positive and negative feedback has been outlined in Sect. 1(v).

A practical version of such an amplifier with push-pull output is shown in Fig. 7.51 (Ref. F10). The overall negative feedback is obtained from the secondary of the output transformer T_1 and is fed through R_5 to the cathode of V_2 . Shunt capacitor C_5 affords some feedback phase correction at very high frequencies. The feedback gain reduction is 9 db, and becomes 11 db with the positive feedback disconnected.

The positive feedback is obtained from the grid of V_4 and is fed through R_1 and C_1 to the grid of V_5 . The positive feedback voltage is developed primarily across R_2

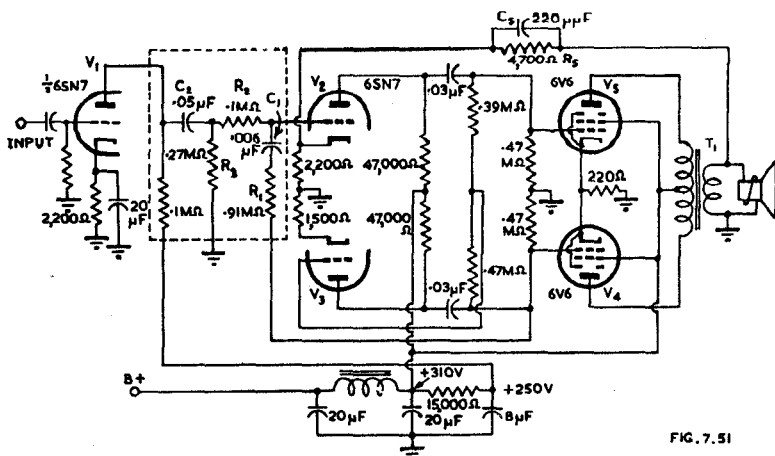

FIG. 7.51

Fig. 7.51. Two stage amplifier using combination of positive and negative feedback (Ref. F10). T_1 ratio is 10,000 : 15 ohms.

and C_2 since the plate resistance of V_1 is relatively small, and the input resistance of the grid of V_2 is high. The increase in gain due to positive feedback is about 26 db at 400 c/s. About one tenth of the voltage on the grid of V_4 is fed back to the grid of V_2 . The resistance of R_1 is therefore made about nine times that of R_2 , and C_2 has about nine times the capacitance of C_1 . Because of the highly degenerative nature of the phase inverter, the balance is not appreciably affected by the additional load of the positive feedback network.

Some phase shift in the positive feedback is obtained at extreme frequencies in the stages V_2 and V_3 due to electrode and stray capacitances, and due to the blocking capacitors. The input capacitance of the grid of V_2 causes a further phase shift, so that the polarity of the product $\beta_1 A_1$ reverses from positive to negative at extremely high frequencies, where β_1 and A_1 apply to stage V_2 . The input capacitance of V_2 is primarily Miller Effect due to feedback through its grid-plate capacitance at very high frequencies where the overall feedback is positive or small.

In some designs it may be necessary to connect a small capacitor from the grid of V_2 to earth, or to use a more elaborate phase shift network to obtain a sufficiently rapid phase turnover in the local feedback.

At extremely low frequencies most of the local feedback current flows through R_2 instead of through C_2 , so that a phase shift is obtained, which together with the phase-shifting action of the $0.03\mu\text{F}$ blocking capacitors in stages V_2 and V_3 , is sufficient to cause the desired phase reversal. In practice, the phase reversal frequencies are placed as far outside the desired pass band as good stability permits.

The output transformer is quite small, the core area being only $\frac{3}{4}$ in. by $\frac{3}{4}$ in.

The maximum third harmonic distortion at 400 c/s is 0.24%, higher harmonics being relatively small, at 8 watts output, measured at the secondary. At 100 c/s the highest harmonic is the second, with 0.12% for 8 watts output. At 50 c/s, with 5 watts output, third harmonic distortion is 0.88%, while at 2000 c/s with 4 watts output the third harmonic is 0.23%. The intermodulation distortion is 40% with no feedback, 8% with negative feedback alone and 1.9% with combined positive and negative feedback under the following conditions—output 8 watts, 4:1 ratio with frequencies 60 and 7000 c/s. With frequencies of 100 and 7000 c/s the intermodulation distortion is only 0.84%. The output circuit regulation is quoted as 0.1 db at 400 c/s as compared with 2.7 db for positive feedback disconnected, or 19 db with no feedback (Ref. F10).

It is possible to apply overall negative feedback together with positive feedback from a tapping on the cathode resistor of a phase-splitter through a coupling resistor to the unbypassed cathode of the preceding r.c. pentode, and thus increase the gain. The increased gain may require additional filtering (Ref. F16). This may also be used with direct coupling (Fig. 7.51A and Ref. F11).

Fig. 7.51A. Direct-coupled triode amplifier V_1 and phase splitter V_2 , with positive feedback from the cathode circuit of V_2 to the cathode of V_1 (Ref. F11).

It is possible to omit the by-pass condensers from the cathode bias resistors in the final and penultimate stages of an amplifier or receiver (or any other two successive stages) and to bring the gain back to normal by means of positive feedback, using only one resistor coupling the two cathodes as in Fig. 7.51B.

Fig. 7.51B. Positive feedback from the cathode of V_2 through R_4 to the cathode of V_1 to offset the loss of gain by the omission of both by-pass condensers.

This circuit (Fig. 7.51B) may also be used with any desired degree of feedback. The effective plate resistance of V_2 may be increased or decreased by the positive feedback as shown by the following analysis and Fig. 7.51C. Here R_1 replaces R_7 , and R_8 in parallel, no input signal is applied but a signal generator E is inserted in the plate circuit. It is assumed that R_4 is very much greater than R_3 . We thus obtain

$$I = \frac{E}{R_A} - \frac{IR_3\mu_2}{R_A} + \frac{IR_3|\beta|A_1\mu_2}{R_B} \quad (61)$$

where $R_A = R_5 + r_{p2} + R_3$

$$R_B = R_5 + r_{p2} + R_3(\mu_2 + 1)$$

$$A_1 = \frac{\mu_1 R_1}{R_1 + r_{p1} + R_2}$$

$$\text{and } |\beta| = \frac{R_2}{R_2 + R_4}$$

From (61) we may derive

$$I = \frac{E}{R_B - R_3|\beta|A_1\mu_2R_4/R_B}$$

$$= \frac{E}{R_5 + r_{p2} + R_3[\mu_2 + 1 - (|\beta|A_1\mu_2R_4)/R_B]}$$

and hence $r_{p2}' = r_{p2} + R_3[\mu_2 - (|\beta|A_1\mu_2R_4)/R_B]$ (62) where $|\beta|$ and A have the values defined below eqn. (61). The second term on the right hand side of eqn. (62) is the increase in effective plate resistance due to the unbypassed cathode resistor of V_2 , while the third term is the decrease in effective plate resistance due to positive feedback. It is obvious that, by a suitable choice of

βA_{11} , it is possible to obtain any desired value of effective plate resistance from very high values to very low, even zero or negative values. If the resistor R_4 is made variable, the effective plate resistance may be varied over a wide range. The addition of overall negative feedback will make the gain nearly constant for all settings of R_4 , and will also decrease the distortion and reduce the effective plate resistance to any values desired (Ref. F17). See also Ref. J19.

The addition of positive feedback will increase the phase shift and may increase the tendency towards instability at very low and very high frequencies; care should be taken to reduce to a minimum the phase shift within the positive feedback loop. The general principles of designing for stability are the same as for negative feedback—see Sect. 3.

It is normally inadvisable to return the positive and negative feedback loops to the same point in the input circuit. If both are taken to the same electrode, a bridge network may be used for isolating their effects. Each 6 db increase in gain due to positive feedback will double the distortion in this stage; for example 24 db increase in gain will increase the distortion in this stage by 16 times. This will then be reduced by the negative overall feedback in accordance with the usual relationship. References to positive and negative feedback—Refs. F10, F11, F12, F13, F15, F16, F17; Sect. 3(v)E.

Fig. 7.51C. Analysis of circuit of Fig. 7.51B to determine the effective plate resistance of V_2 .

Fig. 7.51D. Choke coupled phase inverter (Ref. F14).

(xii) Choke-coupled phase inverter (Ref. F14)

The choke-coupled phase inverter of Fig. 7.51D has been designed to give higher output voltages than the conventional phase splitter, to be practically unaffected by the flow of grid current in V_1 and to have small phase shift. The two identical chokes L in the plate and cathode circuits are tightly coupled so that this duty is performed by a 1:1 a-f transformer. This transformer applies negative voltage feedback to the input circuit, and thus causes a low effective plate resistance. Design must aim at a high total inductance to keep phase errors small, and a low leakage inductance if it is desired to keep the effect of grid current small. A fixed bias voltage is applied between terminals X, having polarity and magnitude to give, in conjunction with the voltage drop in the cathode choke, the correct grid bias. The complete analysis is given in Ref. F14.

The voltage gain is given approximately by

$$A' \approx \frac{\mu R_2}{(\mu + 2)R_2 + r_p} \text{ where } X \gg R_2$$

and the phase shift between input and output is given exactly by

$$\tan \phi = \frac{r_p}{(\mu + 2)R_2 + r_p} \cdot \frac{R}{X}$$

where $X = 2\omega(L + M)$.

X may be taken to include any self-capacitance or other stray capacitance.

As a result of the small phase shift, this circuit may readily be used in feedback amplifiers.

SECTION 3: STABILITY, PHASE SHIFT AND FREQUENCY RESPONSE

(i) *Stability and instability* (ii) *Conditions for stability* (iii) *Relationship between phase shift and attenuation* (iv) *Design of 1 and 2 stage amplifiers* (v) *Design of multi-stage amplifiers* (vi) *Effect of feedback on frequency response* (vii) *Design of amplifiers with flat frequency response* (viii) *Constancy of characteristics with feedback* (ix) *Effect of feedback on phase shift.*

(i) Stability and instability

Equation (2b) of Sect. 1 gives the amplification with negative feedback, at the mid-frequency, in the form

$$A' = A/(1 - \beta A).$$

It is obvious that both A and βA must be vector quantities having different magnitudes and phase angles at very low and very high frequencies from those they have at the mid-frequency. If βA is real and negative, we have negative feedback with a decrease in amplification. If βA is real, positive, and less than 1 in absolute value, we have positive feedback with an increase in amplification. If $\beta A = 1$ the amplification becomes theoretically infinite, and the system is unstable. If βA is real, positive, and greater than 1 in absolute value, the system will be only "conditionally stable" and is likely to oscillate during the warming-up period.

The quantity βA is called the **loop amplification**.

The conditions for stability described in (ii) below are based on the well-known Nyquist criterion of stability. There is, however, an alternative known as the Routh-Hurwitz stability criterion which is useful when the expression is in analytical form. See Ref. H16.

(ii) Conditions for stability

Before proceeding with any particular amplifier, it is necessary to calculate or measure its amplification and phase angle over a very wide band of frequencies. The frequency and phase angle characteristics of an imaginary amplifier are shown in Fig. 7.52. The frequency f_0 at which the phase angle is zero is called the mid-frequency; f_1 and f_2 are the frequencies at which the phase angle displacement is a lead and lag of 90° respectively; frequencies f_3 and f_4 are those giving a lead and lag of 180° respectively.

Taking first the case of a single stage with r.c. coupling, it is possible to plot the locus of the values of βA from zero frequency to infinity with polar coordinates (Fig. 7.53A). This is commonly known as a "Nyquist diagram." If A_0 is the amplification at the mid-frequency f_0 , this will normally be its maximum value and the phase angle displacement will be zero. It will, of course, be negative for negative feedback, thus giving the vector βA_0 as drawn. At any lower frequency f_1 , the value of A may be taken from the curve for this amplifier; let us call it A_1 . The value of β may be regarded as a fixed negative fraction less than unity. We thus have the value of βA_1 , and the phase angle displacement ϕ_1 may also be determined from the phase angle curve. This may then be plotted as a radial vector from 0 to βA_1 , with a leading phase angle displacement ϕ_1 , which implies that the phase of the feedback voltage leads the input voltage by the angle ϕ_1 .

Similarly for any higher frequency f_2 ; we can plot βA_2 with a length proportional to the amplification at this frequency, and a lagging phase angle displacement ϕ_2 . As the frequency increases still further, we have a smaller βA_3 with a larger phase displacement, while in the extreme limit $\beta A = 0$ with $\phi = 90^\circ$ lagging. At the other frequency extreme ($f = 0$) we have $\beta A = 0$ with $\phi = 90^\circ$ leading. In this case the shape of the locus is a circle which is all in the negative region; this amplifier is, therefore always stable.

Any amplifier may have its βA locus plotted by this method; a typical case is Fig. 7.53B for a 2 stage r.c.c. amplifier. Here βA_1 still has appreciable length with ϕ_1 greater than 90° , but $\beta A = 0$ when $\phi = 180^\circ$ either leading or lagging.

FIG. 7.52

Fig. 7.52. Voltage gain and phase angle shift of an imaginary amplifier. The mid-frequency is f_0 and the maximum voltage gain A_0 .

The distance from any point on the locus to point K is equal to $(1 - \beta A)$ where β is negative for negative feedback (see Fig. 7.53B).

If it is desired to find the magnitude and phase angle of βA at any frequency, it is only necessary to measure the gain without and with feedback, to calculate the ratio A_0/A' between them, to draw a circle with centre K and radius A_0/A' units, then to draw a second circle with centre O and radius equal to the measured fed-back voltage $|\beta A|$. The line from the origin to the point of intersection between the two circles is the complex number βA .

For any amplifier to be stable, the βA locus must not include the point K (1,0). It is also desirable for the locus not to cut the X axis beyond the point K,

FIG. 7.53

Fig. 7.53. (A) Locus of βA vectors ("Nyquist diagram") for a single stage resistance capacitance coupled triode amplifier with fixed bias (B) Similar locus for a 2 stage amplifier.

otherwise oscillation may occur during the warming-up period ; such an amplifier is said to be conditionally stable. In the case of more complicated circuits, particularly those with peculiarly shaped βA loci, it is advisable to plot loci for successively increasing values of β up to and somewhat beyond the desired value of β . The criterion of stability should be applied to each—that the locus should not enclose the point K (1,0).

The following rule is also helpful as it covers most cases and avoids having to draw a βA locus. **If βA is less than unity at $\phi = +180^\circ$ and at $\phi = -180^\circ$ the amplifier is stable.**

Another useful rule is that **the maximum permissible value of βA is equal to the maximum value of A (i.e. A_0) divided by the value of A at $\phi = \pm 180^\circ$ (whichever is the larger).**

Also, **if the phase shift is not more than 180° at zero and at infinite frequencies, the amplifier is always stable with any value of β .**

The “attenuation” is the attenuation with respect to the maximum value of A (i.e. A_0). Both the attenuation and the loop amplification βA may be expressed in decibels.

FIG. 7.54

Fig. 7.54. Additional information furnished by a “Nyquist diagram” (see also Fig. 7.53 A and B.)

Certain aspects of the polar diagram for amplifiers with feedback are shown in Fig. 7.54. Circles are shown with centres at point K (1,0) with radii of 0.25, 0.5, 1.0, 2 and 3 units. The circumference of the circle with a radius of 1 unit indicates the locus of points at which the gain is unchanged by feedback. At all points outside this circle, the feedback is negative and degenerative. For example, the circumference of the circle with a radius of 2 units is the locus of points having a gain reduction of 6 db. At all points inside the circumference of the circle with a radius of 1 unit, the feedback is positive and regenerative although not necessarily unstable. For example, the circumference of the circle with a radius of 0.5 unit is the locus of points having a gain increase of 6 db.

Instability occurs when the point K is included by the βA locus. Straight lines are drawn radiating from the origin with stability margins of 15° , 30° , 60° , and 90° . The 30° line is tangential to the circle with a radius of 0.5 unit, so that the point of

tangency has 30° stability margin and 6 db gain increase. At other points along this line the gain increase will be less than 6 db.

An example of the use of the polar diagram in connection with the design of negative feedback amplifiers is given in Sect. 2(vi)B and Figs. 7.37 and 7.38.

It would be permissible for an amplifier to have a βA locus such as the line OABCDEFG in Fig. 7.54 (see Ref. A29). Here the maximum increase of gain due to positive feedback is 6 db, which occurs between C and D. The feedback is negative over the path EFG. The distance OA should not exceed say 0.3 unit, so as to allow for a possible increase in amplifier gain of about 3 db without further increasing the peak of 6 db.

Feedback amplifiers which are designed with a small stability margin should have narrow tolerances on components that have a direct effect on gain or frequency characteristics. It is desirable for βA to be measured and its locus plotted for the pilot model of each design for three conditions, with normal (bogie) valves and with valves at the upper and lower limits for mutual conductance. This is only required in the region of the low and high frequency peaks of response, which are normally beyond the working frequency range. Alternatively and more simply, the height of the low and high frequency peaks may be measured in relation to the response without feedback; in accordance with good practice, the rise with feedback should not exceed 6 db, and lower values are desirable.

A special stability problem occurs when an amplifier may not always be connected to its correct load. One way of overcoming this problem is to design a high-and-low pass filter pair for connection between the amplifier and the load, the high-pass filter being terminated by a resistance (Ref. A29).

If an amplifier is stable with the output terminals open-circuited, short-circuited, or operated into its rated resistive load, then it is stable under all load conditions. The measurements of stability on open-circuit and under rated load resistance can be made with an oscilloscope across the output terminals to check for the presence of ultrasonic oscillations. A check on the short-circuit conditions can best be made using a high-frequency ammeter across the output terminals. An oscilloscope of very high input impedance might also be used by connecting it across the input of one of the stages in the feedback loop (Ref. A28).

(iii) Relationship between phase angle displacement and attenuation

The phase angle displacement of an amplifier is normally a function of the attenuation characteristic. Because of this fact, it is possible to design a feedback amplifier on the basis of either the phase angle displacement or the attenuation characteristic. If the attenuation characteristic* is a straight line with a slope of 6 decibels per octave, then the ultimate phase angle is 90° and so on in proportion; 12 db/octave gives 180° phase angle and 18 db/octave gives 270° . The condition which must be satisfied is that the amplifier is a "minimum phase shift network." This condition is satisfied by most amplifiers, the exceptions being (1) when it contains a transmission line or equivalent circuit with distributed constants, and (2) when it includes an allpass section, either as an individual structure or in a combination which can be replaced by an all-pass filter section plus some other physical structure (Refs. H6, H10, H11).

Fig. 7.54A shows ultimate slopes of 6 and 12 db/octave and higher slopes. The 12 db/octave attenuation characteristic is the limiting value for stability, being on the verge of instability. A practical amplifier requires a safety margin between the slope of its design characteristic and the limiting value of 12 db/octave. A typical design slope is 10 db/octave, giving an angular safety margin of 30° .

Any single reactive element such as a grid coupling condenser, a shunt capacitance or a shunt inductance in conjunction with a resistance provides an attenuation characteristic with an ultimate slope of 6 db/octave. Such a combination is known as a single time constant circuit. Attenuation characteristics are given in Fig. 4.36 (grid coupling condenser or shunt inductance) and Fig. 4.38 (shunt capacitance), for a single time constant in each case.

*Plotted with logarithmic frequency scale.

†This applies to a resistive load only. With a capacitive load, instability is likely to occur.

If a parallel-fed transformer is used, the coupling condenser resonates with the primary inductance at some low frequency and the ultimate slope of the stage is approximately 12 db/octave below the frequency of resonance. If the secondary of a transformer is unloaded, the leakage inductance resonates with the distributed capacitance, giving a slope for the stage of approximately 12 db/octave above the frequency of resonance. Each of these combinations is equivalent to two time constants.

FIG. 7.54A

Fig. 7.54A. Attenuation characteristics for 6, 12, 18 and 24 decibels per octave as given by the "asymptotic" or ultimate characteristics of the amplifiers in their simplest form. The region beyond 12 db/octave is unstable; that below 10 db/octave is stable, and the region between 10 and 12 db/octave is a safety margin to allow for discrepancies between the calculated design and the finished amplifier.

Cathode and screen by-passing

In the case of cathode and screen by-passing, the attenuation characteristics are noticeably curved and the phase angle displacement cannot be calculated as for a straight line, but may be obtained from Figs. 12.3C and 12.11B respectively. In both cases the phase angle displacement reaches a maximum value at some frequency and gradually decreases at lower and higher frequencies.

Cathode by-passing

The maximum slope of the attenuation characteristic and maximum phase angle displacement are given below

B	=	2	3	5	10
Max. loss	=	6	9.5	14	20 db
Max. slope	=	2.25	2.6	3.6	4.8 db/octave
Max. angle	=	20°	30°	42°	55°

$$\text{where } B = 1 + \frac{R_k(\mu + 1)}{r_p + R} \quad \text{and } R = \frac{R_L R_{o2}}{R_L + R_{o2}}$$

For a pentode $B \approx 1 + g_m R_k$.

For typical r.c. triodes and pentodes, B is usually less than 3.

Screen by-passing

This has an effect similar to that of cathode by-passing

B	=	2.5	5	10	20
Max. loss	=	8	14	20	26 db
Max. slope	=	2.4	4	4.5	5.4 db/octave
Max. angle	=	25°	42°	54.5°	64.5°

$$\text{where } B = 1 + \frac{R_s g_m}{m \mu_t (1 + R_L / r_p)}$$

R_s = series screen resistor in ohms

g_m = mutual conductance at operating point, in mhos

m = ratio of plate to screen currents

μ_t = triode amplification factor

R_L = plate load resistance in ohms

and r_p = plate resistance in ohms.

Phase angle characteristics of "step circuit"

The step circuit of Fig. 7.59A has a maximum phase angle displacement at the frequency of the half-attenuation point, and approaches zero at lower and higher frequencies. The curves for a particular case are plotted in Fig. 7.54B, and the value of the maximum phase angle as a function of the attenuation in Fig. 7.54C.

FIG. 7.54B

Fig. 7.54B. Attenuation and phase characteristics of "step circuit" Fig. 7.59A for particular case with step attenuation 20db (Ref. H18).

FIG. 7.54C

Fig. 7.54C. Maximum phase shift as a function of attenuation in the circuit of Fig. 7.59A (Ref. H18).

Total slope of attenuation characteristic

The total slope of the attenuation characteristic of an amplifier in db/octave, at any frequency, is the sum of the slopes of the attenuation characteristics of all the reactive elements in the amplifier at the same frequency, provided that the slopes are constant.

In practice, the best procedure is to plot the individual attenuation characteristics with a linear db scale, then to add the decibel ordinates at various frequencies to determine the total attenuation characteristic. The slope of the latter may then be determined graphically.

Determination of phase angle

When the attenuation characteristic is a straight line forming a sharp angle at the cut-off frequency f_0 , as in Fig. 7.55A, the phase angle displacement is $k \times 45^\circ$ at f_0 , where k is one sixth of the slope in db/octave, and the phase angle characteristic is asymptotic to 0° and $k \times 90^\circ$.

When the attenuation characteristic is that of a normal r.c. amplifier, $k \times 3$ db down at f_0 (as broken curve in Fig. 7.55D) the phase angle displacement is also $k \times 45^\circ$ at f_0 , but at other frequencies the phase angle characteristic differs slightly from that of Fig. 7.55A.

FIG. 7.55 A

Fig. 7.55A. Phase angle for attenuation characteristic as shown; $k=1$ for 6db/octave, $k=2$ for 12db/octave etc. (Based on Bode, Refs. H6, H11).

On account of this fairly close agreement between the phase angle characteristics for the two cases, it is possible to replace the actual attenuation characteristic by an approximate "straight-line" equivalent. Where the attenuation characteristic does not have constant slope throughout, it may be replaced by a succession of intersecting straight lines having slopes of zero or any multiple of 6 db/octave, either positive or negative (e.g. Fig. 7.55B). These, in turn, may be resolved into "semi-infinite"* lines of constant slope, as in Fig. 7.55C. The phase characteristics may be derived by the use of Fig. 7.55A for each junction. The resultant phase angle characteristic may be determined by adding these individual characteristics.

*A "semi-infinite" straight line is one commencing from a definite point and proceeding to infinity in one direction only.

More accurate results may be obtained in some cases by the use of phase angle curves for attenuation characteristics having a sloping portion and a horizontal portion, as given by Bode (Ref. H11, Chapter 15).

FIG. 7.55B

FIG. 7.55C

Fig. 7.55B. Attenuation characteristic with straight line approximation (based on Bode, Ref. H11).

Fig. 7.55C. Semi-infinite lines of constant slope corresponding to straight line approximations in Fig. 7.55B (based on Bode, Ref. H11).

More accurately again, when the slope of the attenuation characteristic is **varying**, the phase angle at any frequency may be determined from a measurement of the amplitude characteristic over a wide frequency range. This procedure is facilitated by the use of special graph paper, plotting the slope of the amplitude characteristic in db/octave against a function of frequency, then measuring the area under the curve and so enabling the slope at one point to be determined (see Ref. A29).

When the slope of the attenuation characteristic reaches a maximum value over a limited frequency range and is less than this value at lower and higher frequencies, the phase angle at the point of maximum slope is less than that indicated by the slope, while at frequencies below and above the region of higher slope the phase angle is greater than that indicated by the slope.

Simple method for determination of phase angle (Ref. H18)

A very simple approximate method, which gives the total phase angle, is based on the straight-line approximate characteristics (Fig. 7.55D). The phase angle displacement at the cut-off frequency f_0 is 45° ; the approximate straight-line phase characteristic is taken as a tangent to the actual curve at the point of greatest slope, with sharp bends at the intersections with 0° and 90° . The maximum error is about 10° .

FIG. 7.55D

Fig. 7.55D "Straight line" approximate characteristics with an attenuation slope of 6db/octave (actual characteristics shown with broken lines) and corresponding phase angle characteristics (Ref. H18).

A typical attenuation characteristic is shown in Fig. 7.55E with three component "semi-infinite" slopes.

The corresponding phase angle characteristics are shown in Fig. 7.55F, where 1 and 2 are to be added, and 3 is to be subtracted to give the resultant. In each case the position of the component phase characteristic is determined by the relationship that the cut-off frequency on the attenuation characteristic gives 45° phase angle.

Fig. 7.55E. Typical attenuation characteristic of amplifier with feedback (broken curve) and component "semi-infinite" slopes (1, 2 and 3) from which Fig. 7.55A is constructed (Ref. H18).

The broken line in Fig. 7.55F is the actual phase characteristic, indicating reasonable accuracy for the method. In all cases the actual characteristic tends to "round the corners" of the approximate characteristic.

The same curves (Figs. 7.55D, E and F) may be used for the low frequency attenuation characteristics by inverting the frequency scales.

(iv) Design of 1 and 2 stage amplifiers

A single stage resistance capacitance coupled amplifier has $+90^\circ$ phase angle displacement at zero frequency due to the grid coupling condenser. The screen and cathode by-pass condensers may cause phase angle displacements up to about $+65^\circ$ and $+30^\circ$ respectively (see Figs. 12.11B and 12.3C) but these come back to zero again at very low frequencies. Consequently the total phase angle displacement is normally less than 180° at any frequency. At the high frequency end the maximum phase angle displacement is -90° . Such an amplifier is stable under all conditions.

A two stage r.c.c. amplifier has twice the phase angle displacement of a single stage amplifier, if both stages are identical. It may therefore produce peaks of frequency response due to positive feedback at low and high frequencies, and care is necessary in design—see Sect. 3(vi) below. It is desirable to "stagger" the low frequency attenuation characteristics by choice of widely different time constants for the grid condensers and following grid resistors; the larger the ratio, the larger will

be the permissible feedback factor. One or both cathode by-pass condensers may be omitted, or the by-passed section of R_k may be reduced in resistance. One or both screen dropping resistors may be reduced in resistance, or replaced by a voltage divider with other consequential adjustments. The values of the cathode and screen by-pass capacitors may be adjusted so that their frequencies of maximum phase angle are "staggered," preferably in the ratio of at least 20 to 1.

The high frequency peak may be reduced by staggering the high frequency response of the two stages, for example by shunting a capacitor from one plate to earth and increasing the capacitance experimentally until the peak is sufficiently reduced. For an exact design method see Sect. 3(vii) below.

The phase angle displacement is increased by the inclusion of an iron-cored transformer within the feedback loop, also by any resonance effects, and such cases should be treated by the method described for multi-stage amplifiers.

Fig. 7.55F. Phase angle characteristic derived from Fig. 7.55E (Ref. H18).

(v) Design of multi-stage amplifiers

In the design of multi-stage amplifiers, Bode's method (A) is most commonly used or its simplification by Learned (B). This method is intended primarily for use with amplifiers having only one feedback path.

The addition of subsidiary feedback to a single feedback loop leads to Duerdorth's multiple feedback system (E) which is based on a modified stability margin (C) and the theory of the summation of attenuation characteristics and subsidiary voltages (D). Duerdorth's system is capable of providing a greater feedback factor than Bode's method, with the same minimum value of stability margin in each case. Some delightfully simple applications of Duerdorth's method are possible and it seems that any amplifier with a single feedback loop can be improved as regards stability by the addition of one or more subsidiary feedback paths. The latter, in their simplest form, may be merely unbypassed cathode resistors.

With any multi-stage amplifier, an important feature is the **degree of damping on transients**. Insufficient experimental work has been carried out to indicate what degree of damping is desirable in a-f amplifiers. A reasonably safe inference is that damping heavier than critical damping is undesirable, because it results in sluggish uptake. Whether critical damping—see Sect. 3(vii)C—is desirable, or some lighter degree of damping is preferable, is an unsolved problem which can only be tackled on an experimental basis. It is stated by those who advocate a light degree of damping that this gives very rapid uptake, and the overshoot which occurs is at an ultrasonic frequency which is certainly inaudible, and in any case would be very seriously attenuated by the loudspeaker. On the other hand, it is well known that some forms of ultrasonic parasitic oscillation give rise to objectionable reproduction.

Design tests

It is highly desirable to measure and plot both the frequency response and phase angle over a sufficiently wide frequency range; both curves may be plotted on the same sheet of logarithmic graph paper. The required frequency range is the useful frequency range of the amplifier plus (at each end) one octave for each 10 db of feedback plus at least one octave.

When it is desired to achieve the maximum degree of feedback it is essential to plot the polar (Nyquist) diagram as in Figs. 7.53B and 7.54. For a method of measuring the phase angle see Refs. H7, H19, H20.

An amplifier may be tested for transient response by applying a rectangular waveform to the input and observing the waveform of the output with a C.R.O. having good frequency and phase characteristics up to the maximum test frequency. If there is any oscillatory response or "overshoot" the feedback may be reduced or some modification made to the feedback loop to provide the desired degree of damping.

Another useful design test is to overload the amplifier with input voltages of various frequencies, and to determine the level to which the input must be reduced to return to normal linear operation (Ref. A29 discussion).

FIG. 7.56A

Fig. 7.56A. Bode's method—Curve (1) attenuation characteristic and (2) phase angle displacement characteristic for constant 150° phase angle displacement above upper working frequency f_0 ; curve (3) constant slope 10 db/octave (Ref. H11).

Alternative methods of design

(a) One method sometimes used is the "cut and try" method of constructing an amplifier and then applying feedback with the feedback factor increasing in steps until instability occurs, and finally decreasing the feedback to provide a safe margin.

If instability occurs with only a small degree of feedback, there are devices which may be experimented with, such as

1. Shunting the primary of the output transformer by a condenser.
2. Connecting a very small condenser from the plate of one of the earlier stages to earth.

to E, and a constant attenuation of 10 db from E to F. The effect of the horizontal "step" EF is to limit the phase angle displacement in this region, to a value less than 180°, which will hold provided that

$$\frac{f_2}{f_1} = \frac{\text{ultimate slope of actual characteristic (Curve 4) in db/octave}}{\text{ultimate slope of desired characteristic (Curve 1) in db/octave}}$$

Since point F is fixed by the actual attenuation characteristic, the position of point E, and hence Curve 1, will be determined by the ratio f_2/f_1 .

Methods for providing the "step" in the characteristic are described in (B) below.

The following relations hold, provided that the ultimate slope of curve 1 is 10 db/octave and the safety margin of the "step" below $|\beta A| = 1$ is 10 db.

Let n = ultimate slope of actual attenuation characteristic, in db/octave

$|\beta_0 A_0|$ = desired value of $|\beta A|$ at the mid-frequency

and f_2 = frequency at which the actual attenuation is equal to $(|\beta_0 A_0| + 10)$ db, then $f_1 = f_2 (10/n)$

number of octaves between f_0 and $f_1 = |\beta_0 A_0|/10$

" " " " f_1 and $f_2 = 3.32 \log(n/10)$.

The frequency ratio may be derived from the number of octaves by the relation—

frequency ratio = antilog $(0.301 \times \text{number of octaves})$

or by the use of the table below :

Frequency Ratio, Octaves and Decades

Frequency Ratio	No. of Octaves	No. of Decades	Frequency Ratio	No. of Octaves	No. of Decades
1.07	0.1	0.03	5.28	2.4	0.72
1.15	0.2	0.06	6.07	2.6	0.78
1.23	0.3	0.09	6.97	2.8	0.84
1.32	0.4	0.12	8.00	3.0	0.90
1.42	0.5	0.15	9.18	3.2	0.96
1.52	0.6	0.18	10.0	3.32	1.00

Frequency ratio = antilog (number of decades)
= antilog $(0.301 \times \text{number of octaves})$

Number of decades = log (frequency ratio)
= $0.301 \times \text{number of octaves}$

Number of octaves = $3.32 \times \log (\text{frequency ratio})$
= $3.32 \times \text{number of decades}$.

Relationship between db/octave and db/decade

db/octave	3	6	9	10	12	15	18
db/decade	10	20	30	33.3	40	50	60

In addition to the attenuation of the shaded area in Fig. 7.56B, it is also necessary to boost the gain near the limits of the working frequency band to provide nearly constant gain (area AHB) and thereby achieve almost zero phase angle at the cut-off frequency f_0 . This may be accomplished by the circuit of Fig. 7.56C in which the Q of the $L_1 C_1$ circuit should be unity, as given by

$$L_1 = 1/\omega^2 C_1 \text{ and } r = 1/\omega_0 C_1$$

where r = series resistance of L_1 . More complicated but more satisfactory networks (low-pass or band-pass "Wheeler" networks) are described in Ref. A29. These

have an ultimate attenuation of 6 db/octave and a phase angle displacement of approximately 90° at all frequencies outside the working band. For other methods see Ref. H11.

The low frequency end may be treated in a similar manner throughout.

Means for producing the desired attenuation characteristics are described by References H6, H10, H11. See also (B) below.

This method of design requires the amplifier to have a very much wider frequency range before feedback is applied than it would need without feedback. The extension is approximately one octave in each direction for each 10 db reduction of gain by feedback plus a sufficient margin of safety (say 1 octave at each end). Thus an amplifier to cover from 40 to 15 000 c/s with 30 db reduction of gain by feedback would require to have a frequency response without feedback (at 40 db down) from 2.5 to 240 000 c/s. This actually applies to the transmission characteristics of the whole feedback loop (amplifier and feedback network together).

(B) Simplified treatment by Learned (Ref. H9)

The following treatment is based on the simplified assumption that the attenuation characteristics are straight lines. This is approximately correct except in the octave immediately above and below the useful frequency band of the amplifier, where the method gives a wider safety margin than is necessary. The method does not, therefore, give the same degree of feedback obtainable with the precise method of Ref. H6. At the same time it is quite suitable for general use.

FIG. 7.57

Fig. 7.57. Low frequency attenuation characteristics of multi-stage amplifier with feedback (simplified treatment).

Low frequency attenuation characteristics

As an example for illustrating the general principle, take an amplifier with nominally flat frequency response down to 20 c/s (actually it will be -2 or -3 db at this frequency). Let the loop amplification $|\beta A|$ be 30 db at useful frequencies.

Draw the attenuation characteristic with a slope of 10 db/octave from 20 c/s downwards (line ABC in Fig. 7.57). Point B is where the value of the loop amplification becomes unity. Extend the line AB to C which is at a level 10 db below $|\beta A| = 1$. At C, insert a horizontal "step" CD, the length of which will be given later. Beyond D the attenuation will fall at a rate of 12, 18, 24, 30 db or more depending on the circuit; each single time constant or non-resonant transformer contributes 6 db, while each resonant circuit contributes 12 db. The frequency ratio between points

FIG. 7.56C

Fig. 7.56C. Simple network in plate circuit to give more nearly constant gain over the working frequency range (based on Ref. A29).

C and D is made equal to the ratio of the slopes of DE and AC , which is equal to the slope of DE divided by 10. The line $ABCDE$, thus determined, is to be used as a guide to the low frequency attenuation characteristic of the amplifier. In reality, of course, the sharp corners will be rounded—the important features are that the slope of the AC region should not exceed 10 db/octave, and that the step should be sufficiently long.

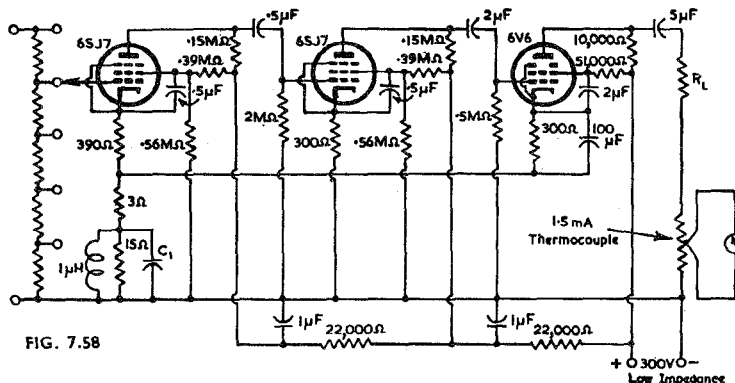

FIG. 7.58

Fig. 7.58. Three stage amplifier with negative feedback illustrating design method (Ref. H9).

FIG. 7.59

Fig. 7.59. Low frequency attenuation characteristics of Fig. 7.58 (Ref. H9).

Example

An example of an amplifier designed in accordance with this method is Fig. 7.58 (Ref. H9). The low frequency attenuation characteristics are given in Fig. 7.59. The 6V6 cathode, 6V6 screen and 6SJ7 screen characteristics are designed to provide a very close approach to a total slope of 10 db/octave with a limiting attenuation of 40 db, so providing the basis of a step. The two grid condensers are designed to give effective attenuation beyond the limit of the step. It is evident that it is possible to design an amplifier which provides the necessary low frequency attenuation charac-

teristics, including the step, without using any resonant circuits. The tolerances on the frequency-dependent components (R and C) must be small.

The feedback loop does not include the plate circuit of the third stage, so that the slope of the high-frequency attenuation characteristic is nominally 12 db/octave. The resonant circuit (incorporating C_1) in the feedback path is employed to stabilize the frequencies in this region by providing a step in the high-frequency attenuation characteristic.

Corrective networks

The design of simple corrective networks is well summarized in Ref. H9. More complicated designs incorporate LCR 2-terminal networks as the plate load impedances and (some) cathode bias impedances (Ref. H11). See also Ref. J16.

One of the simplest and most effective methods of providing the required step in the high frequency attenuation characteristic is the RC network shunting the plate load resistor of the pentode V_1 in Fig. 7.59A (based on Ref. H9). The ultimate attenuation of the step in decibels is given approximately by

$$\text{attenuation} \approx 20 \log (R_1 + R)/R.$$

The cut-off frequency is given by

$$f_1 = 1/2\pi R_1 C$$

and the "flattening-out" frequency by

$$f_2 \approx 1/2\pi RC$$

where $R_1 = R_L R_g / (R_L + R_g)$

and the "flattening-out" frequency is defined as the frequency at which the attenuation is 3 db less than the ultimate attenuation of the step.

FIG. 7.59A

FIG. 7.59B

Fig. 7.59A. Circuit to provide step in high frequency attenuation characteristic (based on Ref. H9).

Fig. 7.59B. Circuit to provide step in low frequency attenuation characteristic (based on Ref. H9).

The equivalent to Fig. 7.59A for the low frequency end is provided by Fig. 7.59B :

Step attenuation $\approx 20 \log (R + R_g)/R_g$

Cut-off frequency $f_1' = 1/2\pi C(R_L + R_g)$

Flattening-out frequency $f_2' \approx 1/2\pi RC$

The value of C_1 is selected to give negligible attenuation at f_2' ; say

$$C_1 \approx 5/[\pi f_2'(R + R_L + R_g)].$$

With these step circuits it is desirable to have as many separate circuits as possible, each with a small step.

Fig. 7.59C. Feedback path including CR network to give a step in the attenuation characteristic, and thereby to improve stability (Ref. H18).

FIG. 7.59C

A step in the attenuation characteristic may also be provided by an LCR circuit in the feedback path, or more simply by a CR circuit as in Fig. 7.59C. Here R may be the cathode resistor of the first valve, $R_1 + R_2$ take the place of the usual feedback resistor, and C effectively increases the value of β at high frequencies. This is a most useful device to improve the stability of a feedback amplifier. A simpler form, omitting R_1 , is sometimes sufficient; this is similar to Flood's "compensated feedback" Sect. 3(vii)C.

(C) Duerdodth's stability margin (Ref. A29)

Duerdodth adopts a pre-determined value (e.g. 6 db) of the rise of gain with feedback at high and low frequencies as a stability margin over values of βA from 0.3 to some value less than 2.0. At higher values of βA he adopts an angular stability margin (e.g. 15°) while below $\beta A = 0.3$ there is no danger of instability. An amplifier designed in accordance with his method might have a high-frequency characteristic such as OABCDEF in Fig. 7.54. See discussion on stability and tolerances in components with this characteristic in Sect. 3(ii) above. One method for achieving such a shape of characteristic is given in Sect. 3(v)E below.

(D) Summation of attenuation characteristics and subsidiary voltages

When two voltages have to be added, as for example with a loop feedback voltage and a subsidiary voltage connected in series, the attenuation characteristic can only be derived by adding the voltages at selected frequencies, with due regard to the phase angle between them.

The phase angle between the two voltages is a function of the difference in slope when plotted as attenuation characteristics, provided that the slopes are constant:

Slope difference	2	4	6	8	10	12	14	16	18	db/octave
Phase angle diff.	30	60	90	120	150	180	210	240	270	degrees

For example: If one characteristic has a slope of 4 db/octave and the second 12 db/octave, the slope difference is 8 db/octave, and the phase angle between the voltages is therefore 120° .

Take the intersection of the two characteristics as the origin (as in Fig. 7.60) and assume that 0 db = (say) 1 volt—both assumptions being for convenience.

Let x be the voltage contributed by the lower slope characteristic at a certain frequency. It may readily be shown that the voltage contributed by the high slope characteristic at this frequency is x^a , where a is the ratio of slopes in db/octave. These two voltages, x and x^a must then be added vectorially, the angle between them being as given by the table above.

The magnitude of the combined characteristic may then be plotted as in Fig. 7.60, and the values of the phase angle may be marked along it.

The method of deriving the magnitude and phase angle of the resultant is illustrated by Fig. 7.61 for the condition where the higher slope characteristic has a slope of 12 db/octave, corresponding to 180° . Vector OA, having magnitude x and phase angle

FIG. 7.60

Fig. 7.60. Illustrating summation of attenuation characteristics (based on Ref. A29).

ϕ indicates the lower slope characteristic, the value of ϕ in degrees being given by $15 \times \text{slope in db/octave}$. Vector OB, having magnitude x^a and phase angle 180° , indicates the higher slope characteristic with a slope of 12 db/octave. For example, when the slopes are 4 and 12 db/octave, $a = 3$ and $\phi = 60^\circ$.

The magnitude of the resultant is given by

$$\text{Resultant} = \sqrt{(x \sin \phi)^2 + (x^a - x \cos \phi)^2}.$$

The phase angle θ of the resultant is given by

$$\theta = \tan^{-1} \frac{x \sin \phi}{x \cos \phi - x^a}.$$

For ease in calculations the following table has been derived for use in all normal cases when the phase angle between the two voltages is a multiple of 30° and less than 180° and when the higher slope is 12 db/octave.

Difference in phase angle*	Resultant	Phase Angle θ of Resultant
30°	$x\sqrt{1 + 1.73x^{0.2} + x^{0.4}}$	$\tan^{-1} - \frac{1}{2x^{0.2} + 1.73}$
60°	$x\sqrt{1 + x^{0.5} + x}$	$\tan^{-1} - \frac{1.73}{2x^{0.5} + 1}$
90°	$x\sqrt{1 + x^2}$	$\tan^{-1} - 1/x$
120°	$x\sqrt{1 - x^2 + x^4}$	$\tan^{-1} \frac{1.73}{1 - 2x^2}$
150°	$x\sqrt{1 - 1.73x^3 + x^{10}}$	$\tan^{-1} \frac{1}{1.73 - 2x^5}$

*between the two voltages, i.e. $180^\circ - \phi$.

A similar procedure can, of course, be applied to any other value of maximum slope.

Procedure when lower slope is zero

The foregoing procedure cannot be used when one of the two attenuation characteristics has a slope of zero, that is when one is a fixed voltage. In this case the procedure is as follows.

FIG. 7.61

FIG. 7.62

Fig. 7.61. Vector relationships in summation of attenuation characteristics.

Fig. 7.62. Vector relationships when one characteristic has zero slope.

As previously, the origin is the point of intersection of the two characteristics, and its level is taken as 0 db equal to 1 volt. The vector relationships are shown in Fig. 7.62.

$$\text{Resultant} = \sqrt{x^2 + 1 + 2x \cos \alpha}$$

$$\text{Phase angle of resultant} = \theta = \tan^{-1} \frac{x \sin \alpha}{1 + x \cos \alpha}$$

where x = voltage at a selected frequency, on the sloping characteristic
and α = phase angle of sloping characteristic (i.e. angle in degrees = $15 \times \text{slope in db/octave}$).

Angle α	Resultant	Phase angle θ of Resultant
30°	$\sqrt{x^2 + 1.73x + 1}$	$\tan^{-1} \frac{x}{2 + 1.73x}$

Angle α	Resultant	Phase angle θ of Resultant
60°	$\sqrt{x^2 + x + 1}$	$\tan^{-1} \frac{1.73x}{2 + x}$
90°	$\sqrt{x^2 + 1}$	$\tan^{-1} x$
120°	$\sqrt{x^2 - x + 1}$	$\tan^{-1} \frac{1.73x}{2 - x}$
150°	$\sqrt{x^2 - 1.73x + 1}$	$\tan^{-1} \frac{x}{2 - 1.73x}$
165°	$\sqrt{x^2 - 1.93x + 1}$	$\tan^{-1} \frac{0.26x}{1 - 0.97x}$

An example of the summation of two attenuation characteristics, one having zero slope and the other having a slope of 10 db/octave, is given in Fig. 7.63. The resultant is asymptotic to 10 db/octave and to the horizontal characteristic, but reaches a minimum value at the frequency of the point of intersection O. The phase angle is marked at points along the resultant, and at all frequencies the phase angle is less than that of the 10 db/octave characteristic, the effect becoming more pronounced

Fig. 7.63. Summation of two attenuation characteristics having slopes of zero and 10 db/octave.

at higher frequencies, particularly beyond point D. The fact that the slope of the resultant in Fig. 7.63 exceeds 12 db/octave to the left of point D, has no effect whatever on the stability as indicated by the angles. It is therefore obvious that the relationship between phase angle and slope of the attenuation characteristic which applies to minimum phase shift networks, does not apply here.

A similar calculation has been made for a slope of 11 db/octave, Fig. 7.64.

The position of point D on the resultant characteristic is a function of the slope of the attenuation characteristic.

slope in db/octave	2	4	6	8	10	11
height of point D	+ 5.7	+ 4.7	+ 3	0	- 5.6	- 11.6 db.

(E) Duerdorth's method employing multiple feedback paths (Ref. A29)

In accordance with this method, one or more additional subsidiary feedback voltages are introduced into the feedback loop so as to decrease the phase angle over the

FIG. 7.64

Fig. 7.64. Summation of two attenuation characteristics having slopes of zero and 11 db/octave.

attenuation portion of the amplitude characteristic without appreciably affecting the characteristics within the working frequency range.

With subsidiary feedback applied over the first stage of a 2-stage amplifier and loop feedback over the whole amplifier, the ratio of gain with and without feedback is given by

$$\frac{A'}{A} = \frac{1}{1 - \beta_1 A_1 - \beta_2 A} \quad (1)$$

where A = overall amplification without feedback

A' = overall amplification with feedback

A_1 = amplification of first stage without feedback

β_1 = value of β for subsidiary feedback over first stage only

and β_2 = value of β for loop feedback over whole amplifier.

It is evident that when subsidiary feedback is used, the several feedback voltages must be added at their common point. This holds even when the subsidiary voltage is entirely inside the feedback loop.

Under the same conditions, the ratio of distortion in the final stage with and without feedback is given by

$$\frac{D'}{D} = \frac{1 - \beta_1 A_1}{1 - \beta_1 A_1 - \beta_2 A} = \frac{A'}{A} (1 - \beta_1 A_1) \quad (2)$$

Thus the application of negative subsidiary feedback to the first stage increases the distortion in the final stage in the same proportion that the gain of the first stage is reduced, provided that the overall feedback loop is unchanged.

If, however, the subsidiary feedback is positive, the gain of the first stage will be increased and the distortion in the final stage will be reduced further. The use of positive subsidiary feedback need not present any stability problems, since the stability criterion is dependent on $(\beta_1 A_1 + \beta_2 A)$. See Sect. 2(xi) and Refs. F11, F12.

With multiple loop amplifiers, the usual Nyquist stability criterion applies to any loop, provided that the amplifier remains stable when the particular loop is broken. Even with amplifiers which are always stable, the Nyquist diagrams obtained by measurements of the several loops in turn may have different shapes and the definition of stability margin becomes meaningless. However, if a mesh of the amplifier can be found which, if broken, simultaneously breaks all the loops, then there is no possi-

bility of oscillation due to the disconnection and the definition of stability margin remains applicable (Ref. A29).

When employing multiple feedback paths with summation of attenuation characteristics and subsidiary voltages, the crossing point of the characteristics should be controlled with considerable accuracy. The crossing point will be modified when the gains of the various stages change owing to changes in the valve characteristics with age, or to overloading caused by an excessive input voltage. The latter may be avoided or reduced in more elaborate amplifiers by the addition of a cathode follower stage, operating as a limiter, as part of the first stage. Precautions to be taken in design are described in Ref. A29.

Some applications employing multiple feedback paths are described below. See also Sect. 2(vi)A.

Fig. 7.65. Part of first stage of feedback amplifier showing one method of applying subsidiary feedback (Ref. A29).

(1) One simple application is the circuit of Fig. 7.65 where the signal voltage across the unbypassed cathode resistor R_k is added to the loop feedback voltage. This is an application of the principle of summation of attenuation characteristics as shown in Figs. 7.63 and 7.64. The voltage across R_k is practically constant over the critical region of the high frequency attenuation characteristic, so that its characteristic has zero slope. This method may only be used when the phase angle of the βA locus is always less than 180° , i.e. the slope of the βA attenuation characteristic is less than 12 db/octave. This method does not reduce the distortion in the final stage to the same level as without subsidiary feedback, or to that using one of the alternative methods below. For this reason the subsidiary voltage should be considerably smaller than the loop feedback voltage. However, this method will improve the stability margin of an amplifier and reduce the amplitude of the high frequency peak.

FIG. 7.66

FIG. 7.67

FIG. 7.68

Fig. 7.66. One form of subsidiary feedback (after Ref. A7).

Fig. 7.67. Another form of subsidiary feedback (after Ref. A7).

Fig. 7.68. Two terminal network as cathode load impedance.

(2) One modification of this method, which has only small degeneration in the working range, is shown in Fig. 7.66. This appears to have been first described by Farren (Ref. A7) and applied to one of the stages inside the feedback loop. The phase shift reaches maxima at low and high frequencies outside the working range, beyond which it approaches zero in both directions. The degeneration increases gradually in both directions to the limiting design values provided by R_1 and R_2 . This arrangement does not modify the fundamental phase shift between the input and output voltages of the stage due to the phase angle of the plate load impedance.

(3) A further modification by Farren (Ref. A7) is shown in Fig. 7.67 which has the advantage at very high and very low frequencies that it reduces the phase shift between the input and output voltages of the stage due to the phase angle of the plate load impedance which would be characteristic of the stage if there were no subsidiary feedback.

Fig. 7.69. Summation of loop and subsidiary feedback voltages to provide improved stability (Ref. A29).

(4) Two terminal networks of the form of Fig. 7.68 are described by Duerdorth as cathode impedances for improving the stability of feedback amplifiers with an ultimate attenuation of 12 db/octave. A value of $L = 10CR^2$ may be used as a first trial and maximum feedback and zero phase angle will then occur at a frequency of approximately

$$f = 0.048/CR$$

where C and R are in farads and ohms respectively. An example of the application of subsidiary feedback on an amplifier with an ultimate attenuation slope of 12 db/octave is given in Fig. 7.69. In this example the peak of subsidiary feedback occurs at twice the maximum frequency of the working band. The stability margin in the critical region has been increased from 10° to 36° with subsidiary feedback, as shown by the Nyquist diagram (Ref. A29).

It often happens that the addition of the subsidiary voltage results in an increase in phase angle just above the working frequency band where the magnitude of the

Fig. 7.70. Three stage amplifier incorporating subsidiary feedback in the form of a 4 terminal network. $m = 0.87$. W = "Wheeler" network (based on Ref. A29).

subsidiary voltage is increasing with frequency, although a decrease in phase angle occurs where the magnitude of the subsidiary voltage is steady or decreasing with frequency. This increase in phase angle will reduce the angular margin over a range of frequencies and, in the extreme case when the frequency of the peak subsidiary voltage is greater than 3 or 4 times the maximum frequency of the working band, may approach "conditional stability."

A similar technique may also be applied to low frequency attenuation characteristics.

- (5) Four terminal networks of the form included in Fig. 7.70 are described by Duerdth for providing subsidiary feedback in amplifiers with an ultimate attenuation slightly over 12 db/octave. Fig. 7.70 has loop feedback from the cathode of V_3 to the cathode of V_1 , main subsidiary feedback from the cathode of V_2 to the grid circuit of V_1 , and minor subsidiary feedback due to the unbypassed cathodes of V_1 and V_3 . The four terminal network is a high-pass m -derived half-section filter terminated in R_o . The cut-off frequency of the filter is made about twice the maximum frequency of the working band (Ref. A29).

FIG. 7.71

Fig. 7.71. Combination of high and low frequency subsidiary feedback.

- (6) A combination of both high and low frequency subsidiary feedback is shown in Fig. 7.71 where $R_1C_1L_1$ is the high-frequency network (as in Fig. 7.68) and $R_2R_3C_2$ is the low frequency network. The latter provides a subsidiary negative feedback at low frequencies only; its value will be affected by the source impedance of the input voltage. If transformer coupling is used, the secondary should be connected to points A and B.

(7) In a three stage amplifier with an ultimate slope of about 18 db/octave, the second stage being a phase splitter which introduces little phase shift, some reduction in the total loop phase angle may be achieved by means of a phase shifting network in the feedback line. A subsidiary feedback path is added from the plate circuit of the phase splitter through a high-pass filter to the cathode of the first stage. This voltage is suppressed in the working band by the filter, but above the working band the loss of the network falls and the subsidiary voltage becomes the predominant factor, thus reducing the ultimate slope to 6 db/octave. Complete stability is thus achieved (Ref. A29 Fig. 26).

(8) A third feedback voltage may be added, if desired, to give two subsidiary feedback paths.

(vi) Effect of feedback on frequency response

In the case of a single stage r.c.c. amplifier (assuming perfect cathode and screen by-passing) the feedback merely widens the frequency range without changing the shape of the voltage gain characteristics (Fig. 7.72).

With two such identical stages, the frequency characteristics are as Fig. 7.73. The peaks, which occur as the value of βA is increased, are due to the reduction in effective negative feedback and the development of positive feedback through phase angle shift, which approaches 180° at very low and very high frequencies. F_1 and F_2 are the frequencies giving 0.707 relative voltage gain for each single stage without feedback. Ref. H4.

These peaks may be reduced or eliminated entirely by designing the amplifier with one stage having a much wider frequency range than the other. Design methods to produce "maximal flatness" are described in Sect. 3(vii) and these may be modified to produce critical damping, if desired.

Alternatively a multiple feedback system may be adopted—for example one overall feedback loop in conjunction with an unbypassed cathode resistor in the first stage (Duerdth's method) as described in Sect. 3(v)E.

See also Sect. 3(iv) and Sect. 2(vi) for the design of two-stage amplifiers.

A special application to a particular two-stage amplifier is Ref. H5.

See also Refs. J8, J11.

FIG. 7.72

FIG. 7.73

Fig. 7.72. Relative voltage gain of a single stage r.c.c. amplifier without feedback and with three selected values of feedback (Ref. H4).

Fig. 7.73. Relative voltage gain of two identical r.c.c. amplifier stages, without feedback and with four selected values of feedback (Ref. H4).

Graphical method for two-stage r.c.c. amplifier

An ingenious graphical method has been developed by Barter (Ref. H17), and may be used for determining the R and C values to give any desired height of peaks at low and high frequencies.

(vii) Design of amplifiers with flat frequency response

(A) Method of H. Mayr (Ref. H13). See also J13.

A resistance-capacitance-coupled amplifier Fig. 7.74 may be regarded, so far as frequency response is concerned, as a tuned circuit with a Q less than 0.5. The value of this Q is given by

$$Q = \frac{1}{b(d+k) + (1/b)(p+k)} \quad (3)$$

where $b = \sqrt{R_0/R_f}$; $d = C_0/C$; $k = C_c/C$;

$$p = C_p/C \text{ and } C = \sqrt{C_0 C_c + C_0 C_p + C_c C_p}.$$

This method may be applied to multi-stage amplifiers with feedback, it being assumed that all stages have the same resonant frequency ($\omega_0/2\pi$). The conditions for maximum flat response are then given by:

$$1 \text{ stage } |(A_0/A)| = \sqrt{1+x^2} \quad (4)$$

$$\phi = -\tan^{-1}x \quad (5)$$

$$\text{where } x = \frac{Q}{n} \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right) \quad (6)$$

N.B. n must be greater than 2.

$$\text{2 stages } |(A_o/A)| = \sqrt{1+x^4} \quad (7)$$

$$\phi = -\tan^{-1} \sqrt{2x/(1-x^2)} \quad (8)$$

$$\text{where } x = Q_2 \sqrt{\frac{Q_1}{nQ_2}} \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right) \quad (9)$$

$$\text{and } Q_1/Q_2 = (n-1) + \sqrt{n(n-2)} \quad (10)$$

Fig. 7.74. Resistance-capacitance coupled stage.

FIG. 7.74

$$\text{3 stages } |(A_o/A)| = \sqrt{1+a_2x^4+x^6} \quad (11)$$

$$\phi = -\tan^{-1}(b_1x - x^3)/(1 - b_2x^2) \quad (12)$$

$$\text{where } x = Q_2 \sqrt{\frac{Q_1}{nQ_2}} \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right) \quad (13)$$

$$a_2 = \frac{1}{\sqrt[3]{n^2}} \left[3 \sqrt{\frac{Q_3^4}{Q_1^4}} + 2 \sqrt[3]{\frac{Q_1^2}{Q_2^2}} \right] \quad (14)$$

$$b_1 = \frac{1}{\sqrt[3]{n^2}} \left[3 \sqrt{\frac{Q_1^2}{Q_2^2}} + 2 \sqrt[3]{\frac{Q_2}{Q_1}} \right] \quad (15)$$

$$b_2 = \frac{1}{\sqrt[3]{n}} \left[3 \sqrt{\frac{Q_2^2}{Q_1^2}} + 2 \sqrt[3]{\frac{Q_1}{Q_2}} \right] \quad (16)$$

$$Q_1/Q_2 = 2(n-1) + \sqrt{2n(2n-3)} \quad (17)$$

$$\text{and } Q_2 = Q_3. \quad (18)$$

N.B. n must be greater than 1.5.

This has also been extended to four stages (Ref. H13).

Symbols used:

A_o = amplification with feedback at mid-frequency ($\omega_0/2\pi$)

A = amplification with feedback at any frequency ($\omega/2\pi$)

α_o = amplification without feedback at mid-frequency ($\omega_0/2\pi$)

ϕ = phase angle

$n = 1 - \alpha_o\beta_o$ = feedback factor

β_o = transfer coefficient (negative for negative feedback)

$\omega_0 = 1/(C\sqrt{R_L R_g})$.

These equations have been plotted in Fig. 7.75 from which it will be seen that the feedback factor has no effect on the shape of the curves for 1 or 2 stages, and only a very slight effect for 3 or 4 stages (curves for limiting values of n are given). Although the curves are shown only for the high frequency limit of the flat top, they may be applied to the low frequency side by changing the sign of the abscissae and, in the case of phase angle, also changing the sign of the ordinates.

This method of design provides the maximum flat frequency response, but the maximum degree of feedback only occurs at the mid-frequency and it falls off rapidly outside the frequency band of the "selective" stage. The feedback becomes zero near the knees of the flat top, and positive at still higher and lower frequencies.

This design ensures stability at all frequencies from zero to infinity.

This method also makes it possible to design for any desired response curve, within the limits of the amplifier. The procedure is to commence with the desired response curve and to determine the response (either modulus or phase angle) corresponding

FIG. 7.75

Fig. 7.75. Frequency response and phase angle of frequency response for 1, 2, 3, and 4 r.c.c. stages designed for maximum flat response by Mayr's method (Ref. H13).

to two arbitrary frequencies ($\omega_1/2\pi$) and ($\omega_2/2\pi$), one near the lower and the other near the upper frequency limit. Then we read from the curves the values of x_1 and x_2 corresponding to the two chosen response values; the value of x_1 corresponding to the lower frequency is, of course, negative.

The mid-frequency may be computed from

$$\omega_0^2 = \omega_1 \omega_2 \frac{x_2 \omega_1 - x_1 \omega_2}{x_2 \omega_2 - x_1 \omega_1} \quad (19)$$

and the ratio Q_1/Q_2 from equation (10), or (17) for 2 or 3 stages or

$$(Q_1/Q_2) = 3(n-1) + \sqrt{3(3n-4)} \text{ for 4 stages.}$$

The Q 's of the various stages are then given by:

$$1 \text{ stage: } Q = \frac{nx_1}{\frac{\omega_1}{\omega_0} - \frac{\omega_0}{\omega_1}} \quad (20)$$

$$2 \text{ stages: } Q_2 = \sqrt{\frac{nQ_2}{Q_1}} \cdot \frac{x_1}{\frac{\omega_1}{\omega_0} - \frac{\omega_0}{\omega_1}}; \quad Q_1 = Q_2 \cdot \frac{Q_1}{Q_2} \quad (21)$$

$$3 \text{ stages: } Q_2 = Q_3 = \sqrt[3]{\frac{nQ_2}{Q_1}} \cdot \frac{x_1}{\frac{\omega_1}{\omega_0} - \frac{\omega_0}{\omega_1}}; \quad Q_1 = Q_2 \cdot \frac{Q_1}{Q_2} \quad (22)$$

$$4 \text{ stages: } Q_2 = Q_3 = Q_4 = \sqrt[4]{\frac{nQ_2}{Q_1} \cdot \frac{x_1}{\omega_1} \cdot \frac{\omega_0}{\omega_1}}; \quad Q_1 = Q_2 \cdot \frac{Q_1}{Q_2} \quad (23)$$

These amplifiers are made up of one rather selective stage, corresponding to Q_1 , and a number of equal broadly-tuned stages, corresponding to Q_2, Q_3, \dots . With increasing feedback the selectivity of Q_1 must be increased, while the selectivity of Q_2 etc. approaches a limiting value which is of the order of the Q of a single stage amplifier without feedback, having the same bandwidth as the complete amplifier with feedback.

The amplifier is first designed, neglecting all capacitances, to have a gain approximately n times the final value. The feedback is designed with a purely resistive feedback network to decrease the gain n times. The value of C_p is then determined at the minimum practicable value, that is the input capacitance of the following stage plus an allowance for strays. Then the values of the other capacitances are given by

$$C_p = \frac{p}{\omega_0 \sqrt{R_L R_g}}; \quad C_c = \frac{k}{\omega_0 \sqrt{R_L R_g}} \quad (24)$$

$$\text{where } p = \frac{b}{2Q} \left[1 - \sqrt{1 + 4Q_b^2 - 4Q^2 \left(1 + \frac{1}{b^2} + d^2 \right)} \right]$$

$$k = \frac{1 - pd}{p + d}; \quad b = \sqrt{R_g/R_L} \text{ and } d = C_g \omega_0 \sqrt{R_L R_g}.$$

The amplification without feedback at the mid-frequency is

$$\alpha_0 = kQ \cdot g_m \sqrt{R_L R_g} \quad (25)$$

There are limits to the physically realizable values of C_p and C_c which are quoted in the article (Ref. H13).

It is shown in (C) below that the condition of maximal flatness gives an oscillatory transient response; for instance when the input voltage is a unit step, the two-stage amplifier has a response which overshoots 4.3%, while the three-stage amplifier overshoots 8% (Ref. H15).

A maximal flatness 2 stage amplifier has a small rise in the response at some high frequency due to positive feedback, compared with the response without feedback. For example, as may be shown by drawing a Nyquist diagram, a 2-stage amplifier with $\alpha_2/\alpha_1 = 10$, $A_0 = 316$, $\beta = 0.016$ has a rise of about 1.4 db due to positive feedback at some high frequency.

(B) Method of C.F. Brockelsby (Ref. H12)

A different approach to the same goal is made by Brockelsby who provides "staggering" by changing the values of load resistance and thereby obtaining different values of gain and frequency response. This method was published earlier than that of Mayr but is less comprehensive, although providing useful additional information. A summary of this method is given below. See also Ref. J13.

Two-stage amplifiers and maximal flatness

The widest frequency range possible without any peaks whatever is known as the condition of "maximal flatness." With a 2 stage amplifier in which both stages have identical gain and frequency response, the condition of maximal flatness is that $\beta A_0 = -1$, corresponding to a gain reduction of 2 times. On the other hand if two r.c.c. pentode stages have "staggered" gain and high frequency response (by using different values of load resistance) the condition of maximal flatness at the high frequency end of the range is that

$$\frac{1}{2}(b + 1/b)^2 = 1 - \beta A_0 \quad (26)$$

where A_0 = amplification at mid-frequency without feedback,

b = factor by which the normal value of load resistance is multiplied for one stage,

$1/b$ = factor by which the normal value of load resistance is multiplied for the other stage,

and β = fraction of the output voltage fed back to the input.

Equation (26) may be expressed in the alternative form

$$F = 2S^2 \quad (26a)$$

where $F = 1 - \beta A_0$ = feedback factor

and $S = \frac{1}{2}(b + 1/b)$ = "staggering coefficient."

In a two stage amplifier with a high frequency peak, the required staggering to produce a peak of known value is given by

$$S^2 = (F/2)(1 - \sqrt{1 - \alpha^2}) \quad (27)$$

where α = ratio of voltage gain at middle frequencies to that at the peak (α is less than 1).

The results are summarized in the following table :

$b =$	1	1.5	2	3	4	5
$S =$	1	1.08	1.25	1.7	2.1	2.6

Feedback factor (F) for maximal flatness (Eqn. 26a) :

$F =$	2	2.3	3.1	5.8	8.8	13.5
-------	---	-----	-----	-----	-----	------

For 1 db rise (Eqn. 27) :—

$F =$	3.7	4.3	5.7	10.6	16	25
-------	-----	-----	-----	------	----	----

For 3 db rise (Eqn. 27) :—

$F =$	6.8	8.0	10.7	19.7	30	46
-------	-----	-----	------	------	----	----

Fig. 7.76 shows the frequency characteristics obtained with 2 stage amplifiers with maximal flatness and for several other conditions. Here

$$x = \omega CR$$

and $F = 1 - \beta A_0$ = feedback factor.

FIG. 7.76

FIG. 7.77

Fig. 7.76. Frequency characteristics of two-stage amplifier. Curve A is without feedback and curves B, C and D respectively for maximal flatness, a 1 db peak and a 3 db peak ($x = \omega CR$; C = normal shunt capacitance of each stage; R = total normal a.c. load resistance for each stage; pentode valves (Ref. H12).

Fig. 7.77. Frequency characteristics of three-stage amplifier. Curve A is without feedback and curves B, C, D are respectively for maximal flatness and with feedback equal to two and four times the m.f. value (Ref. H12).

If the condition of maximal flatness is to hold at the low as well as at the high frequency end of the band, the centre-frequencies of both stages should be identical (Ref. H13).

Three-stage amplifiers and maximal flatness

It has been shown (Ref. H12) that if a substantially flat response over the maximum possible frequency band is required, the optimum arrangement for a three-stage amplifier is to have two stages with wide frequency response and one with narrow.

This finding is based on the assumption that the amplifier has maximal flatness; it is not necessarily the most desirable arrangement under all conditions.*

The condition for maximal flatness is that

$$F = \frac{1}{2} \cdot \frac{(B^3 + 2)^3}{2B^3 + 1} \quad (28)$$

where F = feedback factor

B = staggering factor = $1/b$

and b = factor by which the normal value of load resistance is multiplied for the one (narrow) stage.

[B is always equal to or greater than unity.]

Equation (28) may be approximated within 1.4% when $B \geq 2$ by

$$F \approx 1 + (B^3/4) \quad (29)$$

For example when $F = 10$ (i.e. 20 db feedback), $B \approx 3.3$ and the ratio of bandwidths is approximately 11.

As with the two-stage amplifier, an increased amount of feedback beyond that to give maximal flatness gives high frequency peaks (Fig. 7.77).

The critical amount of feedback to provide self-oscillation is

$$F_c = 5 + 2B^3 + 2/B^3 = 8F_f - 3 \quad (30)$$

where F_c = feedback factor to give critical feedback

and F_f = feedback factor to give maximal flatness.

The stability margin of a three-stage maximal-flatness amplifier is $(F_c - F_f)$ and in a typical example

$F_f = 3.16$ (i.e. 10 db reduction in gain) for maximal flatness

then $F_c = 8 \times 3.16 - 3 = 22.2$ (i.e. 27 db approx.) to give self-oscillation. The stability margin is therefore $27 - 10 = 17$ db approximately.

If the feedback is made very large, and the staggering is adjusted so as always to give maximal flatness, $F_c \approx 8F_f$, which for this example becomes $8 \times 3.16 = 25.2$ (i.e. 28 db approx.) giving a stability margin of 18 db approximately.

Fig. 7.78. Relation between the staggering factor B and the gain reduction factor F for maximal flatness in a three-stage amplifier. Values of B less than unity apply to the "two narrow, one wide" condition; values of B greater than unity apply to the "two wide, one narrow" condition (Ref. H12).

For both two- and three-stage maximal-flatness amplifiers (high frequency response)

1. The feedback which is fully effective in reducing distortion begins to fall at a frequency about F times lower than the knee.

2. The effective gain-reduction factor is about unity, indicating no feedback, at the knee.

3. The knee of the curve for the two-stage amplifier (Fig. 7.76) is at $x = \omega CR = \sqrt{F}$; at this point the attenuation is 3 db. In the three-stage amplifier (Fig. 7.77) the knee of the curve is at $x = \omega CR = \sqrt[3]{F}$; the attenuation is 3 db at $x = (2/3)^{1/3} \sqrt{F}$.

*The arrangement to provide the greatest value of the product (effective feedback) \times (bandwidth) is that due to Duerdoh described in Sect. 3(v)E.

Low frequency response

The equations for the high frequency end may be applied to the low frequency end of the response characteristic, in the simple case when the only frequency variable is the grid coupling condenser, by giving x the value

$$x = 1/\omega C_g R_g \quad (31)$$

where C_g = grid coupling capacitance

and R_g = grid resistor plus the effective source impedance of the preceding stage (approximately R_L in the case of a pentode).

(C) Conditions for critical damping

Critical damping may be defined as that value which gives the most rapid transient response which is possible without overshoot.

The maximal flatness amplifier—see (A) and (B) above—has been examined by J. E. Flood (Ref. H15) in the light of critical damping; the following summary is based on his work. It has been shown that a two-stage maximally-flat amplifier has a response which overshoots 4.3% while the three-stage amplifier overshoots 8% when a step waveform is applied to the grid circuit.

Although this article is concerned mainly with video-frequency or pulse amplification, it is possible that critical damping is a desirable feature in a-f amplifiers and that a condition of under-damping with oscillatory response to transients is to be avoided. See general comments in Sect. 3(v), also Ref. J8.

FIG. 7.79

FIG. 7.80

Fig. 7.79. Two-stage uncompensated amplifier with feedback (Ref. H15).

Fig. 7.80. Three-stage uncompensated amplifier with two time constants within the feedback loop (Ref. H15).

Two stage amplifier with constant value of β (Fig. 7.79)

The following may also be applied to the three stage amplifier of Fig. 7.80 which has only two time constants within the feedback loop.

It may be shown that the condition for critical damping is that

$$1 - \beta A_0 = \frac{(\alpha_1 + \alpha_2)^2}{4\alpha_1\alpha_2} \quad (32)$$

where A_0 = amplification at the mid-frequency without feedback

β is negative and independent of frequency

$\alpha_1 = 1/R_1C_1$ = inverse time constant of V_1

and $\alpha_2 = 1/R_2C_2$ = inverse time constant of V_2 .

When a higher feedback factor than that indicated by eqn. (32) is used, the transient response will be oscillatory; when a lower feedback factor is used, the transient response will be over-damped.

Equation (32) may be put into the form

$$1 - \beta A_0 = (1 + K)^2/4K = K/4 + 1/2 + 1/4K \quad (33)$$

where $K = \alpha_2/\alpha_1$ = ratio of inverse time constants.

This is plotted in the lower curve of Fig. 7.81.

If a fairly large amount of feedback is to be used, the ratio of time constants must be large.

The resultant inverse time constant of the amplifier is given by

$$\alpha = \frac{1}{2}(\alpha_1 + \alpha_2) = \frac{1}{2}\alpha_1(1 + K) \quad (34)$$

This relationship is plotted in the upper curve of Fig. 7.81.

FIG. 7.81

Fig. 7.81. Conditions for critical damping of two-stage uncompensated amplifier (Ref. H15).

Note: The “staggering coefficient” S as used by Brockelsby (Ref. H12) is related to α_1 and α_2 by the equation

$$S = \frac{\alpha_1 + \alpha_2}{2\sqrt{\alpha_1\alpha_2}} = \frac{1}{2} \left(\sqrt{K} + \frac{1}{\sqrt{K}} \right) \quad (35)$$

The condition for maximal flatness is therefore given by

$$1 - \beta A_0 = \frac{(\alpha_1 + \alpha_2)^2}{2\alpha_1\alpha_2} \quad (36)$$

Comparing equations (32) and (36), it will be seen that for any particular ratio of α_2/α_1 , the condition of critical damping permits a feedback factor of only one half that required for maximal flatness of the frequency characteristic. **The transient response of the maximally-flat amplifier is therefore oscillatory.**

A 2-stage critically damped amplifier will normally have a small amount of positive feedback at high frequencies, although the rise in response in a typical case will be less than 1 db above the zero-feedback curve.

Two-stage compensated amplifier

If resistor R_3 in Fig. 7.79 is shunted by a capacitor C_3 and if R_3 is very much greater than R_4 then critical damping is obtained when the inverse time constant of the feedback path is given by

$$\alpha_3 = \frac{-\alpha_1\alpha_2\beta A_0}{2\sqrt{\alpha_1\alpha_2(1 - \beta A_0)} - (\alpha_1 + \alpha_2)} \quad (37)$$

where $\alpha_1 = 1/R_1C_1$; $\alpha_2 = 1/R_2C_2$; $\alpha_3 = 1/R_3C_3$ and β is negative for negative feedback.

Similarly if an inductance L is connected in series with R_4 in Fig. 7.80, and if g_mR_4 is very much less than 1, then critical damping is obtained as indicated by eqn. (37) where $\alpha_3 = R_4/L$.

The inverse time constant for the amplifier is given by

$$\alpha = \sqrt{\alpha_1\alpha_2(1 - \beta A_0)} \quad (38)$$

Using the value of α_3 given by eqn. (37) for the inverse time constant of the amplifier with feedback, critical damping is obtained and the response to a step waveform of the

feedback amplifier is made identical with that of an amplifier without feedback having two stages, each having an inverse time constant equal to the geometrical mean of the inverse time constants of the two stages multiplied by the square root of the feedback factor (eqn. 38).

A particularly simple special case is obtained when

$$\alpha_2 = \alpha_1(1 - \beta A_0);$$

then $\alpha = \alpha_3 = \alpha_2 = \alpha_1(1 - \beta A_0)$.

Values of α_3 for critical damping may be derived from the curves of Fig. 7.82 and values of α from Fig. 7.83.

Three-stage amplifier

Critical damping cannot be obtained in a three-stage amplifier with constant β .

Three-stage amplifier with single time constant in feedback path

In this case there is only one value of feedback factor as given by eqn. (39) for which critical damping can be obtained.

$$1 - \beta A_0 = \frac{(\alpha_1 + \alpha_2 + \alpha_3)^2}{27\alpha_1\alpha_2\alpha_3} \quad (39)$$

$$\alpha = (\alpha_1 + \alpha_2 + \alpha_3)/3 \quad (40)$$

$$= [(\alpha_1\alpha_2\alpha_3(1 - \beta A_0))^{1/3}] \quad (41)$$

$$\alpha_4 = \frac{-3\alpha_1\alpha_2\alpha_3\beta A_0}{\alpha_1^3 + \alpha_2^3 + \alpha_3^3 - (\alpha_1\alpha_2 + \alpha_2\alpha_3 + \alpha_3\alpha_1)} \quad (42)$$

where α_3 = inverse time constant of third stage

α_4 = inverse time constant of feedback path

and α = inverse time constant of amplifier.

Fig. 7.82. Curves for determining α_3 for critical damping of two-stage compensated amplifier (Ref. H15).

FIG. 7.83

Fig. 7.83. Curves for determining α for critical damping of two-stage compensated amplifier (Ref. H15).

Three-stage amplifier with two time constants in feedback path

Critical damping can be obtained provided that

$$1 - \beta A_0 > \frac{(\alpha_1 + \alpha_2 + \alpha_3)^3}{27\alpha_1\alpha_2\alpha_3} \quad (43)$$

Under this condition,

$$\alpha_4 = \alpha_5 = (b \mp \sqrt{b^2 - 4ac})/2a \quad (44)$$

$$\alpha^3 = \alpha_1\alpha_2\alpha_3(1 - \beta A_0) \quad (45)$$

where α = inverse time constant of amplifier

$\alpha_1, \alpha_2, \alpha_3$ = inverse time constants of three stages

α_4, α_5 = inverse time constants in feedback path

$$a = 3\alpha - (\alpha_1 + \alpha_2 + \alpha_3)$$

$$b = 3\alpha^2 - (\alpha_1\alpha_2 + \alpha_2\alpha_3 + \alpha_3\alpha_1)$$

$$\text{and } c = \alpha^3 - \alpha_1\alpha_2\alpha_3.$$

When $1 - \beta A_0$ is less than the right hand side of eqn. (43) the transient response is over damped and less rapid.

A particularly simple case is obtained when

$$\alpha_2 = \alpha_3 = \alpha_1(1 - \beta A_0)$$

$$\text{then } \alpha = \alpha_4 = \alpha_5 = \alpha_2 = \alpha_3 = \alpha_1(1 - \beta A_0) \quad (46)$$

(viii) Constancy of characteristics with feedback

This is sometimes called "stability" (Ref. H8) but refers to the more or less complete independence of the gain of an amplifier with feedback (inside the amplifier frequency range) with regard to changes in valve characteristics and supply voltages. Becker defines the "stability factor" as

$$SF = 1 + \beta A_0 X \quad (47)$$

where $A_0 X$ = lowest gain which the amplifier ever has under the worst operating conditions, without feedback

and SF = stability factor with negative feedback.

(ix) Effect of feedback on phase shift*

The amplification without feedback may be expressed in the complex form

$$A = a + jb = |A| \angle \theta \quad (48)$$

where $|A|$ is the magnitude of the voltage amplification and θ is the phase angle of the output voltage of the amplifier relative to the input voltage, without feedback.

It is obvious that $\theta = \tan^{-1}(b/a)$ and $|A| = \sqrt{a^2 + b^2}$.

The amplification with feedback may be expressed in the form

$$A' = \frac{A}{1 - \beta A} = \frac{a + jb}{1 - (a + jb)\beta} = \frac{a - (a^2 + b^2)\beta + jb}{(1 - a\beta)^2 + b^2\beta^2} \quad (49)$$

provided that there is no phase shift in the feedback network. The phase angle of the output voltage relative to the input voltage, with feedback, is given by

$$\alpha = \tan^{-1} \frac{b}{a - (a^2 + b^2)\beta} = \tan^{-1} \frac{b/a}{1 - \beta A \sqrt{1 + b^2/a^2}} \quad (50)$$

$$= \tan^{-1} \frac{\tan \theta}{1 - \beta A \sqrt{1 + \tan^2 \theta}} \quad (51)$$

When β is negative, as is the case when the feedback is negative, it is evident from (51) that the angle α is less than the angle θ . Hence the phase shift of the output voltage relative to the input voltage is reduced by negative feedback.

SECTION 4 : SPECIAL APPLICATIONS OF FEEDBACK

There are so many applications of feedback, many of which are outside the subject of radio receiver and amplifier design, that it is impossible even to list them here. The following selected applications have some interesting features.

(1) Electronic attenuators

A cathode follower may be used with various cathode load resistors selected by rotary switch, to give the coarse steps, and then the screen voltage may be adjusted to give a fine adjustment of attenuation.

Smith, F. W., and M. C. Thienpont "Electronic attenuators" Comm. 27.5 (May 1947) 20.

(2) Stable admittance neutralization

Two valves in cascade with negative voltage feedback may be used to neutralize the input admittance of an amplifying valve (mainly the result of its input capacitance) and thereby enable the use of a load resistance of 23 megohms with a phototube for a cut-off frequency of 20 000 c/s.

"Stable admittance neutralization" Electronic Eng. 14.167 (Jan. 1942) 594.

(3) An amplifier without phase distortion

O. H. Schade has developed an amplifier without cathode by-pass condensers, screen by-pass condensers, decoupling condensers or output condenser in B-supply filter, which has negligible phase distortion from 10 to 30 000 c/s.

"An amplifier without phase distortion," Elect. 10.6 (June 1937) 26.

(4) Stabilized negative impedances

Negative impedance is produced from a positive impedance of the desired type by positive feedback through an amplifier stabilized with negative feedback.

Ginzton, E. L. "Stabilized negative impedances" Elect. (1) 18.7 (July 1945) 140 ; (2) 18.8 (Aug. 1945) 138 ; (3) 18.9 (Sept. 1945) 140.

(5) Tone Control

This is covered in detail in Chapter 15.

*Method after H. J. Reich "Theory and application of electron tubes."

SECTION 5: VALVE CHARACTERISTICS AND FEEDBACK

(i) *Triode cathode follower* (ii) *Pentode cathode follower* (iii) *Triode with voltage feedback* (iv) *Pentode with voltage feedback, transformer-coupled* (v) *Cathode degenerative triode* (vi) *Cathode degenerative pentode* (vii) *Cathode-coupled triodes* (viii) *Feedback over two stages.*

Although it is important to bear in mind that the application of feedback does not alter the characteristics of a valve, yet there are certain features which can best be visualized by the graphical use of effective valve characteristics with feedback.

(i) Triode cathode follower

The cathode-follower characteristics (Fig. 7.85) may be drawn very readily from the published triode plate characteristics (Ref. D2). The $E_c = 0$ curve remains as the boundary of the grid current region. If the grid circuit impedance is high, it is not practicable to go beyond the $E_c = 0$ curve, just as with plate-loading.

FIG. 7.84

Fig. 7.84. Basic circuit of cathode follower.

The basic circuit is shown in Fig. 7.84 from which it is evident that with zero input voltage ($E_i' = 0$)

$$E_{cb} = E_b - E_c \quad (1)$$

The plate is the most convenient electrode to regard as the common basis for electrode voltages, since it is the only one directly connected to the voltage source. Valve characteristics may be plotted by the method described below so that each curve, instead of applying to constant grid-to-cathode voltage applies to constant grid-to-plate voltage (E_{cb}). In effect, the valve and its load resistor are inverted as compared with normal practice and the cathode here takes the place of the plate.

Applying eqn. (1) for the case where E_{cb} is constant,

$$E_b = E_{cb} + E_c \quad (2)$$

For example, take the case when $E_{cb} = 150$ volts. We may calculate the points along the curve using eqn. (2):

$E_{cb} =$	150	150	150	150	150	volts
$E_c =$	0	-2	-4	-6	-8	volts
$E_b =$	150	148	146	144	142	volts

These points may be plotted to give the $E_{cb} = 150$ volt curve on the existing "plate characteristics," as has been done in Fig. 7.85.

(A) Resistance loaded triode cathode follower

The cathode-follower characteristics may then be used as any ordinary resistance-loaded triode for the determination of power output, voltage gain and distortion. Maximum power output will generally be achieved when R_k is between r_p and $3r_p$, with slightly less distortion with the higher values of R_k . In Fig. 7.85, R_k is taken as 15 000 ohms, with $E_{bb} = 200$ volts. If it were desired to obtain the highest possible voltage swing, a much higher value of load resistance would be selected (e.g. 50 000 ohms). In each case the operating point should be selected so as to avoid both grid current and plate-current cut-off with the highest input voltage. For maximum output, a point slightly above half-way along the loadline is desirable. In Fig. 7.85, a suitable operating point (O) is the intersection of the $E_{cb} = 150$ volt curve with the loadline which occurs at a plate-to-cathode voltage of 145 volts, thus indicating that $E_c = -5$ volts. Alternatively, the bias could have been read from intersection of the $E_c = -5$ (plate characteristic) with the loadline.

When the operating point (O) has been established, it is then necessary to work entirely with the E_{cb} curves, neglecting the E_c curves. In Fig. 7.85 the operating point is at $E_{cb} = 150$ volts, and point A is $E_{cb} = 100$, so that the peak input voltage

FIG. 7.85

Fig. 7.85. Cathode follower characteristics of small general purpose triode. The solid loadline is for $R_k = 15\,000$ ohms, the dashed loadline is for the addition of an a.c. shunt load.

amplitude is 50 volts. It is obvious that the opposite swing will extend to $E_{cb} = 200$ volts (point B) thus giving a peak-to-peak swing of $2 \times 50 = 100$ volts. It will be seen that OA corresponds to $E_c = -5$ volts, while OB corresponds to -5.7 volts, but this is due to the improved linearity with the cathode follower. With plate loading the loadline would be AD, so that cathode loading causes a longer loadline by the amount DB, thus resulting in a slightly greater power output.

The voltage gain is given by

$$A' = \frac{E_B - E_A}{E_{c(b)} - E_{c(a)}} \quad (3)$$

where subscripts A and B indicate the voltages at points A and B on the loadline.

If the cathode is coupled through a coupling condenser C_c to a following grid resistor R_g (Fig. 7.8), the a.c. loadline will be drawn through the operating point O with a slope of $-1/R_L$ where $R_L = R_g R_k / (R_k + R_g)$.

The mutual characteristics of cathode followers may be drawn and interpreted by the method of Ref. C29.

(B) Transformer-coupled triode cathode follower

The same form of cathode-follower characteristic may be used when the load is coupled through a transformer so as to reflect a resistance R_k across the primary. In most cases the load resistance may be taken (at least as a first approximation) to have the same value as for plate loading. In Fig. 7.86 the loadline AOB extends from A (the junction of the $E_c = 0$ and the $E_{cb} = 100$ V curves) to B, on the $E_{cb} = 500$ V curve. The operating point O is the intersection of the loadline with the $E_{cb} = 300$ V curve, thus giving a peak input voltage of 200 volts in both directions. The power output and distortion may be calculated as for plate loading.

If the load resistance R_k is increased, the loadline will rotate about O to the position (say) CD with constant input voltage. This will usually result in a decrease in both

power output and distortion—there is the same advantage (as with plate loading) in keeping the loadline out of the region of bottom curvature. It would be possible, with the higher resistance load, to increase the input voltage so as to extend the loadline from OC to meet the $E_c = 0$ curve.

If the load resistance R_k is decreased, the loadline will rotate about O to the position (say) EF. If the input voltage is unaltered, the plate current will cut off at F and the valve will run into grid current at E, both resulting in distortion. In this, the cathode follower differs from a plate loaded triode, and it is important to ensure that the load resistance does not fall appreciably below the designed value. Fortunately, a loudspeaker has an impedance characteristic which, although it rises considerably above its nominal (400 c/s) value, does not drop appreciably below it. A cathode follower with a loudspeaker load is therefore a good combination from the loading point of view.

FIG. 7.86

Fig. 7.86. Cathode follower characteristics of power triode (type 2A3) with transformer-coupled load. Loadline AB is normal; CD is high resistance load line; EF is low resistance loadline illustrating grid current and plate current cut-off.

If a low impedance driver is used, it is possible to drive a cathode follower into the grid current region with considerably greater power output and efficiency. In the ideal limiting case, the conditions are:

Plate voltage	E_b , volts
Plate current	I_b , amperes
Load resistance	E_b/I_b , ohms
Power output	$\frac{1}{2}E_bI_b$, watts
Plate efficiency	50%

If the cathode follower is to be used as a high-input-impedance voltage amplifier, the conditions vary with the output level. At low output voltages, the operating conditions are of no consequence (within reasonable limits) so far as voltage gain is concerned, and R_k may be equal to r_p . For very high output voltages, the load resistance should be as high as practicable (assuming a purely resistive load), say $R_k = 5r_p$, and the operating current should be as low as practicable without causing plate-

current cut-off. A somewhat lower load resistance may be used for fairly high output voltages.

The transformer primary inductance should have the same value as for plate loading under similar conditions, if full power output is desired at low frequencies. A transformer with low primary inductance will give uniform gain at low level output, but at high output it will cause plate-current cut-off and grid current as for loadline EF in Fig. 7.86.

References C14, C16, C17, C29, D1, D2, D3, D8, D9, D10, D11.

(ii) Pentode cathode follower

A pentode (or tetrode) may be connected in several ways arising from the screen supply and by-pass—

FIG. 7.87

Fig. 7.87. Pentode cathode follower, transformer-coupled, screen by-passed to cathode.

(A) Triode connection (screen tied to plate)

The published "triode" characteristics may generally be used. If no triode characteristics are available, ascertain the characteristics for the screen voltage corresponding to the desired conditions (the plate voltage may be equal or higher).

$$\text{Then } I_k \approx I_b + I_{c2} \quad (4)$$

$$g_m \approx (\text{pentode } g_m) \times (I_k/I_b) \quad (5)$$

$$\text{and } \mu \approx E_{c2}/E_{c1} \text{ (cut-off).} \quad (6)$$

(B) Screen by-passed to earth

There is no exact method using published characteristics.

An approximate method has been described by Shapiro (Ref. D2).

(C) Screen by-passed to cathode—Transformer-coupled (Fig. 7.87)

The cathode follower characteristics may be drawn by the same method as for a triode (Fig. 7.88). The procedure for calculating the power output and distortion is :

FIG. 7.88

Fig. 7.88. Cathode follower characteristics of beam power tetrode and typical of all pentodes. Loadline AOB is normal; CD high resistance; EF low resistance illustrating grid current and plate current cut-off.

1. To determine the maximum plate voltage and current for the operating point. Here $E_b = 285$ V and happens to coincide with the $E_{cb} = 300$ V curve. If desired, mark the value of E'_1 corresponding to point O.

2. Try several values of load resistance (i.e. slope of loadline) until an optimum position for point A is determined, so as to make OA as long as possible, and at the same time give $OB = OA$ with B slightly above plate-current cut-off.

3. Determine E_b for point A (in this case 50 V)—A is then automatically on the $E_{cb} = 50$ V curve.

4. Draw the other limiting E_{cb} curve (in this case $E_{cb} = 550$ V, giving a peak amplitude of 250 V each way).

5. Calculate power output and distortion as for a power triode, using the loadline AOB and the E_{cb} curves.

When a higher resistance load is used with the same input voltage, the loadline rotates about O to (say) COD, where the power output is lower, the distortion slightly less, and point C is well negative with respect to $E_c = 0$. When a lower resistance load is used with the same input voltage, the new loadline may be (say) EOF where E is well into the grid-current region and F is beyond plate-current cut-off. In this respect the pentode is similar to the triode, but the pentode is rather more critical regarding low load resistances; it is, however, quite satisfactory with a speaker load.

If cathode bias is used, the procedure is as for a plate-loaded power pentode.

(D) Screen by-passed to cathode—Resistance-loaded (Fig. 7.89)

The curves are generally the same as for transformer coupling, and the treatment is similar to that for resistance-loaded triodes, except that it is necessary to allow for the d.c. screen current flowing through R_k . The screen current may be taken from the published data for typical operating conditions, or estimated from the ratio of plate to screen currents. The voltage drop through R_k additional to that due to the plate current will be $R_k I_{c2}$. The procedure is to take as the effective plate supply voltage the value $(E_{bb} - R_k I_{c2})$ and then to proceed normally, as for a triode.

(E) Screen voltage from separate supply (Fig. 7.90)

If the screen voltage is obtained from a separate supply, such as a battery, returned to the cathode, then the voltage from cathode to screen may be maintained constant without smoothing out the screen current variations. In this case the screen current does not flow through the cathode resistor R_k . The pentode characteristics for a constant screen voltage may be used without any adjustment for the effects of screen current.

References D1, D2, D3, D11.

Fig. 7.89. Pentode cathode follower, resistance-loaded, screen by-passed to cathode.

Fig. 7.90. Pentode cathode follower, resistance-loaded screen from separate supply.

(iii) Triode with voltage feedback

The basic circuit is Fig. 7.91 in which we can consider the conditions with direct applied voltages (E'_1 and E_b). A fraction of the plate voltage is applied degeneratively to the grid so that

$$|\beta| = R_1 / (R_1 + R_2) \quad (7)$$

where $|\beta|$ is the numerical value of β without regard to its sign.

Consider first the condition for E_c to be zero. It is evident that the condition is that

$$E'_1 = |\beta| E_{b0} \quad (8)$$

where E_{b0} = value of E_b when $E_c = 0$.

Now consider the general condition when the grid is negative with respect to the cathode. If the input voltage E_i' is kept constant, then the grid-to-cathode voltage E_g will change when E_b is changed. The relationship is

$$\Delta E_g = |\beta| (\Delta E_b) \quad \text{when } E_i' \text{ is constant.}$$

Therefore $\Delta E_b = \Delta E_g / |\beta|$

Therefore $E_b = E_{b0} - \Delta E_b = E_{b0} - \Delta E_g / |\beta|$ (9)

Eqn. (9) may be used for the calculation of points on the constant E_i' characteristics, as for example:

E_{b0}	=	100	100	100	100	100	volts
$ \beta $	=	0.2	0.2	0.2	0.2	0.2	
E_i'	=	20	20	20	20	20	volts
$-\Delta E_g$	=	0	-1	-2	-3	-4	volts
$-\Delta E_g / \beta $	=	0	-5	-10	-15	-20	volts
E_b	=	100	95	90	85	80	volts

These have been plotted in Fig. 7.92. It should be noted that E_{b0} is the plate voltage corresponding to zero grid voltage.

(iv) Pentode with voltage feedback—Transformer coupled

Pentodes with a substantial degree of negative voltage feedback (say $|\beta| \geq 0.2$) behave more or less like a cathode follower. Pentodes with a limited degree of feedback, or none, exhibit some special peculiarities. Fig. 7.93 shows input voltage curves for three different values of β ; the curvature on the $\beta = -0.1$ curve continues along its whole length while its slope is gradual and bottom curvature extensive.

Fig. 7.91. Basic circuit of triode with negative voltage feedback.

The full effect of a low degree of feedback is illustrated in Fig. 7.94 where $\beta = -0.1$. The curves are drawn as in the triode case except for the change in β . A suitable loadline AOB has been selected to give about the same power output as without feedback. Provided that the load resistance remains constant, the performance is satisfactory, but the value is critical. With constant input voltage (40 volts peak)

Fig. 7.92. Feedback characteristics of small general purpose triode with 20% negative voltage feedback ($\beta = -0.2$).

FIG. 7.93

Fig. 7.93. Single input voltage curve for each of three values of voltage feedback for beam power tetrode (6V6-GT with $E_{c2} = 250$ V), to illustrate effect of feedback.

FIG. 7.94

Fig. 7.94. Feedback characteristics of beam power tetrode (6L6 or 807 with $E_{c2} = 300$ V) and 10% voltage feedback ($\beta = -0.1$).

the valve will run into grid current as soon as the load resistance either increases or decreases. It is therefore not suitable for use on a loudspeaker load unless the input voltage is reduced. A 10% reduction in input voltage (19% in power output) would be some improvement, but greater reduction is desirable, say 20% to 30% of the input voltage, depending on the operating conditions. Even with an input reduction giving a power output of only 50% maximum, the pentode is still less flexible with regard to load resistance than an ordinary triode. This position improves as the amount of feedback is increased.

See References D4, D12.

Fig. 7.95. Basic circuit of cathode degenerative triode.

(v) Cathode degenerative triode

The circuit diagram of a cathode degenerative triode is shown in Fig. 7.95 from which it is evident that

$$E_c = E'_c - E_k \quad (10)$$

The curves of a cathode degenerative triode may be drawn by the procedure outlined below, although a special set of characteristics is required for each value of R_k . Fig. 7.96 shows the curves for a typical general purpose triode with $R_k = 1000$ ohms. The input voltage curves are straighter than those without feedback, and the two curves coincide only at $I_b = 0$. The E'_c curves have a lower slope, indicating a higher plate resistance, than the E_c curves.

Take the $E'_c = -4$ V curve as an example of the calculations. We know that $R_k = 1000$ ohms and $E'_c = -4$ V. If $I_b = 2$ mA, then $E_k = 2$ V and $E_c = E'_c - E_k = -4 - 2 = -6$ V.

Refer to the plate characteristics to find the plate voltage which will give a plate current of 2 mA at a bias of -6 V—the value is $E_{pk} = 144$ volts.

Fig. 7.96. Current feedback characteristics of general purpose triode (6SN7-GT single unit) with $R_k = 1000$ ohms.

The total voltage (E_b) from plate to earth is

$$E_b = E_{pk} + E_k = 144 + 2 = 146 \text{ V.}$$

Therefore the point ($E_b = 146 \text{ V}$; $I_b = 2 \text{ mA}$) is on the $E'_i = -4 \text{ V}$ curve. Repeat this procedure for $I_b = 0, 4$, and 6 mA to give the whole curve; then perform a similar operation for $E'_i = -6 \text{ V}, -8 \text{ V}$ and so on.

The loadline may then be drawn in the normal manner, except that its slope will be $-1/(R_k + R_L)$. The E'_i curves are to be used for calculating gain and distortion.

The method generally employed with cathode degenerative triodes makes use of the published characteristics. There are several methods including those of Middleton, McIlroy, Huber, Lonsdale and Main; the following treatment is based on Krauss, and may also be applied to cathode followers.

As an example take the characteristics of Fig. 7.97 with $R_k = 8000 \text{ ohms}$, $R_L = 32000 \text{ ohms}$ and $E_{bb} = 400 \text{ volts}$. Draw the loadline corresponding to $R_k + R_L = 40000 \text{ ohms}$, as shown. Add an E_k scale below the E_b scale, based on the equation $E_k = R_k I_b$, commencing from E_{bb} . The value of E_k at any point on the loadline may then be found by projecting downwards to the E_k scale.

The input voltage E'_i is not proportional to any scale on the diagram, because the amplification is not constant. The value of E'_i at any point of intersection along the loadline may be found by drawing up the following table where each value of E_c is taken in turn. The input voltage is actually $(E_k + E_c)$, but for convenience the point ($E_c = -8$) has been selected as the operating point, and so shown in the E'_i column.

E_c	E_k	$(E_k + E_c)$	E'_i	
0	64	64	34.7	Point A
-2	57	55	25.7	
-4	50.2	46.2	16.9	
-6	43.6	37.6	8.3	
-8	37.3	29.3	0	Operating point (O)
-10	31.2	21.2	-8.1	
-12	25.1	13.1	-16.2	
-14	19.6	5.6	-23.7	
-16	14.7	-1.3	-30.6	Point B at $E_k = 11.9$ and $E'_i = -34.7$
-18	10.1	-7.9	-37.2	
-20	6.2	-13.8	-43.1	

The values of E'_i may be plotted against E_k and therefore also against E_b to give the dynamic characteristic, but this is usually unnecessary. Once the maximum input voltage has been selected it is only necessary to mark the extremities on the loadline. For example, if it is desired to swing to $E_c = 0$, then the peak E'_i will be 34.7 volts in each direction. The peak in one direction will be A where $E_c = 0$, and the other will be B, determined by interpolation:

$$\begin{array}{lll} E_c = -16 & E_k = 14.7 & E'_i = -30.6 \\ E_c = -18 & E_k = 10.1 & E'_i = -37.2 \end{array}$$

$$\text{Diff.} = 6.6$$

Also the difference between the desired value (-34.7) and -30.6 is 4.1. The ratio is therefore $4.1/6.6$.

Similarly with E_k : $14.7 - 10.1 = 4.6$.

The value of E_k for point B is therefore $14.7 - 4.6(4.1/6.6) = 14.7 - 2.8 = 11.9$.

The voltage gain and power output may be calculated from $E_b = 5E_{k0}$ using the values of E_k at $E'_i = 34.7$ (point A), $E'_i = 0$ (point O) and $E'_i = -34.7$ (point B). The second harmonic distortion may be found from the ratio AO/OB measured in volts (E_k); i.e. $(64 - 37.3)/(37.3 - 11.9) = 26.7/25.4 = 1.05$. Therefore $H_2 \approx 1\%$ —see Chapter 13 Sect. 2(i).

FIG. 7.97

Fig. 7.97. Method of calculating performance of cathode degenerative triode without drawing special characteristics.

(vi) Cathode degenerative pentode

The general procedure is the same as for triodes, except that allowance must be made for the d.c. screen current flowing through R_k . This is done by taking $(E_{bb} - R_k I_{c2})$ as the effective plate supply voltage, and then by carrying on as for the triode case.

For valves with a high plate resistance this method is not very satisfactory, and a more practical method has been described by Pratt.

References D1, D11.

(vii) Cathode-coupled triodes

It is possible to make a graphical analysis of the cathode-coupled amplifier, using ordinary published valve characteristics (Ref. D6).

(viii) Feedback over two stages

It is possible to draw the equivalent characteristics of two stages in cascade with feedback over both stages, following the method of Pratt (Ref. D1).

Alternatively, it is possible to use the published valve characteristics to obtain a graphical analysis (Ref. D7).

CHAPTER 8

WAVE MOTION AND THE THEORY OF MODULATION

By I. C. HANSEN, Member I.R.E. (U.S.A.)

Section	Page
1. Introduction to electromagnetic waves	403
2. Transmission of intelligence	405
3. References	406

SECTION 1 : INTRODUCTION TO ELECTROMAGNETIC WAVES

(i) *Wave motion* (ii) *Electromagnetic spectrum* (iii) *Wave propagation.*

(i) Wave motion

Before considering the various methods of radio reception, it is desirable to have an understanding of the nature of radio waves and of how they are used to transmit intelligence.

The theory of electromagnetic radiation (Refs. 1, 2, 3) is essentially a mathematical one and any attempt to reduce the theory to non-mathematical terms requires certain assumptions to be made which are not strictly true.

It should be noted that sound waves in air, waves in water and radio waves are propagated in entirely different ways.

In the case of sound, the waves are called "longitudinal" and consist of alternate compressions and expansions of air.

The layers of air as shown in Fig. 8.1 do not move steadily forward with the wave but move to and fro through a limited path in the direction of motion of the wave.

FIG. 8.1

Fig. 8.1. Representation of a sound wave in air.

Referring to Fig. 8.2 and assuming this to be a representation of a water wave, it will be seen that as the wave progresses, a particle (such as a cork) as shown in the figure, moves in a vertical direction which is at right angles to the direction of motion of the wave. This form of wave motion is known as "transverse."

The distance between two successive crests is a measure of the length of the wave, i.e. the wavelength, and the number of complete waves (or cycles) passing any point in one second denotes the frequency in cycles per second.

The medium in which the wave is transmitted determines the speed or velocity of propagation. In the case of sound waves in air, the velocity is approximately 3.4×10^8 metres per second. The velocity of sound in some common media is given in Chapter 20 Sect. 8(iii).

Electromagnetic waves are also transverse. However, radiated electromagnetic energy consists of two component fields, respectively magnetic and electric, both in phase, existing at right angles to each other and to the direction of motion of the wave. In contrast to sound waves in air, electromagnetic waves in free space have a velocity of 3×10^8 metres per second.

FIG. 8.2

Fig. 8.2. Representation of a water wave.

(ii) Electromagnetic frequency spectrum (Ref. 4)

Type of radiation	Wavelength
Hertzian Waves (used for radio communication)	30 000 M — 0.01 cm
Infra Red	0.04 cm — 0.000 07 cm
Visible Light*	7000 Å° — 4000 Å°
Ultra Violet	4000 Å° — 120 Å°
X-Rays	120 Å° — 0.06 Å°
Gamma Rays	1.4 Å° — 0.01 Å°
Cosmic Radiation	about 0.0001 Å°

1 Angstrom unit Å° = 1×10^{-8} cm.

(iii) Wave propagation

Assuming a simple non-directional aerial, the electromagnetic waves are radiated in straight lines at all angles. That portion of the radiation at a large angle to the horizontal is called the "sky" wave. Depending upon the frequency and the angle of radiation, this wave may be reflected by an ionized layer in the earth's upper atmosphere and thus return to the earth at a considerable distance from its origin. By making use of this phenomenon, long distance short wave communication can be accomplished.

In recent years much work has been done in forecasting frequencies that will give best results for communication between any two points at any given time. These predictions, based on a study of the ionosphere, are published regularly in different parts of the world and are an exceedingly valuable aid to reliable communication services. A handbook has been published explaining the basis of the predictions and the methods used in forecasting (Refs. 5, 6, 7, 8, 9, 10). This subject is covered more comprehensively in Chapter 22, Sect. 6.

For the effect of the ionosphere on the reception of radio signals see Chapter 22, Sect. 6.

*For further details, see Chapter 38 Section 13 and Fig. 38.8.

SECTION 2 : TRANSMISSION OF INTELLIGENCE

(i) *Introduction* (ii) *Radio telegraphy* (iii) *Radio telephony.*

(i) Introduction

There are several methods of conveying information using the radiated waves. By switching on and off the transmitter in accordance with a prearranged code, audible sounds will be heard in a suitable receiver. This is known as radio telegraphy. Alternatively the intelligence in the form of speech or music can be superimposed on the transmitted radio frequency by a process of "modulation." This is referred to as radio telephony. There are four major types of this latter system of transmission, known as amplitude, frequency, phase and pulse modulation (Refs. 17, 18, 33).

(ii) Radio telegraphy

This is used primarily for communication purposes over long distances. By means of automatic transmission and reception it is possible to convey messages at a rapid rate half way round the world. Such circuits are less susceptible to interference and mutilation of the message text than corresponding circuits using radio telephony. A radio telegraph (C.W.) transmitter usually consists of a crystal oscillator followed by several r-f power amplifier stages. An automatic or manual switch, operating in a power circuit supplying current to one of the r-f amplifier electrodes, serves to turn the r-f power on or off as required by the coded messages (Ref. 11).

(iii) Radiotelephony

(A) Amplitude Modulation (A-M)

This is commonly used in local medium frequency and long distance shortwave broadcast transmitters. The amplitude of the r-f radiated wave (the carrier) is varied at an audio frequency rate according to similar variations of the intelligence which it is required to transmit. This is usually accomplished by varying the plate voltage of a r-f amplifier by the audio signal. The r-f amplifier may be in the final transmitter stage, in which case a large audio power is required for complete modulation—50% of the modulated r-f stage plate input power. This is called "high-level" modulation. As an alternative, modulation can be employed at an early stage in the transmitter, and linear r-f amplifiers used to raise the power level to that required. Much smaller powers are necessary for this "low-level" modulation system, but the Class B linear r-f amplifiers are less efficient than the Class C counterparts used in the "high-level" method of modulation. Both systems are used extensively, but most high power transmitters employ "high-level" modulation. With amplitude modulation, the power output of the transmitter varies, but the phase and frequency of the carrier remain unaffected (Refs. 12, 13).

(B) Frequency Modulation (F-M)

This is now coming into its own in the mobile equipment field. While it is being used to supplement medium frequency A-M broadcasting, F-M may also be used for the audio channel of television (TV) transmitters. In this system the carrier frequency is varied at audio frequency above and below the unmodulated carrier frequency. This can be achieved by using a reactance valve to alter the frequency of the transmitter master oscillator, the reactance valve being controlled by the audio frequency signal.

In contrast to A-M, the power output from an F-M transmitter does not change, but the frequency of the carrier varies, the deviation in frequency being proportional to the amplitude of the modulating signal (Refs. 14, 15, 16, 24, 32, 33).

(C) Phase Modulation

In this system the audio signal is used to shift the phase of the carrier, the change in phase angle being proportional to the instantaneous amplitude of the modulating signal. The carrier frequency also changes but the power output remains constant.

P-M is not yet in general use and will therefore not be considered further (Refs. 19, 20, 21, 22, 23, 24, 31, 33).

(D) Pulse Modulation

The numerous variations of this system are finding their chief application in the very high frequency communication field. Radar and related distance measuring equipments rely largely on pulse modulation for their successful operation. This modulation system is outside the scope of the Handbook (Refs. 25, 26, 27, 28, 29, 30, 33).

SECTION 1 : INTRODUCTION

When a violin is tuned, the tensions of its strings are adjusted to permit vibration at particular frequencies. In radio, when an arrangement of L , C , and R responds to particular frequencies, it is called a “tuned” circuit.

In principle, the tuned circuit is similar to a pendulum or violin string, tuning fork, etc.—it has the property of storing energy in an oscillating (vibrating) state, regularly changing from kinetic form (magnetic field when current flows through the coil) to potential form (electric field, when the condenser is charged) and back again at a frequency called the **natural resonant frequency**.

FIG. 9.1

In Fig. 9.1 let the condenser C be charged. It will discharge its energy through the inductance L , causing the current to increase all the while, until it reaches the maximum when there is no potential across C . At that instant the energy is all magnetic, and the current continues, fed by the magnetic field, to build a voltage of reversed polarity across C . When all the energy has been transferred from L to C , the voltage across C has its original value, but is reversed in sign, and the current is diminished to zero. The process then reverses, and repeats itself indefinitely, cycle after cycle.

SECTION 2 : DAMPED OSCILLATIONS

Were there no loss of energy, each cycle would be the same, but this is never the case in practice, as the coil must have resistance. The rate at which the energy decreases is proportional to the energy (remaining) in the circuit.

For a detailed account of damped oscillations, as these periodic changes of decreasing amplitude are called, reference should be made to standard textbooks relating to the theory of radio circuits. A list of several such books is given in the accompanying bibliography.

Here we consider briefly the circuit shown in Fig. 9.2a. Let I_0 be the maximum value of the current during a given cycle of the oscillation, and let the time t be measured from the instant of this maximum; then the value of the current i at any subsequent time is given by the equation

$$i = I_0 e^{-\alpha t} \cos \omega_n t, \quad (1)$$

where $\alpha = r/2L =$ damping factor,

$$\text{and } \omega_n = \sqrt{\frac{1}{LC} - \frac{r^2}{4L^2}}.$$

The quantity $f_n = \omega_n/2\pi$ is called the **natural resonant frequency**. In the above formulae L is in henrys, C in farads, r in ohms, ω_n in radians per second and f_n in cycles per second.

The **resonant frequency** f_0 (corresponding to $r = 0$) of the circuit is defined by

$$2\pi f_0 = \omega_0 = \sqrt{1/LC} \quad (2)$$

The ratio of the natural resonant frequency to the resonant frequency is

$$f_n/f_0 = \sqrt{1 - 1/(4Q^2)} \quad (3)$$

$$\text{where } Q = \frac{\omega_n L}{r} = \frac{2\pi f_n L}{r}$$

$$= \frac{\text{reactance of the coil at resonant frequency}}{\text{coil resistance}}$$

This relationship shows that in practice there is little difference between these two frequencies. Q must, for example, be less than four to make f_n differ by 1% from f_0 . Q normally exceeds fifty, for which value the two frequencies differ by about one part in twenty thousand.

If now, in the equation for the current, t is increased by an amount $2\pi/\omega_n$, the period of one cycle, we arrive at the corresponding point in the next cycle. Let i' denote the current at this point, so that

$$\begin{aligned} i' &= I_0 e^{-\alpha(t+2\pi/\omega_n)} \cos \omega_n(t + 2\pi/\omega_n) \\ &= i e^{-2\pi\alpha/\omega_n} \end{aligned}$$

$$\text{or, } i'/i = e^{-\pi r/\omega_n L}, \text{ since } \alpha = r/2L \quad (4)$$

This gives the ratio of the amplitude of one cycle to that immediately preceding.

Logarithmic decrement, δ , is defined by

$$\delta = \pi r/\omega_n L = \log_e (i/i') \quad (5)$$

and is thus the naperian logarithm of the ratio of the amplitudes of two successive cycles.

See also Sect. 11 Summary of Formulae.

SECTION 3 : SERIES RESONANCE

The **series impedance** z of the circuit in Fig. 9.2a at any frequency ($f = \omega/2\pi$) is given by the expression

$$z = \sqrt{r^2 + [\omega L - (1/\omega C)]^2} \quad (6)$$

Thus if an alternating voltage of frequency f be applied in series with the circuit, when the value of r is fixed, we see that z is least, and hence the current reaches its maximum, when $\omega L - 1/\omega C = 0$, i.e. when $\omega = 1/\sqrt{LC} = \omega_0$, the resonant frequency.

It is perhaps surprising that the frequency for maximum current is independent of the circuit resistance r and that maximum current does not occur when the frequency of the applied voltage is equal to the natural frequency f_n . The state of maximum current flow is called **series resonance**.

If E be the r.m.s. value of the applied alternating voltage, the r.m.s. value I of the current produced in the circuit is clearly

$$I = \frac{E}{z} = \frac{E}{\sqrt{r^2 + [\omega L - (1/\omega C)]^2}} \quad (7)$$

$$= E/r, \text{ when } \omega = 1/\sqrt{LC} = \omega_0 \quad (8)$$

The **voltages across the several parts of the circuit** under this condition of series resonance are (Fig. 9.2a) :

$$rI = E \text{ across the resistance} \quad (9)$$

$$\omega_0 LI \text{ across the inductance} \quad (10)$$

$$\text{and } -(1/\omega_0 C)I \text{ across the capacitance.} \quad (11)$$

The voltages across the inductance and capacitance are equal and opposite in sign, thus cancelling each other, and usually they are large compared with the voltage across the resistance. The voltage across the inductance may be expressed as $(\omega_0 L/r)E$, and therefore its ratio to the voltage applied in series with the circuit is $\omega_0 L/r$. **This ratio, usually denoted by Q , is the ratio of the reactance of the coil at resonance to the resistance in series with it, and is called the magnification factor or quality factor.** Thus,

$$Q = \frac{\omega_0 L}{r} = \frac{1}{r} \sqrt{\frac{L}{C}} = \frac{1}{\omega_0 Cr} \quad (12)$$

Q may also be called the **energy factor** and is then defined by

$$Q = 2\pi \frac{\text{peak energy storage}}{\text{energy dissipated per cycle}} \\ = \omega \frac{\text{peak energy storage}}{\text{average power loss}}$$

That this is equivalent to $\omega_0 L/r$ is shown by

$$Q = \omega_0 \frac{\frac{1}{2} LI^2}{\frac{1}{2} I^2 r} = \frac{\omega_0 L}{r}$$

FIG. 9.2

It is shown in Chapter 4 Sect. 5(vi) that the **power factor** is approximately equal to $1/Q$; when Q is greater than 7 the error is less than 1%.

See also Sect. 11 Summary of Formulae.

The general treatment of series circuits with L , C and R is given in Chapter 4 Sect. 6(ii).

SECTION 4: PARALLEL RESONANCE

Let us now examine the result of applying an alternating voltage E across the condenser C in the circuit shown in Fig. 9.2b. The current divides between the two branches, and we find that the (r.m.s.) value of the current in L and r is given by

$$I_L = \frac{E}{\sqrt{r^2 + \omega^2 L^2}} \quad (13)$$

and the r.m.s. value of the current in C by

$$I_c = \omega CE \quad (14)$$

Adding the two currents, with due regard to their phase relation, the r.m.s. value of the total current I is found to be

$$I = E \sqrt{\left(\omega C - \frac{\omega L}{r^2 + \omega^2 L^2} \right)^2 + \left(\frac{r}{r^2 + \omega^2 L^2} \right)^2} \quad (15)$$

When $\omega C = \omega L / (r^2 + \omega^2 L^2)$, the total current I is in phase with the applied voltage E , and has its minimum value

$$I = E \frac{r}{r^2 + \omega^2 L^2} \quad (16)$$

This condition is termed "parallel resonance*", as distinct from the "series resonance" considered earlier. At resonance, the currents in the condenser and coil are large compared with the current in the external circuit and they are very nearly opposite in phase.

The value of ω at which parallel resonance occurs can be determined from the equation

$$\omega_o = \frac{1}{\sqrt{LC}} \cdot \frac{1}{\sqrt{1 + (r^2/\omega_o^2 L^2)}} \quad (17)$$

It was pointed out in the previous section that $\omega L/r$, the ratio of the reactance of the coil to the resistance in series with it, is usually greater than 50. Thus, with an error of about one part in 5000 at $Q = \omega L/r = 50$ and correspondingly smaller errors at larger values of Q , we find that the parallel resonant frequency f_o is given by

$$\omega_o = 2\pi f_o \approx 1/\sqrt{LC}.$$

This is the same result, to the accuracy indicated above, as that obtained in the series resonance case.

With a similarly small degree of error we may write the following simple relations for the **currents at resonance**. The current in the external circuit (Fig. 9.2b) is given by

$$\begin{aligned} I &\approx E \frac{r}{\omega_o^2 L^2} \approx \frac{E.Cr}{L} \approx E.\omega_o^2 C^2 r, \\ &\approx \frac{E}{\omega_o L} \cdot \frac{1}{Q} \approx \frac{E.\omega_o C}{Q} \end{aligned} \quad (18)$$

where $Q = \omega_o L/r$ as before. The current in the inductance and resistance is very closely equal in value to that in the capacitance,

$$I_L \approx -I_c \approx E/\omega_o L \approx -\omega_o CE \quad (19)$$

and is Q times larger than the current in the external circuit

The formulae given so far hold only when the condenser loss is negligible. In order to generalize our expressions in a simple manner let us first consider the two circuits shown in Fig. 9.3a and Fig. 9.3b. At (parallel) resonance for Fig. 9.3a we have found that the current I in the external circuit is

$$I \approx ECr/L \approx E/Q\omega_o L \text{ etc. ;}$$

* Parallel resonance may be defined either as

(a) the frequency at which the parallel impedance of the circuit is a maximum, or
(b) the frequency at which the equivalent reactance of the complete parallel circuit becomes zero (i.e. when the impedance has unity power factor and acts as though it were a pure resistance at the resonant frequency). This can also be expressed by saying that the parallel circuit has zero susceptance at the resonant frequency.

For further details see Chapter 4 Sect. 6(iii) and (iv).
Definition (b) is used in this chapter.

and for Fig. 9.3b, to the same approximation, it is evident that

$$I \approx E/R_s.$$

These two circuits are equivalent at resonance provided we set

$$R_s = L/Cr = Q\omega_0 L = Q/\omega_0 C = Q\sqrt{L/C} \quad (20)$$

Note that $Q = R_s\sqrt{C/L}$, and that R_s is the parallel resistance (across C) equivalent to the series coil resistance r .

It has been shown that the circuit Fig. 9.3a with a condenser C having no losses and an inductance L having series coil resistance r may be replaced by the equivalent circuit Fig. 9.3b having an ideal tuned circuit LC , without losses, shunted by the resistor R_s having a value given by equation (20). It is obvious that the impedance of the parallel combination LCR_s in Fig. 9.3b at resonance is R_s , this being the "resonant impedance" of the circuit. At frequencies other than the resonant frequency, the impedance will be less than the "resonant impedance."

The values of Q in terms of series coil resistance r and equivalent parallel resistance R_s are grouped below for convenience.

$$\text{In terms of } r: \quad Q = \frac{\omega_0 L}{r} = \frac{1}{\omega_0 Cr} = \frac{1}{r} \sqrt{\frac{L}{C}}$$

$$\text{In terms of } R_s: \quad Q = \frac{R_s}{\omega_0 L} = \omega_0 CR_s = R_s \sqrt{\frac{C}{L}}$$

We can now consider the important practical case of the circuit shown in Fig. 9.4, in which a resistance R appears in shunt with the condenser C . R represents the effect of all insulation losses in condenser, coil, wiring, switches and valves, together with the plate or input resistance of the valves.

Fig. 9.3(a). Parallel resonance with series loss resistance.

Fig. 9.3(b). Parallel resonance with parallel loss resistance.

Fig. 9.4. Parallel resonance with both series and parallel loss resistances.

In the present case we have R in parallel with our equivalent parallel coil resistance R_s of Fig. 9.3b. The resultant parallel resistance at resonance, which we will call the **resonant impedance** is, of course,

$$R_D = \frac{1}{1/R + Cr/L} \quad (21)$$

Therefore, the resultant value of Q is

$$Q = \sqrt{\frac{C}{L}} \cdot R_D = \frac{1}{(1/R)\sqrt{L/C} + r\sqrt{C/L}} = \frac{1}{(\omega_0 L/R) + (r/\omega_0 L)} \quad (22)$$

Note that at the resonant frequency the expression $\sqrt{L/C}$ is equal to the reactance of the inductance and also that of the condenser, i.e.

$$\omega_0 L = \sqrt{L/C} = 1/\omega_0 C. \quad (23)$$

See also Sect. 11 Summary of Formulac.

SECTION 5: GENERAL CASE OF SERIES RESONANCE

Fig. 9.5 shows the general type of series resonant circuit. It is often convenient to express the effect of the two resistances at resonance as a resultant equivalent series resistance, r' say. In the circuit of Fig. 9.3 we saw that the effect of a resistance r in series with L was equivalent at resonance to that of a resistance L/CR shunted across C . By similar reasoning it may be shown in the present case (Fig. 9.5) that

Fig. 9.5. Series resonance with losses in inductive and capacitive elements.

the effect of R at resonance is equivalent to that of a resistance of value L/CR in series with L . The resultant equivalent series resistance r' is thus equal to $r + (LC/R)$, and the resultant value of Q is $\omega_0 L/r'$.

See also Sect. 11 Summary of Formulae.

SECTION 6: SELECTIVITY AND GAIN

(i) *Single tuned circuit* (ii) *Coupled circuits—tuned secondary* (iii) *Coupled circuits—tuned primary, tuned secondary* (iv) *Coupled circuits of equal Q* (v) *Coupled circuits of unequal Q* .

(i) Single tuned circuit

The currents and voltages, and hence the gain, of single tuned circuits at resonance are determined by the equivalent series resistance (r' as defined in Sect. 5) and the resonant impedance (R_D as defined in eqn. 21).

At frequencies other than the resonant frequency, the reactances of the coil and the condenser no longer balance. In the series circuit the resistance r' becomes an impedance z which is greater than r' . In the parallel circuit the resonant impedance R_D becomes an impedance Z which is less than R_D .

The appropriate ratios of these quantities determine the **selectivity** or response of the circuit, and they are related to Q and f by the following expression:

$$\frac{A_o}{A} = \frac{z}{r'} = \frac{R_D}{Z} = \sqrt{1 + Q^2 \left(\frac{f}{f_o} - \frac{f_o}{f} \right)^2} \quad (24)$$

where A_o is the voltage gain at the resonant frequency f_o and A the gain at frequency f .

Note that A_o/A is the ratio of current at resonance to that at frequency f in the series case, and the ratio of **total** current at frequency f to that at the resonant frequency in the parallel case (see below).

The phase angle between the applied voltage and the total current is such that

$$\tan \phi = \pm Q \left(\frac{f}{f_o} - \frac{f_o}{f} \right) \quad (25)$$

the positive sign pertaining to the series case and the negative sign to the parallel case.

The equation (24) leads to a simple method for determining Q from the response curve. We see that when $Q[(f/f_o) - (f_o/f)] = \pm 1$ the total current will be decreased by the factor $\sqrt{2}$ in the series case (i.e. decreased to 70.7% of the resonance value), and increased by the same factor in the parallel case. It will be observed that at either of the frequencies satisfying this condition the phase angle ϕ is numerically equal to 45° , as $\tan \phi = \pm 1$, and that the resistance r' or R_D is equal to the reactance.

The condition

$$Q(f/f_0 - f_0/f) = \pm 1 \quad (26)$$

may be written

$$f/f_0 - f_0/f = \pm 1/Q; \quad (27)$$

and for values of Q not too low (> 50 , say) we have, very closely,

$$2\Delta f_0/f_0 \approx \pm 1/Q \quad (28)$$

where $\Delta f_0 = f - f_0$.

$$\text{Thus } \Delta f_0 \approx \pm \frac{f_0}{2Q} \quad (29)$$

and the current is decreased, or increased, by the factor $\sqrt{2}$ at two frequencies f_1 and f_2 , one on each side of the resonant frequency f_0 , determined by

$$f_1 = f_0 - \frac{f_0}{2Q}; \quad f_2 = f_0 + \frac{f_0}{2Q} \quad (30)$$

$$\text{Hence, } Q \approx f_0/(f_2 - f_1) \quad (31)$$

The frequencies f_0 , f_1 and f_2 may be found experimentally, and hence Q may be calculated.

At frequencies very different from f_0 , so that A_0/A is greater than about 10, the equation giving the response is very approximately

$$A_0/A \approx Q(f/f_0 - f_0/f). \quad (32)$$

Also, the expression for the phase angle may be written in the alternative forms

$$\begin{aligned} \tan \phi &= \pm Q(f/f_0 - f_0/f) && \text{from equation (25)} \\ &= \pm Q \frac{\Delta f_0}{f_0} \cdot \frac{2 + (\Delta f_0/f_0)}{1 + (\Delta f_0/f_0)} \end{aligned} \quad (33)$$

Under these conditions we see that in the series case

(a) Across the coil :

$$\frac{\text{Voltage at resonance}}{\text{Actual voltage when well off resonance}} = \frac{L\omega \dot{x}_0}{L\omega \dot{x}} = \frac{Lf \dot{x}_0}{Lf \dot{x}} = Q \left(1 - \frac{f_0^2}{f^2}\right) \quad (34)$$

and (b) Across the condenser :

$$\frac{\text{Voltage at resonance}}{\text{Actual voltage when well off resonance}} = \frac{C\omega \dot{x}_0}{C\omega \dot{x}} = Q \left(\frac{f^2}{f_0^2} - 1\right) \quad (35)$$

Similarly, in the parallel case, we have

$$\frac{\text{Impedance at resonance}}{\text{Impedance at frequencies well off resonance}} = Q \left(\frac{f}{f_0} - \frac{f_0}{f}\right) \quad (36)$$

from which it can be shown that

(a) In the coil :

$$\frac{\text{Current at resonance}}{\text{Current at frequency } f} = \frac{f}{f_0} \quad (37)$$

and (b) in the condenser :

$$\frac{\text{Current at resonance}}{\text{Current at frequency } f} = \frac{f_0}{f} \quad (38)$$

(ii) Coupled circuits—tuned secondary

We consider briefly now two examples of coupled circuits. The first example, shown in Fig. 9.6 illustrates a typical case of a **high frequency transformer with tuned secondary** in a radio receiver.

The symbols to be used are set out below :

g_m = mutual conductance of the valve in mhos,

r_p = plate resistance of the valve in ohms,

L_1 = primary inductance in henrys,

L_2 = secondary inductance in henrys,

M = mutual inductance between L_1 and L_2 in henrys,

$k = M/\sqrt{L_1 L_2}$ = coupling factor,

$Q_2 = L_2 \omega_0 / r = 1/rC\omega_0$,

$\omega_0 = 2\pi \times$ resonant frequency of secondary in cycles per second,

$R_D = \omega_o L_2 Q_2 =$ resonant impedance of secondary in ohms,

$e_i =$ input voltage,

$e_o =$ output voltage,

and $A =$ stage voltage gain (amplification).

When the secondary is tuned, its impedance (at ω_o) is simply r , and it reflects into the primary a resistance equal to $M^2 \omega_o^2 / r$. The primary signal current I_p is, therefore,

$$I_p = \frac{g_m \cdot r_p \cdot e_i}{\sqrt{X_p^2 + (r_p + M^2 \omega_o^2 / r)^2}} \quad (39)$$

where X_p is the reactance of the primary.

When the conditions are such that the primary reactance can be neglected, we have

$$I_p \approx g_m \cdot r_p \cdot e_i / (r_p + M^2 \omega_o^2 / r) \quad (40)$$

It follows that the secondary current I_s is given by

$$I_s = \frac{M \omega_o I_p}{r} \approx \frac{g_m \cdot e_i}{(r / M \omega_o) + (M \omega_o / r_p)} \quad (41)$$

Hence the induced voltage across L_2 (and C), that is e_o , is

$$e_o = \frac{g_m \cdot e_i \cdot L_2 \omega_o}{(r / M \omega_o) + (M \omega_o / r_p)} \quad (42)$$

$$\text{or } \frac{e_o}{e_i} = A_o = \frac{g_m}{(1 / M \omega_o Q_2) + (M / r_p L_2)} \quad (43)$$

$$= \frac{g_m k R_D \sqrt{L_1 / L_2}}{1 + k^2 (R_D / r_p) \cdot (L_1 / L_2)} \quad (44)$$

When r_p is very much greater than $\omega_o^2 M^2 / r [= k^2 R_D (L_1 / L_2)]$ we have simply

$$I_p \approx g_m \cdot e_i \quad (45)$$

$$I_s \approx g_m \cdot e_i \cdot M \omega_o / r, \quad (46)$$

$$\text{and } e_o / e_i = A_o \approx g_m \omega_o M Q_2 = g_m \cdot k R_D \sqrt{L_1 / L_2} \quad (47)$$

If the inductances L_1 and L_2 have the same ratio of diameter to length, or form factor, and the turns are N_1 and N_2 respectively, then $\sqrt{L_1 / L_2}$ in the above formulae may be replaced by N_1 / N_2 . The plate resistance r_p in parallel with the primary is reflected as a series resistance $M^2 \omega_o^2 / r_p$ into the secondary. If the value of this reflected resistance is greater than say 5% of r , its effect should be taken into account when computing the selectivity of the secondary. This selectivity, then, is determined by means of the formula

$$z / r' = \sqrt{1 + Q_2'^2 [f / f_o - f_o / f]^2} \quad (48)$$

where $r' = r + M^2 \omega_o^2 / r_p$,

$$\text{and } Q_2' = \frac{\omega_o L_2}{r'} = \frac{1}{(1 / Q_2) + (k^2 L_1 \omega_o / r_p)}.$$

Note that Q_2' and r' must not be used when calculating the gain A_o .

Fig. 9.6. Amplifier stage using a high frequency transformer with a tuned secondary.

Fig. 9.7. Amplifier stage using a double tuned high frequency transformer.

(iii) Coupled circuits—tuned primary, tuned secondary

The second example of coupled circuits is shown in Fig. 9.7. This is a typical high frequency transformer with tuned primary and tuned secondary. Intermediate frequency transformers in super-heterodyne receivers are usually of this type. Very thorough discussions of such transformers have been given from the theoretical point

of view by Aiken (Ref. C2). For the design procedure see Chapter 26 Sect. 4. In this case the resistance in parallel with the primary at resonance is

$L_1/C_1 r_p + L_1/C_1 R_1 = L_1/C_1 R'$, where $1/R' = 1/r_p + 1/R_1$; and the resistance of the secondary is $L_2/C_2 R_2$, so that the resistance reflected into the primary is $\omega_o^2 M^2 C_2 R_2/L_2$. The primary current I_p is, therefore,

$$I_p = \frac{g_m e_i}{\omega_o C_1} \cdot \frac{1}{L_1/C_1 R' + \omega_o^2 M^2 C_2 R_2/L_2} \quad (49)$$

The secondary current I_s can readily be shown to be

$$I_s = (M \omega_o C_2 R_2/L_2) I_p, \quad (50)$$

and the induced voltage e_o across L_2 and C_2 to be

$$e_o = L_2 \omega_o I_s = (M C_2 R_2 \omega_o^2) I_p.$$

Therefore the voltage gain at the resonant frequency, A_o , is given by

$$\frac{e_o}{e_i} = A_o = \frac{g_m M \omega_o}{L_1/R' R_2 C_2 + \omega_o^2 M^2 C_1/L_2}. \quad (51)$$

This relation for the gain may also be expressed as

$$A_o = \frac{g_m k \omega_o \sqrt{L_1 L_2}}{k^2 + 1/Q' Q_2} \quad (52)$$

$$\text{or, } A_o = \frac{g_m \sqrt{R' R_2}}{k \sqrt{Q' Q_2} + 1/(k \sqrt{Q' Q_2})}, \quad (53)$$

where, as before, $k = M/\sqrt{L_1 L_2}$, and Q' , Q_2 have their usual meaning, i.e. $R'/L_1 \omega_o$ and $R_2/L_2 \omega_o$ respectively.

The expression for calculating the selectivity is lengthy and complicated and a graphical treatment described later is preferable (Sect. 7).

As k is increased from low values, the gain increases until $k\sqrt{Q' Q_2} = 1$, after which it decreases. This value of $k = 1/\sqrt{Q' Q_2}$ is known as the **critical coupling factor** (k_c).

(iv) Coupled circuits of equal Q

When the primary and secondary circuits are identical, and the coupling factor is equal to k_c , and the plate and grid return resistances are very high, we see that the voltage gain obtained is exactly half that with a single tuned circuit. The critical coupling factor in this case, of course, is

$$k_c = 1/Q \text{ where } Q = Q' = Q_2.$$

For values of k less than k_c , the response curve (gain versus frequency) has a single maximum at f_o , the resonant frequency of each of the circuits. When k exceeds the critical value, however, the amplification curve becomes double-humped, i.e. there are two frequencies of maximum response, and these are separated by equal amounts above and below f_o . The distance between these two peaks increases with k , and very approximately we find that

$$(f_2 - f_1)/f_o \approx \sqrt{k^2 - 1/Q^2} \quad (54)$$

$$\approx \sqrt{k^2 - k_c^2}, \quad (55)$$

when f_1 and f_2 are the frequencies for maximum response, i.e. $(f_2 - f_1)$ is the **band width between peaks**. The amplitude of these two peaks is substantially the same as the maximum possible gain $g_m R/2$, where $R = R_1 = R_2$.

Frequently, an approximate formula for band-width is used:

$$(f_2 - f_1)/f_o \approx k \quad (56)$$

While k largely determines the band-width, the depth of the valley at f_o , and hence the uniformity of the response in the pass band of frequencies, is determined by the relation of Q to k . For a constant value of k (above critical coupling) the dip becomes more pronounced as Q is increased, while the frequency separation between peaks becomes greater; conversely as Q is decreased the dip becomes less pronounced and the frequency separation between peaks becomes less. The ratio of the response at f_o to that at the two peaks is found to be $2b/(1 + b^2)$, where $b = k/k_c$.

A value for k in the order of 1.5 times critical, i.e. $kQ = 1.5$, is often used for i-f amplifiers requiring band pass characteristics. However, the exact value chosen for kQ depends of course, on the bandwidth requirements.

Further points on the resonance curve can be obtained from the result that the frequency band width between the points on either flank of the resonance curve, at which the response is equal to the minimum in the "valley" between the two peaks, is $\sqrt{2}$ times the peak separation. It can be shown also that, in general, the gain at any frequency f is given by

$$\frac{A_o}{A} = \sqrt{\left[1 - \frac{Q^2 Y^2}{1 + k^2 Q^2}\right]^2 + \left[\frac{2QY}{1 + k^2 Q^2}\right]^2} \quad (57)$$

where $Y = f/f_o - f_o/f$.

This expression may well be solved graphically according to a procedure developed by Beatty (Ref. C7); this procedure will be described below.

(v) Coupled circuits of unequal Q

In the general case where Q_1 and Q_2 are unequal, the two peaks of maximum response do not appear immediately k exceeds the critical value k_c . The value of k at which the two peaks just appear has been defined as the **transitional coupling factor** by Aiken (Ref. C2). The value of this coupling factor k_t is

$$k_t = \sqrt{\frac{1}{2}(1/Q_1^2 + 1/Q_2^2)}. \quad (58)$$

The band width between peaks is found to be

$$(f_2 - f_1)/f_o = \sqrt{k^2 - k_t^2} \quad (59)$$

This useful result is discussed in an editorial by G. W. O. Howe (Ref. C5). Further it has been shown that here, as in the symmetrical case, the band width between the points on the flanks, level with the minimum response in the "valley" between the peaks, is $\sqrt{2}$ times the peak separation.

In this case, too, the selectivity curve remains symmetrical as k increases (above k_t). The amplitude of the peaks decreases, however, as k increases, and also as the ratio of R_1/R_2 (or R_2/R_1) increases. Aiken (Ref. C2) gives selectivity curves for the three cases (i) $R_1 = 10R_2$, (ii) $R_1 = 50R_2$ and (iii) $R_1 = 200R_2$ with $L_1 = L_2$ and $C_1 = C_2$. Some idea of the magnitude of this decrease in peak amplitude may be obtained from the following figures taken from Aiken's curves:

$R_1/R_2 = 10$		$R_1/R_2 = 50$		$R_1/R_2 = 200$	
k/k_c	A/A_{opt}	k/k_c	A/A_{opt}	k/k_c	A/A_{opt}
3	0.67	7	0.33	15	0.17
6	0.62	15	0.28	20	0.15

In this table A_{opt} is the optimum value of the gain, i.e. the gain at resonant frequency with critical coupling ($= g_m \sqrt{R_1 R_2 / 2}$).

The gain at f_o when $k > k_t$ is given by $[2b/(1 + b^2)]A_{opt}$, where $b = k/k_c$, as in the case of equal Q 's; as the gain at the peaks is less than A_{opt} however, the response curve is flatter in the present case.

See also Sect. 11 Summary of Formulae.

SECTION 7: SELECTIVITY—GRAPHICAL METHODS

(i) Single tuned circuit (ii) Two identical coupled tuned circuits.

(i) Single tuned circuit

A single tuned circuit in the plate load of a valve has the well-known frequency response shown in Fig. 9.8. At the resonant frequency, where the reactance is zero

there occurs the maximum value of the response, and the gain falls away on both sides. This curve may be computed from eqn. (24), namely

$$A_o/A = \sqrt{1 + Q^2 Y^2},$$

and $\tan \phi = \pm QY,$ from eqn. (25)
 where $Y = (f/f_o - f_o/f).$

These formulae, however, lend themselves to a simple graphical treatment as indicated in Fig. 9.9.

The ratio of the gain A_o at resonance to the gain A at any other frequency may be plotted as a vector quantity, OP in Fig. 9.9, having both magnitude and phase. At resonance, when the frequency is f_o , it becomes OP_o in Fig. 9.9, where OP_o is of unit length since A_o/A is then equal to unity. At any other frequency f , the ratio A_o/A is then given by OP where the point P is fixed by the relation

$$\text{length } P_oP = Q(f/f_o - f_o/f).$$

The phase angle is the angle P_oOP .

Near resonance, when f is nearly equal to f_o , this may be approximated by

length $P_oP \approx 2Q\Delta f/f_o$ where $\Delta f = f - f_o$
 so that Δf measures the amount of detuning. Thus, near resonance, the length P_oP is nearly proportional to the amount of detuning.

WHERE :-

A_o = GAIN AT RESONANCE
 A = GAIN AT f
 f_o = RESONANT FREQUENCY

$$Q = \frac{2\pi f_o L}{R}$$

$$Y = \left[\frac{f}{f_o} - \frac{f_o}{f} \right]$$

K = COEFFICIENT OF COUPLING

$$OP_o = 1$$

$$OP = \frac{A_o}{A}$$

$$OX = \frac{2QY}{1 + K^2 Q^2}$$

$$XP = 1 - \frac{Q^2 Y^2}{1 + K^2 Q^2}$$

$$OT = \frac{2}{\sqrt{1 + K^2 Q^2}}$$

(ii) Two identical coupled tuned circuits

It is found that when two identical tuned circuits are coupled, either by some common reactance in the circuit or by mutual inductance, the locus of the point P is the parabola

$$x^2 = (y + 1)/(1 + k^2 Q^2).$$

This parabola is shown in Fig. 9.10 where OP_o again represents A_o . To use this graph to determine the gain, we first compute the quantity $OX = 2QY/(1 + k^2 Q^2)$, then from X draw a line perpendicular to OX to cut the curve at P . The line OP represents the gain (A_o/A) while P_oOP is the phase angle.

The form of the parabola depends upon the magnitude of kQ . It is found that when $OT < \sqrt{2}$, corresponding to $kQ > 1$, there are two frequencies of maximum gain as shown by the two vectors marked OP' in Fig. 9.10. When the attenuation is plotted against Δf_o , as in Fig. 9.11, it becomes clear that a much flatter top may be obtained by using coupled pairs of circuits than by using single tuned circuits. Fig. 9.11 serves also to show the variation in band width with variations of OT (i.e. changes of kQ). It will be seen that the shape of the skirt of the curve is practically independent of the value of kQ .

See also Sect. 11 Summary of Formulae.

SECTION 8 : COUPLING OF CIRCUITS

(i) *Mutual inductive coupling* (ii) *Miscellaneous methods of coupling* (iii) *Complex coupling*.

(i) **Mutual inductive coupling**

As already emphasized, when the mutual inductive coupling between two tuned circuits is increased above a critical value, k_c , two peaks appear in the response curve, symmetrically situated with regard to the resonant frequency f_o . No other types of coupling possess this useful property. Where optimum gain and selectivity are required it can be shown that these will be obtained with a coupling about 80 per cent of the critical value—(Ref. C45). Greater selectivity can be achieved with less coupling than this value while increased gain will result from tighter coupling.

When the highest possible selectivity without serious loss of gain is desired from a pair of tuned coupled circuits, a practical compromise is to reduce coupling to $0.5 k_c$ at which value the gain is 0.8 times the optimum. The selectivity then approaches that which would be obtained by separating the two circuits with a valve (assuming this be done without altering Q' and Q_2). For other relationships between gain and selectivity, refer to Reed (Ref. C1) or to Aiken (Ref. C2).

(ii) **Miscellaneous methods of coupling**

There are other types of coupling which may be used between tuned circuits as alternatives to mutual inductance. Four such circuits are shown in Figs. 9.12, 9.13, 9.14 and 9.15. **High impedance or "top" coupling** is used in the circuits shown in Figures 9.12 and 9.13 and low impedance, or "bottom" coupling, is used in the circuits of Figures 9.14 and 9.15

FIG. 9.12

Fig. 9.12. High impedance capacitive coupling.

FIG. 9.13

Fig. 9.13. High impedance inductive coupling.

FIG. 9.14

Fig. 9.14. Low impedance capacitive coupling.

A fifth type is **link coupling** shown in Fig. 9.16A, in which a relatively small coupling inductance L_1' is coupled to L_1 and similarly L_2' to L_2 and L_1' is connected directly in series with L_2' . The behaviour of this circuit is the same as that to be described for Fig. 9.15.

"The coupling between two circuits, from a general point of view, is the relation between the possible rate of transfer of energy and the stored energy of the circuits" (Ref. C5, Sept. 1932).

From this definition it follows that for **low impedance coupling**

$$k = \frac{X_m}{\sqrt{(X_1 + X_m)(X_2 + X_m)}} \approx \frac{X_m}{\sqrt{X_1 X_2}} \text{ when } X_1 \text{ and } X_2 \gg X_m$$

and that for **high impedance coupling**

$$k = \sqrt{\frac{X_1 X_2}{(X_1 + X_m)(X_2 + X_m)}} \approx \frac{\sqrt{X_1 X_2}}{X_m} \text{ when } X_1 \text{ and } X_2 \ll X_m$$

where X_m is the coupling reactance and X_1 and X_2 are the effective reactances of either the coils or the condensers* with which the circuits are tuned.

* X_1 and X_2 must be of the same "kind" (i.e. either inductive or capacitive) as X_m .

The effective reactances X_1 and X_2 in the high impedance case are calculated by regarding the actual tuning reactances ($L_1\omega_o$ and $L_2\omega_o$, or $1/C_1\omega_o$ and $1/C_2\omega_o$) as being in parallel with the coupling reactance X_m ; while in the low impedance case, X_1 and X_2 are calculated by taking X_m to be in series with the actual tuning reactances.

Fig. 9.15. Low impedance inductive coupling.

Fig. 9.16A. Link coupling.

Mutual inductive coupling belongs to the low impedance coupling group; here $X_m = M\omega_o$, $X_1 = L_1\omega_o$, $X_2 = L_2\omega_o$; so that $k = M/\sqrt{L_1L_2}$, in agreement with our previous definition in this particular case.

For a general analysis of the calculation of coupling coefficients see Chapter 26 Sect. 4(vii).

Application of the formulae given above to the circuits shown in Figures 9.12, 9.13, 9.14, 9.15 and 9.16A give the following results for the coefficient of coupling k :

Circuit	k (exact)	k (approximate)
Fig. 9.12	$\frac{C_m}{\sqrt{(C_1 + C_m)(C_2 + C_m)}}$	$\frac{C_m}{\sqrt{C_1C_2}}$, when $C_m \ll (C_1, C_2)$
Fig. 9.13	$\sqrt{\frac{L_1L_2}{(L_1 + L_m)(L_2 + L_m)}}$	$\frac{\sqrt{L_1L_2}}{L_m}$ when $L_m \gg (L_1, L_2)$
Fig. 9.14	$\sqrt{\frac{C_1C_2}{(C_1 + C_m)(C_2 + C_m)}}$	$\frac{\sqrt{C_1C_2}}{C_m}$ when $C_m \gg (C_1, C_2)$
Fig. 9.15	$\frac{L_m}{\sqrt{(L_1 + L_m)(L_2 + L_m)}}$	$\frac{L_m}{\sqrt{L_1L_2}}$, when $L_m \ll (L_1, L_2)$
Fig. 9.16A	$\frac{M_1M_2}{L_m \sqrt{\left(L_1 - \frac{M_1^2}{L_m}\right)\left(L_2 - \frac{M_2^2}{L_m}\right)}}$ or $\frac{k_1k_2}{\sqrt{(1 - k_1^2)(1 - k_2^2)}}$	$\frac{M_1M_2}{L_m \sqrt{L_1L_2}}$, when individual couplings are small. k_1k_2 , when individual couplings are small.

where $L_m = L_1' + L_2'$,

$$k_1 = \frac{M_1}{\sqrt{L_1L_m}}, \text{ and } k_2 = \frac{M_2}{\sqrt{L_2L_m}}.$$

When the coupling increases above k , for the tuned circuits shown in Figs. 9.12, 9.13, 9.14, 9.15 and 9.16A, the two peaks in the response curve of the secondary move at unequal rates from the original resonant frequency (determined by $L_1C_1\omega_o^2 = L_2C_2\omega_o^2 = 1$). For the first four of these examples in the special case $L_1 = L_2$, $C_1 = C_2$, and for the fifth generally, one peak remains approximately stationary

(at ω_o), while the other peak moves to one side: the shift of the semi-stationary peak depends upon the series resistances of the two circuits and decreases with them, being zero in the ideal case $r_1 = r_2 = 0$: the second peak is lower in frequency in Figs. 9.12 and 9.15, but higher in Figs. 9.13, 9.14 and 9.16A. The selectivity and bandwidth (between peaks) may be calculated from the formulae (57) and (55) respectively—already quoted for transformer coupling—provided the appropriate value of k is used. It is theoretically possible, although seldom convenient, to combine two types of coupling in equal amounts to give symmetrical separation of the two peaks. Normally, when this is required simple mutual inductive coupling is used.

It may be shown that for all types of coupling the centre frequency is determined by the effective reactances obtained by taking the coupling reactance into account. Thus, for example, for Fig. 9.15, $(L_2 + L_m)C_2\omega_c^2 = 1$, where ω_c corresponds to the frequency of the minimum between the peaks; while for Fig. 9.16A, $(L_2 - M_2^2/L_m)C_2\omega_c^2 = 1$.

(iii) Complex coupling

With any single type of coupling the gain and the band width vary with the frequency. Clearly, then, a single type of coupling cannot give satisfactory performance in the tuned radio frequency stages of a receiver where the frequency range is two or three to one. From the formulae already given it can be seen that for transformer coupling both the gain and the band width are approximately proportional to the frequency (assuming that Q_1 and Q_2 do not vary greatly); for other types of simple coupling k depends upon the square of the frequency, and hence band width and gain are functions of frequency.

FIG. 9.16B

FIG. 9.16C

FIG. 9.16D

Fig. 9.16B. Constant bandwidth using inductive and capacitive coupling.

Fig. 9.16C. Constant bandwidth using capacitive coupling.

Fig. 9.16D. Complex coupling with mutual inductive and top capacitive coupling.

In practice, a reasonably constant band width over the tuning range can be obtained by a suitable combination of the types of coupling already described. Two common arrangements are shown in Figs. 9.16B and 9.16C.

For the circuit shown in Fig. 9.16B the coupling reactance $X_m = \omega M + 1/\omega C_m$, while for that shown in the Fig. 9.16C it is

$$\frac{1}{\omega C_L} + \frac{C_H}{\omega C_1 C_2}.$$

The corresponding coupling factors are respectively

$$k \approx \frac{M + 1/\omega^2 C_m}{\sqrt{L_1 L_2}} \quad (k < 0.05),$$

$$\text{and } k \approx \frac{C_H}{\sqrt{C_1 C_2}} + \frac{\sqrt{C_1 C_2}}{C_L} \quad (k < 0.05).$$

Aiken (Ref. C2) gives a practical design procedure for obtaining the values of the components which give the best average results over the whole tuning range.

When k has been determined, the band width and selectivity may be calculated from eqns. (55) and (57) given earlier. Also, for circuits with the same values of Q , a suitable value of k is given by $kQ = 0.5$ —as in the case of transformer coupling—when the greatest possible selectivity without notable loss of gain is desired.

In Fig. 9.16D there is a combination of mutual inductive coupling and top capacitive coupling, as commonly used in aerial and r-f coils, and, effectively, in i-f transformers. The analysis is given in Chapter 26 Sect. 4 (vii).

See also Sect. 11 Summary of Formulae.

SECTION 9 : RESPONSE OF IDENTICAL AMPLIFIER STAGES IN CASCADE

When two or more amplifier stages having identical circuits and values are connected in cascade, the overall gain is the product of the gains, and the resultant selectivity is the product of the selectivities of all the stages. For n stages, therefore, the total gain is A_o^n ; the selectivity for single tuned circuits is

$$(A/A_o)^n = (1 + Q^2 Y^2)^{-n/2},$$

while for coupled pairs

$$\left(\frac{A}{A_o}\right)^n = \left[\left(1 - \frac{Q^2 Y^2}{1 + k^2 Q^2}\right)^2 + \left(\frac{2QY}{1 + k^2 Q^2}\right)^2 \right]^{-n/2}$$

When $k^2 Q^2$ is very small, the selectivity of n coupled pairs is almost the same as that of $2n$ single tuned circuits. Thus there is a limit to the improvement of selectivity obtained by reduction of the coupling of coupled pairs of tuned circuits. When it is possible to increase Q , there is a corresponding improvement in selectivity. The tendency with several stages of single tuned circuits is to produce a very sharp peak at the centre frequency, which may seriously attenuate the higher audio frequencies of a modulated signal. Conditions are much better with coupled pairs, because two peaks with small separation appear as Q is increased, if the coupling is not too close. Difficulties occur when Q is increased so much that a deep "valley" or trough occurs between the peaks. The practical limit is usually a ratio of 1 : 1.5 overall gain between the response at the bottom of the valley and that at the two peaks. It is then good practice to add another stage employing a single tuned circuit which substantially removes the "valley" of the preceding circuits. The procedure by which the best results may be obtained is described by Ho-Shou Loh (Ref. C13). In this manner a nearly flat response may be obtained over a range of frequencies 10 Kc/s to 20 Kc/s wide, with very sharp discrimination against frequencies 20 Kc/s or more away from the centre frequency, 450 to 460 Kc/s.

See also Sect. 11 Summary of Formulae.

SECTION 10 : UNIVERSAL SELECTIVITY CURVES

In Figs. 9.17 and 9.18 are shown universal selectivity curves taken from Maynard's data (Ref. D2). These curves apply to a pair of coupled tuned circuits, and are not restricted to circuits of equal Q . Fig. 9.17 gives the gain at various frequencies off the centre frequency in terms of the gain at the centre frequency, for various coefficients of coupling; the ordinate scale D is proportional to $Q\Delta f_o/f_o$. The Q shown in Figs. 9.17 and 9.18 is Q_2 for all expressions containing a and b .

The phase difference between the currents in the primary and secondary circuits can readily be obtained from Fig. 9.18. There we have plotted an angle θ as a function of D for various coefficients of coupling, and the phase shift is $\theta \pm 90^\circ$, the positive sign being taken when the coupling is negative, and the negative sign when k is positive.

The parameter b , which is a measure of the coupling, becomes simply k/k_o when the tuned circuits have equal values of Q ; also, in this case, the variable D becomes simply $2Q\Delta f_o/f_o$. For convenience, scales have been added to give A_o/A in terms of $Q\Delta f_o$ for a number of values of f_o for two identical coupled circuits.

In deriving the curves of Figs. 9.17 and 9.18 it was assumed that Q and k do not vary appreciably over the range considered, thus giving symmetrical selectivity curves;

and that Q is reasonably high (> 25 say). Very low values of Q require a different curve for each value, but the effect is only to alter slightly the skirts of the curves without altering appreciably the main portions.

As an illustration of the use of Fig. 9.17 consider the example $f_0 = 1000$ Kc/s, $Q_1 = Q_2 = 200$, $k/k_c = 2 = b$: we see that the peak occurs at $Q\Delta f_0 \approx 800$, i.e. $\Delta f_0 = 4$ Kc/s, and that the gain in the valley compared with the gain at the peak = 0.8; these results agree well with those calculated from the formulae already given, namely

Band width is: $f_0 \sqrt{k^2 - k_c^2} \approx 8.6$ Kc/s.

Ratio of gain in valley to that at peak is:

$$\frac{2k/k_c}{1 + (k/k_c)^2} = \frac{2b}{1 + b^2} = \frac{4}{5}$$

Phase change at $\Delta f_0 = (+) 4$ Kc/s: (from Fig. 9.18) phase change $\approx 20 \pm 90^\circ$.

In conclusion, we give the selectivity curves of Fig. 9.19 to illustrate some of our remarks in preceding sections. These curves have been derived from those of Fig. 9.17, but here the abscissa is A_{opt}/A , where A_{opt} is the gain at the centre frequency where $k = k_c$.

These curves are for the case of two identical coupled circuits; they show how the maximum gain, band width and depth of the valley between peaks vary with the ratio k/k_c .

In all expressions using a , the Q mentioned is the secondary Q , namely Q_2 .

SECTION 11: SUMMARY OF FORMULAE FOR TUNED CIRCUITS

(1) NOMENCLATURE

- L = inductance (in henrys unless otherwise stated)
 C = capacitance (in farads unless otherwise stated)
 f_o = resonant frequency (in cycles per second unless otherwise stated)
 f_n = natural resonant frequency (in cycles per second unless otherwise stated)
 f = frequency (in cycles/sec. unless otherwise stated)
 $\Delta f_o = f - f_o$ (in cycles/sec.)
 $Y = (f/f_o - f_o/f)$
 $\pi = 3.1416$ approximately
 k = coefficient of coupling
 $\omega = 2\pi f$, $\omega_o = 2\pi f_o$, $\omega_n = 2\pi f_n$ radians per second
 r = series resistance (in ohms)
 r' = resistance of a series resonant circuit at resonance (in ohms)
 R = shunt resistance (in ohms)
 R_o = effective shunt resistance of a parallel resonant circuit at resonance when $R = \infty$ (in ohms)
 R_D = resonant impedance (in ohms)
 e = voltage across the circuit at a time t
 E = initial voltage of charged condenser
 $\epsilon = 2.718$ (ϵ is the base of Napierian Logarithms)
 t = time (in seconds)
 α = damping factor
 δ = logarithmic decrement
 λ = wavelength in metres
 i = current at frequency f (in amperes)
 i_o = current at resonant frequency f_o
 A = gain at frequency f
 A_o = gain at frequency f_o
 Q = magnification factor.

Selectivity Curves for Two Identical Coupled Circuits,
 Showing the Variation in Maximum Gain,
 Band Width and Depth of Valley with k/k_c

(2) NATURAL RESONANT FREQUENCY (f_n)

Exact formula

$$f_n = \frac{1}{2\pi\sqrt{\frac{1}{LC} - \frac{r^2}{4L^2}}} \text{ cycles per second} \quad (1)$$

Approximate formula for use when r is small compared with $2\sqrt{L/C}$:—

$$f_n \approx f_o = \frac{1}{2\pi\sqrt{LC}} \text{ c/s.} \quad (2)$$

For numerical use this may be put in the form

$$f_n \approx f_o = \frac{159\,200}{\sqrt{LC}} \text{ c/s, where } L \text{ is in microhenrys} \quad (3)$$

and C is in microfarads ;

$$\text{or } f_n \approx f_o = \frac{159\,200}{\sqrt{LC}} \text{ Kc/s, where } L \text{ is in microhenrys} \quad (4)$$

and C is in micromicrofarads.

(3) WAVELENGTH (λ)

$$\text{Wavelength (in metres)} = 1884\sqrt{LC}, \quad (5)$$

where L is in microhenrys and C is in microfarads.

$$\begin{aligned} \text{Wavelength} \times \text{frequency} &= 2.9979 \times 10^8 \text{ metres per second} \\ &\approx 3 \times 10^8 \text{ metres per second.} \end{aligned} \quad (6)$$

Note : Equations (5) and (6) are based on the velocity of electromagnetic radiation in a vacuum as determined by Dr. Essen and others in 1951 (see Ref. E1).

$$\text{Wavelength} \approx \frac{300\,000}{\text{frequency in Kc/s}} \approx \frac{300}{\text{frequency in Mc/s}} \quad (7)$$

(4) DAMPED OSCILLATIONS

$$e = Ee^{-\alpha t} \cos \omega_n t, \text{ where } \alpha = r/2L \text{ (damping factor)} \quad (8)$$

$$\delta = r/2f_n L \text{ (logarithmic decrement)} \quad (9)$$

(5) SERIES RESONANCE

 L , C , and ω_o :

For resonance

$$LC\omega_o^2 = 1$$

$$\omega_o L = 1/\omega_o C \text{ ohms}$$

$$\omega_o = 1/\sqrt{LC} \text{ radians/second}$$

$$\omega_o L = \sqrt{L/C} \text{ ohms}$$

$$\omega_o C = \sqrt{C/L} \text{ mhos.}$$

 L , C and f_o :

For resonance

$$2\pi f_o L = 1/2\pi f_o C \text{ ohms} \quad (10)$$

$$LC = \frac{1}{39.48 f_o^2} \text{ (henrys} \times \text{farads)}$$

$$\text{or } LC = \frac{2.533 \times 10^{10}}{f_o^2} \mu\text{H} \times \mu\text{F}$$

where L is in microhenrysand C is in microfarads.

$$Q = \omega_o L/r' = 1/r' C \omega_o, \quad (11)$$

where r' is the effective series resistance at resonance,i.e. $r' = r + L/CR$ where r is the series resistanceand R the parallel resistance.

$$\text{Therefore } Q = \frac{\omega_o L_1}{r + L/CR} = \frac{1}{r/\omega_o L + 1/RC\omega_o} \quad (12)$$

$$= \frac{1}{\omega_o Cr + 1/RC\omega_o} = \frac{1}{r\sqrt{C/L} + \sqrt{L/C}R} \quad (13)$$

When $L/CR \ll r$: $Q \approx \omega_o L/r \approx 1/\omega_o Cr$.**Magnification factor (Q)** : Ratio of the voltage across either reactance to the voltage across the circuit.

(6) PARALLEL RESONANCE

$$\text{At resonance, } \omega_o = \frac{1}{\sqrt{LC}} \cdot \frac{1}{\sqrt{1 + r^2/\omega_o^2 L^2}} \approx \frac{1}{\sqrt{LC}}. \quad (15)$$

$$Q = R_D / \omega_o L = R_D \omega_o C, \quad (16)$$

where R_D , the resonant impedance, is the effective shunt resistance of the circuit at resonance,

and $1/R_D = 1/R + Cr/L$.

$$\text{Therefore } Q = \frac{1}{r\sqrt{C/L} + \sqrt{L/C}/R} \text{ etc., as in (12), (13) above.}$$

When R is infinite (i.e. no shunt resistance),

$$R_D = R_s = L/Cr = Q/\omega_o C = \omega_o LQ = Q^2 r. \quad (17)$$

Magnification factor

$$\text{Ratio of total circulating current to input current} = Q \quad (18)$$

(7) SELECTIVITY

(a) Series Resonant Circuit

$$i_o/i = A_o/A = \sqrt{1 + Q^2(f/f_o - f_o/f)^2} = \sqrt{1 + Q^2 Y^2}. \quad (19)$$

$$\tan \phi = QY = Q\Delta f_o/f_o \cdot \frac{2 + \Delta f_o/f_o}{1 + \Delta f_o/f_o}; \quad (20)$$

i lags behind i_o when $f > f_o$, and leads i_o when $f < f_o$.

When $\Delta f_o/f_o$ is small,

$$i_o/i \approx \sqrt{1 + 4Q^2(\Delta f_o/f_o)^2}, \quad (21)$$

$$\text{and } \tan \phi \approx 2Q\Delta f_o/f_o. \quad (22)$$

$$\text{When } i_o/i \text{ is large, } i_o/i \approx QY. \quad (23)$$

(b) Parallel Resonant Circuit

$$A_o/A = R_D/Z = i/i_o = \sqrt{1 + Q^2 Y^2} \quad (24)$$

$$\tan \phi = -QY; \quad (25)$$

where i and i_o are the total currents;

i leads i_o when $f > f_o$ and lags behind i_o when $f < f_o$.

$$\text{When } \Delta f_o/f_o \ll 1, i/i_o \approx \sqrt{1 + 4Q^2 \Delta f_o^2/f_o^2}. \quad (26)$$

$$\text{and } \tan \phi \approx -2Q\Delta f_o/f_o. \quad (27)$$

$$\text{When } i/i_o \gg 1, i/i_o \approx QY. \quad (28)$$

(8) R-F TRANSFORMER, UNTUNED PRIMARY, TUNED SECONDARY

When the primary impedance can be neglected,

$$\text{Gain } A_o = \frac{\frac{g_m}{r_p L_2} + \frac{1}{\omega_o M Q_2}}{\frac{1}{k R_{D\Delta}} \sqrt{\frac{L_2}{L_1}} + \frac{k}{r_p \Delta} \sqrt{\frac{L_1}{L_2}}} \quad (29)$$

The gain may be expressed in a number of alternative forms, for example,

$$A_o = \frac{\mu \omega_o M Q_2}{r_p + \frac{(\omega_o M)^2 Q_2}{\omega_o L_2}} = \frac{\mu \omega_o M Q_2}{r_p + \frac{\omega_o^2 M^2}{r}} \quad (30)$$

where r is the series resistance of the secondary.

In the special case where $\omega_o^2 M^2/r \ll r_p$, we have

$$A_o \approx g_m \omega_o M Q_2. \quad (31)$$

Selectivity

To determine selectivity, the effect of the resistance reflected into the secondary should be taken into account when its value $\omega_o^2 M^2/r_p > 5\%$ of r . The effective series resistance r' is $r + \omega_o^2 M^2/r_p$; so that the effective value of Q_2 , Q_2' say, is

$$Q_2' = \omega_o L_2/r' = \frac{1}{\frac{1}{Q_2} + \frac{k^2}{r_p} \cdot \omega_o L_1}. \quad (32)$$

The selectivity is then obtained from

$$A_o/A = \sqrt{1 + Q_2'^2 Y^2}. \quad (33)$$

(9) R.F. TRANSFORMER, TUNED PRIMARY, TUNED SECONDARY

Gain

The gain at resonance (A_o) is

$$A_o = \frac{g_m \sqrt{R'R_2}}{1 + k\sqrt{Q'Q_2} + k\sqrt{Q'Q_2}} \quad (34)$$

where $1/R' = 1/r_p + 1/R_1$ and $1/Q' = L_1\omega_o/R' = \omega_o L_1/r_p + 1/Q_1$.

Maximum gain occurs when $k = k_c = 1/\sqrt{Q'Q_2}$, the **critical coupling coefficient**, and is given by

$$A_o(\text{max.}) = g_m \sqrt{R'R_2/2}. \quad (35)$$

Also, when $k = k_c/2$, the value of A_o is approximately 0.8 of $A_o(\text{max.})$.

Identical circuits ($L_1 = L_2$, $C_1 = C_2$, $R' = R_2 = R$, $Q' = Q_2 = Q$)

Critical Coupling: $k_c = 1/Q$. (36)

Maximum gain (at resonance) $= g_m R/2$. (37)

$=$ half gain of a single tuned circuit.

Band width between peaks (f_1 and f_2),

$$(f_2 - f_1)/f_o = \sqrt{k^2 - k_c^2}. \quad (38)$$

Selectivity

$$A_o/A = \sqrt{\left[1 - \frac{Q^2 Y^2}{1 + k^2 Q^2}\right]^2 + \left[\frac{2QY}{1 + k^2 Q^2}\right]^2} \quad (39)$$

Gain at peaks, f_2 and f_1 , is very closely equal to the optimum value $A_o(\text{max.})$.

Circuits of unequal Q

Transitional coupling factor, k_t , is

$$k_t = \sqrt{\frac{1}{2}(1/Q'^2 + 1/Q_2^2)}. \quad (40)$$

Band width between peaks is

$$(f_2 - f_1)/f_o = \sqrt{k^2 - k_t^2}. \quad (41)$$

Selectivity

$$\frac{A_o}{A} \approx \sqrt{\left[1 - \frac{Q'Q_2 Y^2}{1 + k^2 Q'Q_2}\right]^2 + \left[\frac{2Y\sqrt{Q'Q_2}}{1 + k^2 Q'Q_2}\right]^2} \quad (42)$$

When $k^2 Q^2 \gg 1$ and $\Delta f_o/f_o \ll 1$,

$$A_o/A \approx \sqrt{1 - 8\Delta f_o^2/f_o k^2}. \quad (43)$$

(10) COUPLING COEFFICIENTS

High impedance coupling*

$$k \approx \frac{C_m}{\sqrt{C_1 C_2}} \text{ for capacitive coupling (Fig. 9.12)} \quad (44)$$

$$= \frac{\sqrt{L_1 L_2}}{L_m} \text{ for inductive coupling (Fig. 9.13)} \quad (45)$$

where C_m = coupling capacitance and L_m = coupling inductance.

Low impedance coupling*

$$k \approx \frac{\sqrt{C_1 C_2}}{C_m} \text{ for capacitive coupling (Fig. 9.14)} \quad (46)$$

$$\approx \frac{L_m}{\sqrt{L_1 L_2}} \text{ for inductive coupling (Fig. 9.15)} \quad (47)$$

where C_m = coupling capacitance and L_m = coupling inductance.

Link coupling*

$$k \approx \frac{M_1 M_2}{L_m \sqrt{L_1 L_2}} \text{ (Fig. 9.16A),} \quad (48)$$

where M_1 = mutual inductance between L_1 and L_m ,

and M_2 = mutual inductance between L_2 and L_m .

* For exact values see table in Section 8.

SECTION 1 : SINGLE LAYER COILS OR SOLENOIDS

(i) *Current-sheet inductance* (ii) *Solenoid wound with spaced round wires* (iii) *Approximate formulae* (iv) *Design of single layer solenoids* (v) *Magnitude of the difference between L_s and L_o* (vi) *Curves for determination of the "current sheet" inductance* (vii) *Effect of concentric, non-magnetic screen.*

(i) Current-sheet inductance

For the ideal case of a very long solenoid wound with extremely thin tape having turns separated by infinitely thin insulation we have the well-known formula for the low frequency inductance which is called the "current-sheet inductance" L_s :

$$L_s = 4\pi N^2 A' / l \text{ electromagnetic units} \quad (1)$$

where N is the total number of turns, A' is the cross-sectional area in cm^2 and l is the length in cm. This result for L_s may be expressed also as

$$L_s = 0.100 \, 28 a^2 N^2 / l \text{ microhenrys} \quad (2)$$

when l is measured in inches, and a is the radius of coil, also in inches.

For solenoids of moderate length—more precisely, for those for which a/l is not small compared with unity—there is an end-correction, and we find that

$$L_s = (0.100 \, 28 a^2 N^2 / l) K, \quad (3)$$

where K is a function of a/l , which approaches unity as a/l tends to zero. Values of K , computed by Nagaoka (Bulletin, Bureau of Standards, 8, p. 224, 1912), are shown by the curves in Fig. 10.1.

The concept of current sheet inductance is introduced because such (theoretical) inductances can be calculated with high precision, and the formulae used in practical cases can be derived from these results by making approximate allowances for the deviations from the ideal case. In many cases these deviations are less than 1%.

(ii) Solenoid wound with spaced, round wires

The low frequency inductance, L_o , of an actual solenoid wound with round wire is obtained from the equivalent cylindrical current-sheet inductance L_s by introducing two correction terms, thus :

$$L_o = L_s - 0.0319aN(A + B) \text{ microhenrys,} \quad (4)$$

where a is the radius of the coil, in inches, measured to the centre of the wire, A is a constant taking into account the difference in self-inductance of a turn of wire from that of a turn of the current sheet, and B depends on the difference in mutual inductance of the turns of the coil from that of the turns of the current sheet. The quantity A is a function of the ratio of wire diameter to pitch, and B depends only on the total number of turns, N . Values of A and B are shown by means of curves in Fig. 10.2.

Fig. 10.1. Nagaoka's Constant (K) for a wide range of d/l .

This formula for L_0 , together with the values of A and B , have been taken from the above quoted Bulletin of the Bureau of Standards. The value thus obtained for L_0 is given as correct to one part in a thousand.

The equation given above for L_0 can be expressed in the alternative forms :

Fig. 10.2. Constants A and B as used in the formula for the correction of "current sheet" formulae for application to round wire with spaced turns (eqn. 4).

$$L_o = L_s \left[1 - \frac{l(A+B)}{\pi a N K} \right] = L_s \left[1 - \frac{P}{\pi a K} (A+B) \right] \quad (5)$$

where P , the pitch of the winding in inches, is equal to l/N .

As an example of the use of these formulae and curves, let us consider the following case: a coil of 400 turns of round wire of bare diameter $D = 0.05$ inch, is wound with a pitch of 10 turns per inch, on a form of such a diameter that the mean radius to the centre of the wire is 10 inches. Then,

$$a = 10, l = NP = 40, N = 400, P = 0.1, D/P = 0.5.$$

The value of K corresponding to $2a/l = 0.5$ is 0.8181 from Fig. 10.1. Therefore,

$$L_s = 0.10028 (400)^2 \times (100/40) \times 0.8181 \\ = 32\,815 \text{ microhenrys.}$$

From Fig. 10.2 with $D/P = 0.5$, $N = 400$,

$$A = -0.136 \\ B = 0.335$$

Therefore $A + B = 0.199$.

The correction is, therefore, $0.0319 \times 10 \times 400 (0.199)$
 $= 25.4$ microhenrys.

The total inductance $L_o = 32\,815 - 25 = 32\,790$ microhenrys, and the error which would be introduced by calculating as a current sheet inductance is less than 0.08%.

(iii) Approximate formulae

In many instances it is not necessary to calculate L_o to the accuracy given by the expression above. There are available a number of approximate formulae suitable for slide-rule computation. For example:

$$A \approx 2.3 \log_{10} 1.7 S \quad (6)$$

where $S = D/P$, i.e. the ratio of wire diameter to pitch, with an accuracy of 1% for all values of S .

$$B \approx 0.336 [1 - (2.5/N + 3.8/N^2)] \quad (7)$$

accurate to 1% when N exceeds four turns.

(a) Wheeler's Formula

$$L_s = \frac{a^2 N^2}{9a + 10l} \quad (8)$$

This expression is accurate to 1% for all values of $2a/l$ less than 3. Wheeler's formula gives a result about 4% low when $2a/l = 5$.

(b) Approximate expression based on a value of K given by Esnault-Pelterie

$$L_s \approx 0.1008 \frac{a^2 N^2}{l + 0.92a} \quad (9)$$

This expression is accurate to 0.1% for all values of $2a/l$ between 0.2 and 1.5.

(c) For solenoids whose length is small compared with the diameter

$$L_s = \frac{a^2 N^2}{[9 - (a/5l)] a + 10l} \quad (10)$$

which is accurate to 2% for all values of $2a/l$ up to 20. The error approaches +2% when $d/l = 2.0$ to 3.5 and at $d/l = 20$. The error approaches -2% in the range $d/l = 10$ to 12.

Let us apply Wheeler's and Esnault-Pelterie's formulae to the solenoid already considered, namely:

$$a = 10 \text{ in.}, l = 40 \text{ in.}, N = 400.$$

$$\text{Wheeler's formula gives } L_s = \frac{10^2 \times 400^2}{90 + 400} = 32\,650 \text{ microhenrys.}$$

Esnault-Pelterie's formula yields

$$L_s = 0.1008 \frac{10^2 \times 400^2}{40 + 9.2} = 32\,790 \text{ microhenrys.}$$

These results agree, within the stated limits, with the value 32 815 obtained previously.

(iv) Design of single layer solenoids

The difference between L_s and L_o is usually less than 1%. Design formulae are based on L_s , as this is easier to compute, and then the correction is estimated.

Two of the many possible formulae are given in the Bureau of Standards Circular 74 (Ref. 2).

(A) Where it is required to design a coil which shall have a certain inductance with a given length of wire, the dimensions of the winding and the kind of wire being unrestricted within broad limits. This design problem includes a consideration of the question as to what shape of coil will give the required inductance with the minimum resistance.

We have the relations :

$$L_s = 0.10028 a^2 N^2 K / l \text{ from (3),}$$

$$l = NP, \lambda = 2\pi aN,$$

where λ is the length of wire. Eliminating N gives :

$$L_s = 0.00450 \frac{\lambda^{3/2}}{\sqrt{P}} \left(K \sqrt{\frac{2a}{l}} \right) \text{ microhenrys} \quad (11)$$

This gives the inductance in terms of the length of wire, the pitch P , and the shape $2a/l$, as K is a function of $2a/l$.

From the graph of the quantity $K\sqrt{2a/l}$ against $2a/l$, its maximum value is found to occur at $2a/l = 2.46$. **Thus, for a given length of wire, wound with a given pitch, that coil has the greatest inductance, which has a shape $d/l = 2.46$ approximately ;** or to obtain a coil of a required inductance, with a minimum resistance, this relation should be realized. Further, the inductance diminishes rapidly for coils longer than this optimum value, but decreases only slowly for shorter coils.

The optimum value of d/l can also be obtained roughly from the approximate expression for K :

$$K = 1/(1 + 0.45 d/l).$$

$$\text{Therefore } (d/l)_{opt} = (1/0.45) = 2.2 \text{ approximately} \quad (12)$$

(B) Given the diameter of the coil, the pitch and inductance, to determine the length of the coil.

A suitable form of the equation is obtained by substituting for N its value l/P in the formula :

$$L_s = 0.10028 a^2 N^2 K / l \text{ from (2) ;}$$

we find :

$$L_s = 0.20056 (a^3/P^2)(Kl/2a) \quad (13)$$

$$\approx 0.200 (a^3/P^2)f \quad (14)$$

where $f = K(l/2a)$. The quantity f , clearly a function of $2a/l$, is shown by the curve in Fig. 10.3.

For example, supposing we require a coil of 200 microhenrys to be wound on a former of 1 inch diameter, let us determine the length of the coil for a pitch of 0.02 inch.

From the equation,

$$f = \frac{200 \times (0.02)^2}{0.200 \times (0.5)^3} = 3.2.$$

Then, from Fig. 10.3, the value of $2a/l$ corresponding to $f = 3.2$ is 0.28. Hence the length of the coil is

$$l = 2a/0.28 = 1/0.28 = 3.6 \text{ inches.}$$

The number of turns required would be :

$$N = l/P = 3.6/0.02 = 180 \text{ turns.}$$

The length of wire needed would be :

$$\lambda = 2\pi aN = \pi 180 = 565.5 \text{ inches.}$$

When the calculated length is too long, the turns per inch should be increased. Let us consider the effect of using 100 T.P.I. in the above example :

$$f = \frac{200 \times (0.01)^2}{0.200 \times (0.5)^3} = 0.8.$$

FIG. 10.3

Fig. 10.3. Variation of f with $(2a/l)$. Curves derived from U.S. Dept. of Commerce Circular C74 "Radio instruments and measurements".

From Fig. 10.3, we see that the value of $2a/l$ is 0.9, and hence

$$l = 1/0.9 = 1.1 \text{ inches.}$$

Formula for determining the coil length when the coil diameter and winding pitch are known for coils such that $d < 3l$.

As an alternative to the use of Fig. 10.3, we derive a simple result for solenoids such that $2a/l < 3$. Here we have

$$K \approx 1/[1 + 0.45(2a/l)] \quad (15)$$

$$\text{Hence, } f = K \cdot \frac{l}{2a} = \frac{l}{2a} \cdot \frac{1}{1 + 0.45(2a/l)} \quad (16)$$

$$\text{Therefore, } 0.9(2a/l) = -1 + \sqrt{1 + 1.8/f} \quad (17)$$

Thus, in the first case above, where $f = 3.2$,

$$0.9(2a/l) = -1 + \sqrt{1 + 1.8/3.2} = 0.25,$$

$$\text{and } 2a/l = 0.25/0.9 = 0.28;$$

for the second case, where $f = 0.8$,

$$0.9(2a/l) = \sqrt{1 + (1.8/0.8)} - 1 = 0.803,$$

$$\text{and } 2a/l = 0.803/0.9 = 0.89.$$

These values agree well with those above.

The limitation $2a/l < 3$ is equivalent to $f \leq 0.14$.

Eqn. (14) for L_s is suitable too when the former diameter and coil length have been decided. For example, suppose we require a coil of inductance 500 microhenrys on a former of diameter 2 inches, and having a coil length of 2 inches.

Then, from equation (14)

$$L_s = 0.200(a^3/P^2) \cdot f, \quad (18)$$

we have

$$P = \sqrt{(0.200a^3 \cdot f)/L_s} \quad (19)$$

Here $a = 1$, $L_s = 500$, $f = Kl/2a = 0.688$.

Therefore,

$P = \sqrt{0.200 \times 0.688/500} = 0.0167$ inch,
equivalent to 60 T.P.I.

Simple procedure for computing the length and total turns when the coil diameter and pitch of winding are known for coils such that $d < 3l$.

Substituting in equation (17),

$$0.9(2a/l) = -1 + \sqrt{1 + 1.8/f},$$

where $f = 5L_s P^2/a^3 = 5L_s/n^2 a^3$, n being T.P.I.

Putting $F = 1.8/f$ and $y = 0.9(2a/l)$,

we obtain

$$y = -1 + \sqrt{1 + F}, \quad (20)$$

where $F = 0.36n^2 a^3/L_s$,

and $l = 1.8a/y$.

As an example, let us consider a coil of 2 inches diameter, wound with 33 T.P.I. of required inductance 380 microhenrys.

$$(a) F = 0.36n^2 a^3/L_s = 0.36 \times 33^2 \times 1^3/380 = 1.031$$

$$(b) y = -1 + \sqrt{1 + F} = -1 + \sqrt{2.031} = 0.426$$

$$(c) l = 1.8a/y = 1.8/0.426 = 4.23 \text{ inches}$$

$$(d) N = nl = 33 \times 4.23 = 139\frac{1}{2} \text{ turns.}$$

Another method applicable to the same type of problem is due to Hayman.

From Wheeler's formula (equation 8) :

$$L_s \approx \frac{a^2 N^2}{9a + 10l},$$

the length l is eliminated by the substitution $l = N/n$, n being the turns per inch ; and then the resulting expression is solved for N , yielding :

$$N = \frac{5L_s}{na^2} \left[1 + \sqrt{1 + \frac{0.36a^3 n^2}{L_s}} \right] \quad (21)$$

For convenience in computation, the quantity $x = 5/na^2$ is introduced, so that finally

$$N = xL_s [1 + \sqrt{1 + (9/ax^2 L_s)}] \quad (22)$$

As an example, we take the same problem as above, namely, $a = 2$ inches, $n = 33$, $L_s = 380$ microhenrys. The procedure is as follows :

$$(a) x = 5/na^2 = 5/(33 \times 1) = 0.151,$$

$$(b) x^2 = 0.0227,$$

$$(c) 9/ax^2 L_s = 9/(1 \times 0.0227 \times 380) = 1.042,$$

$$(d) N = 380 \times 0.151 \times (\sqrt{2.042} + 1) = 139 \text{ turns,}$$

$$(e) l = N/n = 139/33 = 4.2 \text{ inches.}$$

(C) Given the diameter and length of coil, value of capacitance and frequency of resonance, to determine the number of turns.

See Chapter 38 Sect. 9(v)B.

(v) Magnitude of the difference between L_s and L_o

In Sect. 1(iv) it was stated that in many practical cases the difference between L_s and L_o is less than 1 per cent. Here, we examine briefly the necessary conditions for this difference to be small.

A formula given in Sect. 1(ii) for L_o , namely :

$$L_o = L_s [1 - P(A + B)/\pi a K] \text{ from equation (5)}$$

is in a useful form ; clearly the ratio of $P(A + B)/\pi a K$ to unity determines the order of the difference between L_s and L_o . From the curves of Fig. 10.2, $A = +0.5$ for $P/D = 0.95$ and decreases steadily to -0.7 for $P/D = 0.25$, while $B = 0.114$ at $N = 2$ and 0.336 at $N = 1000$, and remains approximately constant for higher values of N . Hence, for coils having P/D between 0.95 and 0.25 —as most have—the value of $(A + B)$ is less than 0.83 ; i.e.

$$P(A + B)/\pi a K < (P/a) \times (0.26/K).$$

Thus, when $(2a/l) = d/l < \frac{1}{2}$, $K > 0.82$, so that $P(A + B)/\pi a K < 0.32 P/a$.

The correction is less than 1% when $P/a < 0.03$.

Similarly, for $2a/l < 1$, $K > 0.69$, and the correction is less than 1% when $P/a < 0.026$. Corresponding results for $2a/l < 5$ and $2a/l < 10$ are $P/a < 0.012$ and $P/a < 0.0078$.

In the table opposite are given some examples of the minimum turns per inch, n , for a number of coil diameters required to make the difference between L_s and L_o less than 1% :

Fig. 10.4. Curves for the determination of Current Sheet Inductance (L_s) for small solenoids, plotted against length of coil (l). For other pitches refer to Fig. 10.5.

Minimum turns per inch, n for

$\left(\frac{\text{Coil diameter}}{\text{length}}\right)$ not exceeding	$d = 5$ inches	$d = 2$ inches	$d = 1$ inch	$d = \frac{1}{2}$ inch
0.5	13	33	66	132
1	16	40	80	160
5	32	80	160	320
10	52	130	260	520

In many practical cases the ratio of pitch to wire diameter lies between 0.8 and 0.95 in which range $A = 0.4 \pm 0.1$; and N , the number of turns, exceeds 10, so that $B = 0.3 \pm 0.035$. In such cases $A + B = 0.7 \pm 0.135$. Hence, from eqn. (4):

$$L_o = L_s - 0.0319a n N(A + B),$$

we have, under such conditions,

$$L_o \approx L_s - 0.0223a n N, \quad (23)$$

with an error not exceeding 20% of $0.0223a n N$; and thus in many cases not exceeding 0.2% of L_o .

(vi) Curves for determination of the "current sheet" inductance

(A) Method of using the curves

Figure 10.4 applies to a winding pitch of 10 turns per inch only; for any other pitch the inductance scale must be multiplied by a factor, which is easily determined from Fig. 10.5. The diameter of a coil is considered to be twice the distance from coil axis to centre of the wire.

FIG. 10.5

Fig. 10.5. Winding pitch correction for Fig. 10.4.

(B) To design a coil having required "current sheet" inductance

Determine a suitable diameter and length, and from Fig. 10.4 read off the "current sheet" inductance for a pitch of 10 T.P.I. The required inductance may then be obtained by varying the number of turns per inch. The correct number of turns may be found by calculating the ratio of the required inductance to that read from Fig. 10.4 and referring it to Fig. 10.5 which will give the required turns per inch.

Alternatively if the wire is to be wound with a certain pitch, a conversion factor for that pitch may first be obtained from Fig. 10.5, and the required inductance divided by that factor. The resultant figure of inductance is then applied to Fig. 10.4 and suitable values of diameter and length determined.

(C) To find the "current sheet" inductance of a coil of known dimensions

Knowing the diameter and length, determine from Fig. 10.4 the inductance for a pitch of 10 T.P.I. Then from Fig. 10.5 determine the factor for the particular pitch used, and multiply the previously determined value of inductance by this factor.

(vii) Effect of concentric, non-magnetic screen

A shield surrounding a coil acts as a short-circuited turn coupled to the coil and reflects an impedance into the coil. The value of this reflected impedance is given by the expression $M^2 \omega^2 / Z_t$, where M is the mutual inductance between the coil and the shield, and Z_t is the impedance of the shield. In practice, the resistance of the screen may be neglected, so that the effective impedance of the coil Z'_c , is

$$Z'_c = r_o + j\omega L_o + M^2 \omega^2 / j\omega L_t \quad (24)$$

where r_o and L_o are the resistance and the inductance of the coil in the absence of the shield, and L_t is the inductance of the shield. The expression for Z'_c may be put in the forms:

$$Z'_c = r_o + j\omega(L_o - M^2/L_t), \quad (25a)$$

$$= r_o + j\omega(1 - M^2/L_o L_t), \quad (25b)$$

$$= r_o + j\omega L_o', \quad (25c)$$

$$= r_o + j\omega L_o(1 - k^2); \quad (25d)$$

where L_o' is the effective inductance of the enclosed coil, and k is the coefficient of coupling between the coil and the can. The presence of the shield thus lowers the effective inductance, and we have

$$L_o' = L_o(1 - k^2), \quad (26a)$$

$$\text{or } (L_o - L_o')/L_o = k^2 \quad (26b)$$

It has not proved possible to obtain a simple, accurate formula for the apparent decreases in inductance of a shielded coil, but various estimates have been made by Hayman, Kaden, Davidson and Simmonds, Bogle and others (see bibliography). Here we review briefly some of the published work.

(A) H. Kaden (Electrishe Nachrichten Technik, July, 1933, p. 277)

Kaden first showed that the shape of the shield is not important. Then, in his theoretical treatment, he replaced the actual solenoid in the concentric cylindrical shield by a magnetic dipole placed at the centre of a spherical screen; the dipole having the same magnetic moment as the solenoid and the spherical screen a radius equal to the geometrical mean of the three dimensions of the cylinder. In this way he obtained an expression for the relative decrease in inductance of the solenoid.

$$\frac{L_o - L_o'}{L_o} = \frac{2 V_c \alpha}{3 V_t K}, \quad (27)$$

where V_c is the volume of the coil, V_t is the volume of the shield, K is Nagaoka's constant, and α is a constant which depends upon the permeability and the shield and the dimensions. When the shielding is effective and the shield is non-magnetic, α is approximately 1 and then:

$$\frac{L_o - L_o'}{L_o} \approx \frac{2 V_c}{3 V_t K} \quad (28)$$

(B) C. F. Davidson and J. C. Simmonds (Ref. 41)

Following Kaden, these authors also considered the case of a spherical screen. Here the solenoid was taken to consist of a small number of closely spaced circular turns placed at the centre of the sphere. The change in inductance was found to be

$$L_o - L_o' = 0.1 a N^2 (a/b)^3 \cdot f(a/b), \quad (29)$$

where a is the coil radius, N is the number of turns, b is the shield radius and $f(a/b)$ is a function of (a/b) . This function f is approximately 0.5 for values of $(a/b) > 0.5$, and it increases to 0.73 at $(a/b) = 0.9$. Thus, for values of $(a/b) < 0.5$, we have :

$$L_o - L_o' \approx (0.05 a N^2) (a/b)^3, \quad (30)$$

in agreement with Kaden's result. The authors point out that their formula holds only for very short solenoids; they indicate how the change in inductance of long solenoids in spherical screens may be calculated, but it is clear that no simple formula can be thus obtained.

(C) R.C.A. Application Note No. 48 (June, 1935)

In this Application Note (Ref. 48) curves are given for k^2 in the case of a concentric cylindrical shield whose length exceeds the coil length by at least the radius of the coil. These curves (Fig. 10.6) show k^2 as a function of the ratio coil length to coil diameter ($l/2a$) for various values of the ratio coil radius to shield radius ranging from 0.2 to 0.9. It is stated that these values of k^2 have been calculated and also verified experimentally. The shields are not closed at the ends, but see (D) below.

It is stated that these curves may also be used for cans of square cross-section by taking A as 0.6 of one side of the can.

(D) A. G. Bogle (Ref. 45)

Bogle obtains an approximate theoretical formula for the effective change in inductance, valid in a restricted range, and then, from measurements of L_o' , he derives an empirical expression which is of the same form as the theoretical formula, but which gives good results over a wide range.

For a coil inside a concentric cylindrical shield, Bogle's expression is :

$$\frac{L_o - L_o'}{L_o} = \frac{1}{1 + 1.55g/l} \left(\frac{a}{b}\right)^2 \quad (31)$$

where b is the shield radius, and $g = b - a$, the distance between the coil and the shield. It is assumed that the shield length l , is not less than $l + 2g$. An accuracy of 2% over a wide practical range is claimed for this simple result.

An investigation of this expression shows that it is useful in almost all practical cases, the only restriction being the non-stringent one that the length of the coil must not be very much less than the distance between the coil and the shield, i.e. $g/l > 1$.

For very long coils this formula shows that

$$(L_o - L_o')/L_o = a^2/b^2$$

in agreement with theoretical expectations. It is in accord, too, with the R.C.A. curves for k^2 in that the proportional change in inductance depends upon the two ratios a/b and l/a , as can be seen by writing the formula in the form :

$$\frac{L_o - L_o'}{L_o} = \frac{1}{1 + 1.55 \frac{a}{l} \left(\frac{b}{a} - 1\right)} \left(\frac{a}{b}\right)^2.$$

Bogle showed also that when $l_i > l + 2g$ the effect on L_o' of closing the ends of the shield is negligible. He investigated the effect of eccentricity of the coil, of ellipticity of the screening tube, and of small axial displacements in a closed screen; and found that in practice these would not need to be taken into account.

Sowerby has published data charts (Ref. 44) calculated from Bogle's formula.

(E) W. G. Hayman (Ref. 51)

Hayman gives an empirical formula for coils in concentric cylindrical cans :

$$(L_o - L_o')/L_o = (a/b)^2, \quad (32)$$

provided $l_i \gg l$. For coils of length $l > \frac{1}{2}l_i$, there is an end-correction factor, and he gives :

$$(L_o - L_o')/L_o = (1 - 1/2l_i)^2 (a/b)^3 \quad (33)$$

It is true that there is fair agreement between Hayman's calculated and measured values of L_o' for a number of coils ; but, nevertheless, the useful range of eqn. (32) must be somewhat restricted.

(F) Where the coil diameter and length are equal, the curves of Fig. 11.13 can be used for a shield can with ends.

It is recommended that either the R.C.A. curves for k^2 , reproduced in Fig. 10.6, or Bogle's formula be used. Comparison of the results obtained from these curves and from the formula will be found to be in good agreement except for very

FIG. 10.6

Fig. 10.6. Curves for determination of decrease in inductance produced by a coil shield (reprinted by kind permission of Radio Corporation of America).

small values of l/g where Bogle's formula should not be used. In the tables below comparisons are made in a number of typical cases :

Table 1 : Comparison between estimates of the percentage reduction in inductance caused by a cylindrical screen for various coil shapes when the ratio of coil diameter to screen diameter = 0.7.

SECTION 2 : MULTILAYER SOLENOIDS

(i) Formulae for current sheet inductance (ii) Correction for insulation thickness
(iii) Approximate formulae (iv) Design of multilayer coils (v) Effect of a concentric screen.

(i) Formulae for current sheet inductance

(A) Long coils of a few layers

The Bureau of Standards Circular No. 74 gives a simple formula for the current sheet inductance, correct to 0.5% for long solenoids of a few layers ; it is

$$L_s = L_s' - \frac{0.0319N^2ac}{l} (0.693 + B_s), \quad (1)$$

where N = total number of turns,

c = radial depth of winding,

l = length of winding

B_s = a tabulated function of l/c

a = radius of coil to centre of winding,

and $L_s' = (0.10028a^2N^2/l)K$.

This result may be expressed in the form :

$$L_s = L_s' \left[1 - \frac{c(0.693 + B_s)}{\pi a K} \right] \quad (2)$$

The quantity $B_s = 0$ for $l/c = 1$; it rises to 0.279 for $l/c = 10$, and then increases very slowly, being 0.322 at $l/c = 30$.

(B) Short coils of rectangular cross-section

The solution of the problem for short coils is based on that for the ideal case of a circular coil of rectangular cross section. Such a coil would be closely realized by a winding of wire of rectangular cross section, arranged in several layers, with negligible insulating space between adjacent wires.

When the dimensions l and c are small in comparison with a (see Fig. 10.7) the inductance is given closely by **Stephan's formula**, which, for $l > c$, takes the form :

$$L_s = 0.031\ 93aN^2 \left[2.303 \left(1 + \frac{l^2}{32a^2} + \frac{c^2}{96a^2} \right) \log_{10} \frac{8a}{g'} - y_1 + \frac{l^2 y_2}{16a^2} \right] \quad (3)$$

while for $l < c$, that is for pan-cake coils, the formula becomes :

$$L_s = 0.031\ 93aN^2 \left[2.303 \left(1 + \frac{l^2}{32a^2} + \frac{c^2}{96a^2} \right) \log_{10} \frac{8a}{g'} - y_1 + \frac{c^2 y_3}{16a^2} \right] \quad (4)$$

where $g' = \sqrt{c^2 + l^2}$ and y_1, y_2 and y_3 are functions of c/l which are tabulated in the Bureau of Standards Circular No. 74 (p. 285).

The formulae of this section have been put in the form of a family of curves by Maynard (Ref. 38).

FIG. 10.7

(ii) Correction for insulation thickness

Unless the percentage of the cross section occupied by the insulation is large the formulae given in Sect. 2(i) apply very well to an actual coil. When the spacing P is appreciably greater than the diameter of the wire D a correction term should be added to L_s to give L_o . Thus :

$$L_o = L_s + 0.073\ 35aN [\log_{10} (P/D) + 0.0675] \quad (5)$$

(iii) Approximate formulae

(A) Long coils of a few layers

For long coils of a few layers $l/c > 10$ and $B \approx 0.3$, so that we obtain from equation (1) ;

$$L_s \approx \frac{0.1003a^2 N^2 K}{l} \left[1 - \frac{c}{\pi a K} \right] \quad (6)$$

$$\approx \frac{a^2 N^2}{9a + 10l} \left[1 - \frac{c}{10\pi a l} (9a + 10l) \right] ; \quad (7)$$

$$\text{or } L_s \approx \frac{a^2 N^2}{9a + 10l} - \frac{caN^2}{10\pi l} \quad (8)$$

(B) Short coils

For short coils such that both l and c are much less than a , it follows from Stephan's formula that :

$$L_s = 0.073\ 35aN^2 \left[\log_{10} \frac{8a}{\sqrt{l^2 + c^2}} - 0.4343y_1 \right] \quad (9)$$

$$= \frac{aN^2}{13.5} \log_{10} \frac{3.6a}{\sqrt{l^2 + c^2}} \text{ when } \frac{l}{c} \text{ or } \frac{c}{l} \text{ lies between } 0.35 \text{ and } 1 \quad (10)$$

$$= \frac{aN^2}{13.5} \log_{10} \frac{4.02a}{\sqrt{l^2 + c^2}} \text{ when } \frac{l}{c} \text{ or } \frac{c}{l} \text{ lies between } 0.15 \text{ and } 0.35 \quad (11)$$

$$= \frac{aN^2}{13.5} \log_{10} \frac{4.55a}{\sqrt{l^2 + c^2}} \text{ when } \frac{l}{c} \text{ or } \frac{c}{l} \text{ lies between } 0 \text{ and } 0.15 \quad (12)$$

These results are accurate to 5% as l and c approach a , and are increasingly accurate as l and c decrease compared with a . When l/a and c/a are both very small, it is sufficient to use the approximation :

$$L_s \approx \frac{aN^2}{13.5} \log_{10} \frac{4}{\sqrt{l^2 + c^2}}$$

for all values of the ratio l/c .

(C) Bunet's formula

Bunet (Ref. 24) gives the following approximate formula applicable to coils whose diameters are less than three times their length :

$$L_s = \frac{a^2 N^2}{9a + 10l + 8.4c + 3.2cl/a} \quad (13)$$

The range of usefulness of this formula can be best judged from its accuracy for various coil dimensions given below :

	Accuracy		
For $c/a = 1/20$	1% for $(2a/l)$ up to 3	4% for $(2a/l) = 5$	
For $c/a = 1/5$	1% for $(2a/l)$ up to 5	2% for $(2a/l) = 10$	
For $c/a = 1/2$	1% for $(2a/l)$ up to 2	3% for $(2a/l) = 5$	
For $c/a = 1$	1% for $(2a/l)$ up to 1.5	5% for $(2a/l) = 5$	

It is easy to verify that for long coils of a few layers Bunet's formula is approximately :

$$L_s \approx \frac{a^2 N^2}{9a + 10l} - \frac{a^2 N^2 (3.2cl/a)}{(9a + 10l)^2} \quad (14)$$

$$\approx \frac{a^2 N^2}{9a + 10l} - \frac{CaN^2}{10\pi l} \quad (15)$$

in accord with the result given previously for this type of coil.

(D) Wheeler's formula for short coils

Wheeler gives a formula for short coils having l and c less than a (Ref. 22). This result, which he states was obtained theoretically, is :

$$L_s = \frac{aN^2}{13.5} \log_{10} \frac{4.9a}{l+c} \quad (16)$$

The accuracy is given as 3% when $(l+c) = a$, and is stated to improve as $(l+c)/a$ decreases towards zero.

This formula is slightly different in form from those given in (B) of this section. Nevertheless, the numerical agreement is quite good, as can be seen from the following considerations :

For the case $l = c$,

$$\frac{3.6a}{\sqrt{l^2 + c^2}} = \frac{3.6a}{0.707(l+c)} = \frac{5.1a}{l+c};$$

when $l = 3c$ or $c = 3l$,

$$\frac{4.02a}{\sqrt{l^2 + c^2}} = \frac{4.02a}{0.792(l+c)} = \frac{5.1a}{l+c};$$

when $l = 10c$ or $c = 10l$,

$$\frac{4.55a}{\sqrt{l^2 + c^2}} = \frac{4.55a}{0.91(l+c)} = \frac{5.0a}{l+c};$$

Thus when $\log 4.9/(l+c)$ is compared with the logarithms of these quantities the percentage difference is found to be small.

Another formula due to Wheeler (Ref. 22) which covers the shape of many universal windings, is

$$L_s = \frac{0.8a^2 N^2}{6a + 9l + 10c}$$

accurate to within about 1% when the three terms in the denominator are about equal.

(iv) Design of multilayer coils**(A) Short coils**

The Bureau of Standards Circular No. 74 gives two of the possible approaches to the design of short multilayer coils.

(1) The two forms of Stephan's equation given in eqns. (9) to (12) may be expressed as :

$$L_s = \frac{\lambda^{5/3}}{P^{2/3}} G, \quad (17)$$

where λ is the wire length, P is the distance between centres of adjacent wires and G is a function of the shape of cross section (l/c) and of the shape ratio of the coil (c/a). The quantity G is represented by means of curves. This equation is used, in cases where the ratios l/c and c/a have been decided, to determine the necessary wire-length for a given pitch, or vice versa. The mean radius of the winding is then obtained from

$$a = \sqrt[3]{\frac{\lambda c P^2}{2\pi l (c/a)^2}}; \quad (18)$$

and the total number of turns is given by $N = \lambda/2\pi a$ or lc/P^2 .

It can be shown that, for a given resistance and coil shape, the square cross section ($l/c = 1$) gives a greater inductance than any other form; and, further, for a square cross section, the inductance for a given length of wire is a maximum for $c/a = 0.662$.

(2) Stephan's formulae may also be expressed in the form:

$$L_s = 0.03193aNg^2, \quad (19)$$

where g is a known function of l/c and c/a .

This form is useful when a , c and l have been decided to give N , and thence P . We have

$$P = \frac{lc}{N}$$

and $\lambda = 2\pi aN$.

(B) Universal coils

The usual problem is the calculation of the inductance of a given number of turns before winding the coil, with only former size and wire size known. It is stated in Ref. 20 that the inductance of universal coils is about 10% greater than that of normal multilayer windings of the same external dimensions.

A suitable procedure is to determine the gear ratio from the formula,

$$\text{gear ratio} = \frac{1}{2}n(P+1)/P \quad (20)$$

as described in Chapter 11, Sect. 3(iv). The radial depth of winding, c , can then be obtained from the formula

$$c = Nqw'/(P+1) \quad (21)$$

where N = number of turns in coil,

q = number of crossovers per winding cycle

[Refer Table 1 in Chapter 11, Section 3(iv)]

w' = diameter of wire plus insulation,

and P = an integer defined in Chapter 11, Section 3(iv).

Since the length of the winding, l , is equal to the sum of the cam throw and the wire diameter, the dimensions of the coil are then known and the inductance can be calculated from the methods previously described.

Example: A coil of 500 turns of 38 A.W.G. enamelled wire (0.0044 inch) is to be wound on a 0.5 inch diameter former with a 0.1 inch cam. From Chapter 11 Sect. 3(iv), $P = 43$ and $q = 2$. Therefore

$$c = 500 \times 2 \times 0.0044/44 \text{ inch} = 0.1 \text{ inch}$$

$$l = 0.1 \text{ inch} + 0.0044 \text{ inch} = 0.1044 \text{ inch}$$

and $a = 0.25 \text{ inch} + c/2 = 0.3 \text{ inch}$.

(v) Effect of a concentric screen

No formulae have apparently been given for the change in inductance produced by a concentric shield. It is clear that the percentage change in inductance of a multilayer coil will be less than that of a single layer coil of equal outside dimensions; and that the greater the winding depth c the less will be the effect of the shield. For solenoids of a few layers the percentage change in inductance will be very closely the same as for a single layer solenoid of corresponding dimensions.

SECTION 3 : TOROIDAL COILS

(i) *Toroidal coil of circular section with single layer winding* (ii) *Toroidal coil of rectangular section with single layer winding* (iii) *Toroidal coil of rectangular section with multilayer winding.*

(i) Toroidal coil of circular section with single layer winding

The current sheet inductance of a single layer coil wound on a torus, that is a ring of circular cross-section, is given by

$$L_s = 0.031\ 93N^2 [R - \sqrt{R^2 - a^2}] \text{ microhenrys,} \quad (1)$$

where R is the distance in inches from the axis to the centre of cross-section of the winding, a is the radius of the turns of the winding and N is the total number of turns.

(ii) Toroidal coil of rectangular section with single layer winding

For this type of coil the current sheet inductance is readily shown to be :

$$L_s = 0.011\ 70N^2 h \log_{10} \frac{r_2}{r_1} \text{ microhenrys,} \quad (2)$$

where r_1 is the inner radius of the winding, r_2 is the outer radius of the winding and h is the axial depth of the winding.

The difference between L_s and L_o for single layer toroidal coils is usually small. Where high precision is required the value of L_o may be obtained from L_s by using the corrections shown in Bulletin, Bureau of Standards, 8 (1912) p. 125.

(iii) Toroidal coil of rectangular section with multilayer winding

Dwight (Ref. 11) has obtained an expression for the current sheet inductance of this type of coil. His expression contains only simple terms, but it is too long to reproduce here. In an example quoted by the author the calculated and measured values of an inductance agreed within 1%.

Richter (E.E. Supplement. Dec. 1945, p. 999) stated that in practice fair results are obtained by use of the empirical formula :

$$L = 0.0117N^2 h' \log_{10} (r_2'/r_1') \quad (3)$$

where h' , r_2' and r_1' are determined as follows :

Let t_1 be the thickness of winding on the inside face,

t_2 be the thickness of winding on the outside face,

t_3 be the thickness of winding on the inside edge of the top and bottom faces, and

t_4 be the thickness of winding on the outside edge of the top and bottom faces,

then

$$r_2' = r_2 + t_2/3 ; r_1' = r_1 - t_1/3 ; h' = h + (t_3 + t_4)/3 ;$$

h , r_1 and r_2 having the same meanings as in Section 3(ii).

SECTION 4 : FLAT SPIRALS

(i) *Accurate formulae* (ii) *Approximate formulae.*

(i) Accurate formulae

The current sheet inductance of flat spirals can be obtained from Stephan's formula for short multilayer coils [see Sect. 2(i)].

(a) Wire of rectangular cross section

For spirals wound with metal ribbon or with thicker rectangular wire the procedure is as follows :

Use Stephan's formula with these conventions :

for l put the width of the wire ;

for c put NP , where P is the distance between the centre of cross section of a turn and the corresponding point of the next turn ;

for a put $a_0 + (N - 1)P/2$, where $2a_0$ is the distance (Fig. 10.8) across the centre of the innermost end of the spiral.

The correction for cross section is given in the Bureau of Standards Circular No. 74 in the form :

$$L_0 = L_s - 0.0319aN(A_1 + B_1),$$

where A_1 and B_1 are tabulated functions. The accuracy obtained for L_0 is 1%.

(b) Round wire

For spirals wound with round wire the same conventions are adopted to obtain a and c , but a simplified form of Stephan's equation, obtained by setting $l = 0$, is used. It is

$$L_s = 0.3193aN^2 \left[2.303 \log_{10} \frac{8a}{c} - \frac{1}{2} + \frac{c^2}{96a^2} \left(2.303 \log_{10} \frac{8a}{c} + \frac{43}{12} \right) \right].$$

The inductance L_0 of a spiral is given more closely by :

$$L_0 = L_s - 0.0319aN(A + B),$$

where A and B are shown in Fig. 10.2.

(ii) Approximate formulae

For round wires it follows immediately that

$$L_s \approx 0.03193 \times 2.303aN^2 \left[\log \frac{8a}{c} - \frac{0.5}{2.303} \right]$$

$$\approx \frac{aN^2}{13.5} \log \frac{4.9a}{c}.$$

Wheeler has given an approximate formula for spirals where $c > 0.2a$. It is :

$$L_s = \frac{a^2N^2}{8a + 11c}.$$

The first of these formulae is the more accurate as the ratio c/a decreases, while the second is the more accurate the closer c/a approaches unity. The agreement between them is quite fair :

For $c/a = 0.2$, we have from the first result,

$$L_s \approx (aN^2/13.5) \log 24.5 = 0.103aN^2,$$

while from Wheeler's formula

$$L_s \approx aN^2/(8 + 2.2) = 0.098aN^2.$$

For $c/a = 0.5$, we obtain, respectively,

$$L_s \approx (aN^2/13.5) \log 9.4 = 0.97aN^2/13.5 \text{ and}$$

$$L_s \approx aN^2/(8 + 5.5) = aN^2/13.5.$$

SECTION 5 : MUTUAL INDUCTANCE*

(i) Accurate methods (ii) Approximate methods.

(i) Accurate methods

Accurate methods for the calculation of mutual inductance between coils of many different shapes and relative dispositions are given in the Bureau of Standards Circular No. 74, and in the Bureau of Standards Scientific Paper No. 169. The book by Grover (Ref. 15) covers the subject comprehensively in Chapters 12, 15 and 20. The possible accuracy of these methods is always better than one part in one thousand.

The mutual inductance of coaxial single-layer coils, with tables to facilitate the calculation, is covered in Ref. 15 Chapter 15 (see also Ref. 5).

*By the Editor.

There are few simple formulae which can be used for the more common practical cases, such as are possible with self inductance. The following exact method may be used for two windings on the same former with a space between them, both windings being similar in pitch and wire diameter (Fig. 10.9).

FIG. 10.9

Assume that the space between the windings is wound as a continuation of the windings on the two ends, to form a continuous inductor from A to D with tapings at points B and C. Then the required mutual inductance, M , between the two original windings is given by

$$M = \frac{1}{2}(L_{AD} + L_{BC} - L_{AC} - L_{BD}) \quad (1)$$

where L_{AD} is the inductance between points A and D, and similarly for other terms. These inductances may be calculated from the formulae given in earlier sections of this chapter.

References to accurate methods : Refs. 2, 3, 5, 13, 14, 15, 18.

FIG. 10.10

Fig. 10.10. Chart giving coefficient of coupling for a specified spacing between two coaxial solenoids having identical dimensions. The quantities S and L are measured in terms of coil diameters. (Ref. 56.)

(ii) Approximate methods

The coefficient of coupling for a specified spacing between two coaxial solenoids having identical dimensions, but not necessarily identical numbers of turns, is given by Fig. 10.10 (Ref. 56). The accuracy should be better than 5%.

SECTION 6 : LIST OF SYMBOLS

Note : Inductances are given in microhenrys and dimensions in inches.

- L_s = current sheet inductance
- L_o = low frequency inductance
- L_o' = effective inductance of a shielded coil
- N = total turns in coil
- n = turns per unit length
- l = coil length
- P = pitch of winding = $1/n$
- a = coil radius (from axis to middle of winding)
- $d = 2a$ = coil diameter
- A' = cross sectional area of coil
- D = (bare) wire diameter
- $S = D/P$
- λ = total length of wire
- K = Nagaoka's constant—see Fig. 10.1
- A, B = correction terms—see Fig. 10.2
- $f = Kl/2a$ —see Fig. 10.3
- $F = 1.8/f$
- $y = 1.8/l$
- b = radius of concentric cylindrical screen
- l_t = length of concentric cylindrical screen
- $g = b - a$, i.e. coil to screen spacing
- k = coefficient of coupling between coil and concentric can
- c = radial depth of winding
- $g' = \sqrt{l^2 + c^2}$
- B_s = correction term, function of l/c
- y_1, y_2, y_3 = functions of l/c in Stephan's formula
- q = number of crossovers per winding cycle
- R = mean radius of a toroidal coil of circular cross section
- r_1 = inner radius of a toroidal coil of rectangular cross section
- w' = diameter of wire plus insulation
- r_2 = outer radius of a toroidal coil of rectangular cross section
- h = axial depth of a toroidal coil of rectangular cross section
- M = mutual inductance

SECTION 1: INTRODUCTION

The space available for coils in a radio receiver is invariably limited, and part of the design work on each coil is the obtaining of maximum Q in a minimum volume. In the case of i-f transformers the volume is clearly defined by the shield used, and the same applies to r-f coils in cans, but where shielding is not used with r-f coils the increased Q obtainable from larger diameter formers is offset against the increased damping from components and magnetic materials, such as the receiver chassis, adjacent to the coil.

The resulting form factor for each individual winding requiring maximum Q and minimum self-capacitance is usually such that the length of the winding is very approximately equal to its diameter. To obtain this shape for i-f, broadcast and short-wave coils the winding method is varied.

I-F transformers use universal windings, and where the Q and distributed capacitance requirements are not severe a single coil wound with a large cam (perhaps $\frac{3}{8}$ in.) will be satisfactory, even without an iron core, if litz wire [see Sect. 5(i)] is used. However higher Q values are usually required than are obtainable in this way and in such cases each winding consists of two or more pies, perhaps with an iron core.

The same types of coils are satisfactory in the broadcast band, although in the case of signal frequency coils which are tuned over a ratio of more than three to one it is essential to use very narrow windings or two or more pies to reduce the distributed capacitance of the winding. Litz wire and iron cores are commonly used to give a secondary Q of 100 or more.

Another method of decreasing distributed capacitance is the use of progressive universal windings in which the winding finger travels along the former in addition to moving to and fro. Such coils are rarely built up to a greater height than five wire thicknesses, and are equally useful with or without iron cores. Solenoids are also used either with iron cores or on comparatively large diameter formers if an iron core is not used.

At frequencies between 2 and 6 Mc/s (which are used in receivers providing continuous coverage between the normal short-wave and broadcast bands, or for oscillators giving second harmonic mixing for the short wave band) the progressive universal winding is particularly useful because the winding length of solenoids may be too great with the usual range of former diameters, and the number of turns is insufficient to allow them to be split into many sections.

A set of worm driving gears which spreads the appropriate number of turns over a length approximately equal to the coil diameter is required. This usually necessitates a faster worm drive than is used for broadcast coils. Litz wire with a large number of strands is useful in obtaining maximum Q .

For the 6 to 18 Mc/s band the solenoid is used, almost always with solid wire, and this type of coil remains useful at least up to 100 Mc/s. Increased wire diameters and spacings are used at higher frequencies to obtain form factors similar to those used at low frequencies.

SECTION 2 : SELF-CAPACITANCE OF COILS

(i) *Effects of self-capacitance* (ii) *Calculation of self-capacitance of single-layer solenoids* (iii) *Measurement of self-capacitance.*

(i) Effects of self-capacitance

The self-capacitance of a coil is due to the electrostatic coupling between individual turns and between the turns and earth. When the self-capacitance is between un-insulated turns in air its Q may be high, but the greater the amount of dielectric in the field of the coil the greater will be the losses.

Short wave coils of enamelled wire on a solid former do not have serious dielectric losses if good quality materials are used, but at broadcast and intermediate frequencies the universal windings used have comparatively high-loss dielectrics and unless self-capacitances are kept to a low value the reduction in Q may be appreciable.

In the case of coils which are to be tuned over a range of frequencies, comparatively small values of shunt capacitance can have a large effect on the possible tuning range.

In all cases the self capacitance of a coil has an apparent effect on its resistance, inductance and Q , and at frequencies considerably below the self resonant frequency of the coil—

$$\text{apparent inductance} = L \left(1 + \frac{C_0}{C} \right)$$

$$\text{apparent resistance} = R \left(1 + \frac{C_0}{C} \right)^2$$

$$\text{and apparent } Q = Q / \left(1 + \frac{C_0}{C} \right)$$

where C_0 = self-capacitance of coil

C = external capacitance required to tune L to resonance

L = true inductance of coil

R = true resistance of coil

and Q = true Q of coil.

(ii) Calculation of self-capacitance of single-layer solenoids

Until recently the work of Palermo (Ref. C3) had been taken as the standard on the self-capacitance of single-layer solenoids. However Medhurst (Ref. C2) has disputed the theoretical grounds on which Palermo's work is based. As the result of a careful analysis and a large number of measurements he states that the self-capacitance, C_0 , of single-layer solenoids with one end earthed, and without leads, is

$$C_0 = HD \text{ } \mu\mu\text{F} \quad (1)$$

where D = diameter of coil in cm.

and H depends only on the length/diameter ratio of the coil. A table of values of H is given below and when used in conjunction with a capacitance correction for the "live" lead, Medhurst states that the accuracy should be within 5%.

TABLE 1

$\left(\frac{\text{Length}}{\text{Diameter}}\right)$	H	$\left(\frac{\text{Length}}{\text{Diameter}}\right)$	H	$\left(\frac{\text{Length}}{\text{Diameter}}\right)$	H
50	5.8	5.0	0.81	0.70	0.47
40	4.6	4.5	0.77	0.60	0.48
30	3.4	4.0	0.72	0.50	0.50
25	2.9	3.5	0.67	0.45	0.52
20	2.36	3.0	0.61	0.40	0.54
15	1.86	2.5	0.56	0.35	0.57
10	1.32	2.0	0.50	0.30	0.60
9.0	1.22	1.5	0.47	0.25	0.64
8.0	1.12	1.0	0.46	0.20	0.70
7.0	1.01	0.90	0.46	0.15	0.79
6.0	0.92	0.80	0.46	0.10	0.96

Lead capacitance can be determined separately and added to the coil self-capacitance. Fig. 11.1 (from Medhurst) can be used for this purpose.

Fig. 11.1. Variation of capacitance with wire length for vertical copper wires of various gauges (Ref. D6).

It is interesting to compare Medhurst's formula with another by Forbes Simpson [Ref. G17 and Sect. 5(i) of this chapter]. Forbes Simpson's formula is applicable to coils with a length/diameter ratio of unity, a pitch of 1.5 times the wire diameter and with leads at each end equal in length to the diameter of the coil. His formula is

$$C_0 = D(0.47 + a) \mu\text{F} \quad (2)$$

where D = diameter of coil in cm.

and a = a constant depending on the gauge of wire, lying between 0.065 for 42 S.W.G. (38 A.W.G. approx.) and 0.11 for 12 S.W.G. (10 A.W.G. approx.) where one lead of the coil is connected to chassis.

In eqn. (2) there is no equivalent of the H in eqn. (1) because the length/diameter ratio is a constant. The length of "live" lead taken into account in eqn. (2) is equal to D , and it is possible to determine its effect from Fig. 11.1. For 12 S.W.G. wire the capacitance is 0.11 μF per cm. so that eqn. (1) (with lead correction) could be written

$$C_0 = 0.46D + 0.11D = 0.57D$$

for the conditions of eqn. (2) and using 12 S.W.G. wire. Similarly, using the value of a given for 12 S.W.G. wire in eqn. (2), eqn. (2) could be written

$$C_0 = 0.47D + 0.11D = 0.58D.$$

The data in Fig. 11.1 are not sufficient to compare the equations using the lower limit of a given by Forbes Simpson but for 20 S.W.G. eqn. (1) becomes

$$C_0 = 0.55D$$

for the conditions of eqn. (2), while eqn. (2) for 42 S.W.G. becomes

$$C_0 = 0.535D.$$

(iii) Measurement of self-capacitance

A graphical method of self-capacitance determination due to Howe is shown in Fig. 11.2. Values of external capacitance in $\mu\mu\text{F}$ required to tune a coil to resonance are plotted against $1/f^2$ where f is the resonant frequency in Mc/s. The self-capacitance is the negative intercept of the straight line with the capacitance axis.

An alternative method is to determine the external capacitances necessary to tune a coil to frequencies of f and $2f$. If the two capacitances are C_1 and C_2 respectively,

$$\text{self-capacitance} = \frac{C_1 - 4C_2}{3}.$$

Fig. 11.2. Construction for determination of self-capacitance of coil.

SECTION 3 : INTERMEDIATE-FREQUENCY WINDINGS

- (i) Air-cored coils (ii) Iron-cored coils (iii) Expanding selectivity i-f transformers
(iv) Calculation of gear ratios for universal coils (v) Miscellaneous considerations.

(i) Air-cored coils

Most commercial receivers have two i-f transformers with four circuits tuned to about 455 Kc/s. To obtain adequate selectivity in such a case the required Q for each winding (mounted on the chassis but not connected in the circuit) is 100 or more.

This Q can readily be obtained with air cored coils of about 1 mH inductance provided that litz wire and comparatively large coil cans are used. Without litz it is difficult to exceed a Q of 50, but even this may be sufficient when more i-f stages than usual are used.

When a single pie is used, Q is to some extent dependent on coil shape but if five times the winding depth plus three times the winding width equals the external diameter, Q will be close to the maximum for the wire and type of winding.

There are three methods of increasing the Q , and when all are used to practical commercial limits, production Q figures of 150 can be maintained. The first requirement is litz wire, probably nine strands for a Q of the order of 100, and twenty or more strands for a Q of 150. Large coil cans are necessary, up to two inches in diameter, with formers of such a size as to make the outside coil diameter little more than half the can diameter. Lastly, self-capacitance must be reduced to a minimum, because its Q is always low and in the case of a single pie winding it may amount to say 25 $\mu\mu\text{F}$, a large percentage of the total capacitance. Splitting the winding into pies reduces self-capacitance, at the same time improving the form factor, and a suitable compromise between Q and economy is obtained by winding with three pies. Self-capacitance is also reduced by winding narrow pies, although a limit is set by the difficulty of winding litz wires with a cam of less than 0.1 inch, or perhaps even $\frac{1}{8}$ inch. In addition, as the cam is reduced the height of the coil increases and larger losses from damping of the coil by the can may more than offset the reduced losses in a smaller self-capacitance.

When the windings have more than one pie, the inductance is dependent on pie spacing. For this reason, and to increase the speed of winding, multi-section coils are wound with the former located by a gate, a different slot in the gate being used for each individual pie. Spacing between primary and secondary windings is kept constant by means of a double winding finger which winds primary and secondary at the same time.

A disadvantage of air cored i-f coils is that a trimmer capacitance is needed to resonate the tuned circuit. The cheapest types of trimmers usually have poor stability with respect to time, vibration, humidity and temperature, and satisfactory types may cost more than a variable iron core with provision for adjusting it.

(ii) Iron-cored coils

The advantages of iron cores used in i-f transformer windings are that

- (a) they increase the inductance of the winding, thereby giving a saving in wire cost and winding time for a given inductance,
- (b) they increase the Q of the winding, thereby allowing cheaper litz (or solid wire in an extreme case) to be used,
- (c) they restrict the field of each winding, to an extent depending on the type of core used, and thus allow a smaller, cheaper coil can to be used without excessive damping,
- (d) they provide a satisfactory method of adjusting the tuned circuit to resonance. Because of this the total tuning capacitance can be of a stable high Q type (e.g. a silvered-mica capacitor), and there is no trouble from capacitance between primary and secondary trimmers giving an asymmetrical resonance curve, or from capacitance between say first i-f and second i-f trimmers leading to regeneration.

To obtain the greatest benefit from an iron core it is necessary to have all of the turns close to the core. In particular cases, especially at high frequencies, Q may be decreased due to increased distributed capacitance if the coil is too close (e.g. wound on the core) but in normal i-f applications in which a former comes between coil and core the thinner the former can be made, the better will be the Q .

Also because of this effect it sometimes happens that by winding a coil with thinner litz (fewer strands), and so bringing the top turns closer to the iron and further from the can, an increase in Q is obtained.

Another benefit from bringing all of the turns as close to the iron core as possible is that the range of inductance adjustment provided by the core is increased. If fixed capacitors with $\pm 10\%$ tolerance are used to tune the i-f windings, it is necessary to provide at least $\pm 15\%$ inductance adjustment from the iron core to allow for winding variations and changes in stray capacitances due to valves and wiring. It is necessary to split the i-f winding into pies to obtain a variation of this order with normal cheap i-f cores.

An additional advantage of splitting the winding is that at least half of the turns in the coil are brought much closer to the core so that Q is increased above the amount to be expected from the reduction in distributed capacitance.

To obtain the previously mentioned Q of 100 at an inductance of about 1 millihenry with a small iron core, a coil can somewhat larger than one inch diameter would probably be needed with a coil wound in three pies of 5 strand 41 A.W.G. litz.

Much higher Q 's are obtainable with special core shapes and materials, and a 455 Kc/s i-f transformer with a Q of 260 in the can is mentioned in Ref. A15. However difficulty is usually experienced from instability even with valves of comparatively low slope, such as the 6SK7-GT, if i-f transformers with a Q above about 150 are used.

A possibility of increasing Q with iron-cored coils which does not usually arise with air-cored coils is that if the coil is wound directly on to a non-adjustable iron core or on to a small individual former, it can be mounted in different planes inside the coil can. By mounting the coil with its axis at right angles to the axis of the can it is possible to obtain an increase in Q of the order of 10% (depending on the diameters of coil and can) and this method also has the advantage of making both cores adjustable from above the chassis. The chief disadvantage is that coupling between primary and secondary takes place mainly between adjacent edges of the two windings and variations in the height of the windings, due to variations in wire thickness, noticeably affect the coupling. In addition, trouble may be experienced from regeneration because with this method of mounting the field of the bottom winding extends further

outside the coil can. Unless a good joint is made between can and chassis this trouble will be further aggravated.

(iii) Expanding selectivity i-f transformers

The simplest method of expanding i-f transformer response to give peaks symmetrically spaced about the intermediate frequency is by switching a tertiary winding. Two other possibilities* of obtaining the desired result are the simultaneous switching of series and shunt coupling capacitors between the two windings, and the switching of capacitors to alter the coupling in a Π or T network (Ref. G13). In each of these cases, however, it is necessary to switch components in high potential sections of the circuit whereas tertiary switching can be carried out in low potential circuits.

FIG. 11.3

Fig. 11.3. Expanding selectivity with switched tertiary coil.

former increases, it is possible with tertiary switching to maintain satisfactory symmetry in production with a Q of 150 and with simple alignment procedures. In a normal receiver with a single i-f amplifier it is only necessary to expand the selectivity of the first i-f transformer because the diode damping on the secondary (and perhaps primary) of the second i-f reduces its selectivity considerably.

Fig. 11.3 gives a typical circuit. It will be seen that the inductance of the tertiary winding is switched into the tuned circuit in the expanded position. This does not lead to appreciable detuning because the inductance of the secondary is some thousands of times larger than that of the tertiary.

Suitable methods of winding the tertiary coil vary with the method of primary winding but the object is always to obtain maximum coupling with minimum tertiary inductance. When the primary is pie-wound the tertiary should be wound between two pies as close to the middle of the coil as possible. From three to five tertiary turns are required (assuming approximately critical coupling without the tertiary and three hundred or more primary turns in a 455 Kc/s i-f transformer). The type of wire is not important except for its covering, and solid wire of the finest gauge which will give no trouble with handling or cleaning is probably most suitable.

It is essential that the insulation resistance between primary and tertiary be very high. In a typical case a leakage of 100 megohms between primary and tertiary would give the control grid of the following i-f amplifier a positive voltage of five volts. Because of this the tertiary winding should be double-covered wire and the completed coil must be thoroughly dried out and then immediately impregnated in some moisture resisting compound.

If the primary consists of a single winding the tertiary is best wound in solenoid form on top of it. Similar results are obtainable for the same number of coupling turns.

To align such a transformer the switch should be turned to the "narrow" position and the receiver aligned normally for maximum gain. When the switch is turned to "broad" the output should drop, but when the signal generator is detuned, equal peaks should be found symmetrically spaced about the intermediate frequency.

*See also Chapter 9 Sect. 8; Chapter 26 Sect. 5.

Receivers have been manufactured in which movement of a complete winding altered the coupling, and whilst this eliminates switching problems, the additional mechanical problems are at least as troublesome. Moreover it is difficult to keep constant the damping effect of the coil can and the mechanical coupling of the moving coil so that the whole object of the variable coupling (i.e. symmetrical expansion of the pass-band) is liable to be lost.

Although symmetrical expansion becomes more difficult as the Q of the trans-

If the peaks are not symmetrical, undesired couplings are probably responsible. All traces of regeneration must be removed and, because the stability requirements are more severe than usual, unusual effects are liable to be uncovered. For example, regeneration may occur due to coupling between a loop formed by the generator input leads and the output of the i-f amplifier (twisting generator leads will cure this) or coupling may occur between first and second i-f transformers within the steel chassis. When this happens, rotating one or both transformers will probably give cancellation but leave production receivers susceptible to the trouble. Additional spacing between transformers is advisable with each primary and secondary wired for minimum regenerative coupling.

The switch used for the tertiary winding should preferably be of the "break before make" variety. A "make before break" switch momentarily short circuits the tertiary winding during switching, giving a sudden reduction and increase in sensitivity which can be heard as a click.

Even after a satisfactory i-f selectivity curve has been obtained, the over-all curve may be too narrow if a r-f stage is used in the receiver. In such cases the r-f stage should also be expanded [Chapter 35 Sect. 5(iii)].

FIG. 11.4

Fig. 11.4. Type of finger recommended for universal winding.

(iv) Calculation of gear ratios for universal coils

To obtain electrical consistency between universal coils in production runs it is essential to wind the coils with good mechanical stability. For this, machines must be adjusted correctly, but a suitable gear ratio is of equal importance.

The method of gear ratio calculation given below has been used successfully for production coils, and gives a straight pattern on the side of each coil.

The instructions make provision for a spacing between centres of adjacent wires of $8/7$ of the wire diameter. This diameter should be measured, and the required spacing depends on the type of winding finger used. The most satisfactory types, and the ones for which the spacing factor will be found suitable, are those in which the wire passes to the bottom side of the finger before being placed in position on the coil. Fig. 11.4 shows such a finger, and it will be seen that the tension on the wire pulls the finger down to the face of the coil.

Fingers in which the wire passes through a groove on the top and then takes up its own position on the surface of the coil may require more spacing than that specified. Other factors may also affect the spacing required, but a small amount of experiment will decide this. It will be noticed that some types of litz wire tend to spread when wound, and so need more spacing than would be expected from measurement.

Symbols

- d = former diameter (inches)
 c = cam throw (inches)
 n = nominal number of crossovers per turn (see Table 1)
 q = number of crossovers per winding cycle, i.e. before wire lies alongside preceding wire (see Table 1).
 v = nominal number of turns per winding cycle (see Table 1)
 R = gear ratio = former gear/cam gear
 w = modified wire diameter (inches)—see Note below
 $P = qc/(w + x)$ = an integer
 x = smallest amount necessary to make $(P + 1)/v$ an integer (inches).

Note. For fabric covered wire, w = (measured diameter of covered wire) $\times 8/7$. If the wire is enamelled only, the same formula is used but the bare wire diameter is multiplied by $8/7$.

Procedure

(A) From $n \div (2d/3c)$ determine the largest convenient value for n . Do not use values of n less than 2 for bare enamelled wire. Obtain values of q and v from Table 1 below for the value of n chosen.

TABLE 1

n	4	2	1	$2/3$	$\frac{1}{2}$	$1/3$	$\frac{1}{4}$
q	4	2	2	2	2	2	2
v	1	1	2	3	4	6	8

(B) Determine w from information given in the note above.

(C) Calculate P from $P = qc/(w + x)$.

(D) Obtain R from $R = \frac{1}{2}n(P + 1)/P$.

Example 1

Given $d = \frac{1}{2}$ in. and $c = 0.1$ in. determine the gears to wind a coil with 42 S.W.G. enamelled wire.

(A) $(2d/3c) = 1.0/0.3$. Take $n = 2$, giving $q = 2$ and $v = 1$ from the table.

(B) The diameter of bare 42 S.W.G. wire is 0.004 in., so $w = 0.00457$ in.

(C) $P = qc/(w + x)$ and $(P + 1)/v$ must be an integer, i.e. P must be an integer since $v = 1$.

$$qc/w = 200/4.57 = 43.7.$$

But $P = qc/(w + x)$ = an integer.

Therefore $P = 43$.

(D) $R = \frac{1}{2}n(P + 1)/P = \frac{1}{2} \times 2(43 + 1)/43 = 44/43$.

Example 2

Given $d = \frac{1}{4}$ in. and $c = \frac{1}{4}$ in. determine the gears to wind a coil with 0.016 in. litz wire.

(A) $2d/3c = 2/3$. Take $n = 2/3$, giving $q = 2$ and $v = 3$.

(B) $w = 0.016$ in. $\times 8/7 = 0.0183$ in.

(C) $qc/w = 500/18.3 = 27.3$.

But $(P + 1)/v$ = an integer.

Therefore $P = 26$.

(D) $R = \frac{1}{2}n(P + 1)/P = 1/3 \times 27/26$.

To obtain suitable gears:—

$$R = 2/3 \times \frac{1}{2} \times 27/26 = (28/42) \times (27/52).$$

When it is known that n will be 2, as is the case with the majority of coils, the method reduces to dividing the modified wire diameter into twice the cam throw (ignoring any fractions in the answer). This gives P and the required ratio is $(P + 1)/P$.

For further information on universal coil winding see Refs. 1 to 18.

(v) Miscellaneous considerations

(A) Direction of windings

Although the coupling between primary and secondary is assumed to be due to mutual inductance, the capacitive coupling is appreciable. Depending upon the direction of connection of the windings, the capacitive coupling can aid or oppose the inductive coupling. When the two types are in opposition and of the same order a slight change in one—the capacitive coupling is particularly liable to random variation—gives a much larger percentage variation in the effective coupling. In a bad case, production sensitivity variations from this cause may be quite uncontrollable.

To avoid the trouble, i-f transformers are usually connected for aiding capacitive and inductive coupling. This is done by connecting the i-f amplifier plate to the beginning of one winding and the following grid to the end of the other winding when the two coils are wound in the same direction. Other connections to give the same winding sense will give the same result.

Even with aiding couplings it is desirable to reduce capacitive coupling to a minimum to obtain a symmetrical response curve and care should be taken in the placing of tuning capacitors and with details such as keeping the grid wire of the secondary winding well away from the plate wire or the plate side of the primary winding.

(B) Amount of coupling

An undesirable feature, from a production point of view, of i-f transformers in which the coupling is less than critical, is that receiver sensitivity becomes more dependent on i-f coil spacing. For a transformer with approximately critical coupling a spacing difference of 1/32 inch makes no appreciable difference to sensitivity in a typical case. However if the transformer were under-coupled the sensitivity change would be noticeable.

Transformers which are slightly over-coupled can be aligned for symmetrical response curves without undue trouble by detuning each winding (say with an additional capacitor of the same size as the tuning capacitor) while the other winding of the transformer is aligned for maximum sensitivity. Symmetry is of course dependent on the absence of regeneration.

(C) Losses

Unless care is taken, the sum of a number of apparently negligible losses may result in appreciable reduction in Q . Many artificial coverings have greater losses than silk, but this is usually obvious when a sample coil is wound. Less obvious losses may occur in details such as the material used to seal the end of a winding or in the placing of shunt capacitors or even coil lugs close to the actual i-f winding. An assembly of straight parallel wires between top and bottom of the i-f can may cause appreciable decrease in Q , particularly if large blobs of solder are placed close to the windings.

To eliminate such losses it is advisable to check the Q of a winding, sealed with low-loss material and baked to remove all moisture, when suspended well away from any substances which will introduce losses. The mechanical structure of the complete i-f assembly can then be added, one section at a time, and the Q read at each stage, a final reading being taken when the coil is mounted in the receiver.

(D) F-M i-f transformers

For details of F-M i-f construction and other i-f information of practical interest see Chapter 26 Sect. 4(vi).

(E) Other ferromagnetic materials

The development of a non-metallic ferromagnetic material named **Ferroxcube** has been announced by Philips (Refs. A28, A29, A30, A31, A32, A33).

Several grades of Ferroxcube are manufactured. They have in common a high specific resistance of 10^3 to 10^8 ohm cm. and a high initial permeability of from 50 to 3000 depending on the type. Ferroxcube IV, which is useful to 40 Mc/s, has a permeability of 50, and Ferroxcube III with an upper frequency limit of about 0.5 Mc/s has a minimum permeability of 800.

Because of the closeness of the Curie point to room temperature (the Curie point of Ferroxcube III is 110° — 160°C) some change of permeability occurs with changing temperature. For instance the permeability of Ferroxcube III can be almost halved by an increase in temperature from 20°C to 80°C . However, the permeability of Ferroxcube V is decreased less than 10% by a similar temperature change under the same conditions. Between 10° and 40°C the change in permeability averages 0.15% per 1°C for the various types of Ferroxcube.

In cases in which the magnetic circuit is normally completely enclosed, the high permeability of Ferroxcube can be used to minimize losses by means of an air gap. If the gap is such as to reduce the effective permeability to one tenth of its original value (which could still be high), losses and the effect of heat on effective permeability will also be reduced in the same proportion.

The properties of Ferroxcube allow considerable reductions to be made in the size of such items as i-f transformers or carrier-frequency filters, and it is an excellent material for magnetic screens or for permeability tuning. However its saturation point is rather low and it is not used for power transformer or output transformer cores.

Ref. A27 describes research on **ferromagnetic spinels** by the Radio Corporation of America. These spinels are ceramic-like ferromagnetic materials characterized by high permeability (up to greater than 1200), high electric resistivity (up to 10^8 ohm cm), and low losses at radio frequencies. Wide ranges in these and other properties are obtainable by varying the component ingredients and methods of synthesis.

Ferrosinels are being used increasingly in electronic equipment operating in the frequency range of 10 to 5000 Kc/s. At power and low audio frequencies the ferrosinels are not competitive with laminated ferromagnetic materials, and at very high frequencies the losses in ferrosinels are excessive when high permeability is required. It is possible however to produce a ferrosinell, with low permeability, useful at frequencies in the order of 100 Mc/s. The application of ferrosinels as core bodies in the deflection yoke, horizontal deflection transformer and high voltage transformer for television receivers is now finding wide acceptance. The ferrosinels are especially suited to television video frequencies as their use in these components results in improved performance at lower cost and with smaller space.

In the standard broadcast receiver, the ferrosinels are expected to be used in the radio frequency circuits as "trimmers" and as permeability tuning cores. With a properly designed coil it is possible to tune a circuit, by the movement of a ferrosinell rod, from 500 to 3000 Kc/s, or to cover the standard American broadcast band (540 to 1730 Kc/s) with only three eighths of an inch movement of the rod.

By using a ferrosinell with a high electric resistivity as the core body for radio frequency inductances, the wire body may be placed on the ferrosinell without additional insulation. In fact, the conductor may be affixed by the printed circuit technique for some applications.

SECTION 4: MEDIUM WAVE-BAND COILS

(i) *Air-cored coils* (ii) *Iron-cored coils* (iii) *Permeability tuning* (iv) *Matching*.

(i) Air-cored coils

With large diameter formers reasonable Q can be obtained on the broadcast band with air-cored solenoids. However in limited spaces, coils are wound with two or more pies or by progressive universal winding when high Q is required. The progressive winding has the advantage of being less susceptible to inductance variation through careless handling or winding, and from the production point of view it is desirable because it can be wound without stopping.

Although high Q is not necessary for broadcast band oscillator coils, it is desirable. Low Q tuned circuits need larger reaction windings which in turn give increased

phase shift in the voltage fed back from the plate into the grid circuit. Consequently an even larger reaction winding is required and the result may be reactance reflected into the secondary circuit which makes it impossible to tune the required range—if the police band (U.S.A.) is to be included. In any case the reflected reactance, which is a variable throughout the tuning range, complicates the tracking problem.

A method of decreasing the coupling inductance required, which is applicable to progressive but not to ordinary universal windings, is to thread both secondary and primary wires together through the winding finger, wind the required number of primary turns, terminate the primary and proceed with the secondary winding until completed. This method is possible with progressive windings because of the gaps which occur throughout the winding, whereas with a normal universal winding there is no room for a primary between turns of the secondary.

For r-f and particularly for aerial coils the need for high Q is greater. The sensitivity, signal-to-noise ratio and image ratio of a receiver are all governed by the aerial coil Q .

Since the amount of wire used in an aerial coil secondary is so much less than in the i-f transformers it is often possible to use more expensive litz.

Probably the most satisfactory method of coupling the aerial to the grid of the first valve (or the plate of the first valve to the grid of the second) is by means of a high impedance primary. This can take the form of a universal winding of the finest wire the machines will conveniently handle, wound at an appropriate distance from the secondary to give about 20% coupling (depending on the Q of the secondary, the amount of mistracking that can be tolerated, and the types of aerial expected to be used). In the case of progressive universal secondaries it sometimes happens that the primary must be wound as closely as possible to the secondary to obtain the required degree of coupling.

The primary should be resonated by its own self-capacitance, or by an additional capacitor, below the intermediate frequency so that no normal aerial can tune the primary to the intermediate frequency and so cause instability. A typical value of primary inductance is 1 mH and a 150 μF capacitor would be suitable for use with it.

To increase the aerial coil gain at the high frequency end of the broadcast band a capacitor of the order of 4 μF might be used between aerial and grid of the first valve. Since the capacitor decreases image ratio at the same time as it increases sensitivity and signal-to-noise ratio, some requirement other than flat sensitivity across the broadcast band might be desirable.

Similar considerations apply to the coupling of the r-f valve except that primary inductances are usually larger (say 4 mH) and their tuning capacitors may be increased in size until the gain is reduced to the required figure.

The direction of connection for high impedance coils and oscillator coils is the same as that already detailed for i-f transformers; the grid is connected to the end of the secondary further from the primary, to reduce capacitance coupling, and then, considering the secondary and primary to be one tapped coil wound in the one direction, the aerial (or plate) is connected to the other extreme of the winding.

(ii) Iron-cored coils

The use of suitable iron cores greatly simplifies the problem of obtaining high Q windings. In fact, for any reasonable Q requirement it is only a matter of obtaining a suitable core.

Whilst for a given Q and coil size a coil wound on an iron slug will be less affected by its surroundings than an air-cored coil, owing to the concentration of the flux in the core, high Q secondaries (e.g. 250) will be found to require very careful placement if serious Q losses are to be avoided, particularly at the high frequency end of the broadcast band. Even an open circuited primary at the appropriate distance for correct coupling may noticeably decrease the Q .

The primary should be wound on the opposite side of the secondary from the iron core, which will not pass completely through the secondary because of the necessity for leaving room for adjustment. Under these conditions movement of the core to

compensate for differences between individual receivers will not seriously affect the coupling between primary and secondary.

To avoid losses due to adjacent components with high Q coils, iron cores can be used which completely enclose the winding. These cores give higher Q 's than the more usual slugs with a similar winding and reduce the external field of the coil to such an extent that in extreme cases it may be difficult to obtain sufficient coupling between the secondary and an external high impedance winding.

An advantage of using an iron core in the oscillator coil is that, apart from giving increased Q , it can greatly increase the coupling between primary and secondary, thereby decreasing the primary reactance for a given amount of coupling.

(iii) Permeability tuning

The increasing use of permeability tuning is an indication of the extent to which the design and production difficulties associated with this type of tuning are being overcome.

Fig. 11.5. Aerial coupling circuits used with permeability tuning.

No gang condenser is needed, so that even with the added complication in the coil assembly a cheap broadcast band tuning unit is possible. Gang microphony is automatically eliminated, and a value of tuning capacitor can be chosen which will make the effects of, for instance, capacitance variations due to valve replacement negligible over the whole tuning range. This capacitor can be a low-loss type and it may be given a suitable temperature coefficient if desired. The space saving owing to the elimination of the tuning capacitor is appreciable, even taking into account the additional space required for the iron cores and their driving mechanism.

By a suitable choice of coil and core constants the oscillator grid current can be maintained at or very close to the desired figure at all points in the broadcast band. Aerial coil gain can also be kept constant.

One of the most serious troubles in the design of a permeability tuning unit is in obtaining satisfactory coupling between the aerial and the permeability-tuned aerial coil. If a normal primary is used the coupling variations with changing core position, as the coil is tuned over the broadcast band, are excessive. Similarly a tapped inductor can not be used because the core alters the coupling between the two sections of the winding too much. Fig. 11.5A, B and C show three methods which have been used.

The circuit of Fig. 11.5A couples the aerial straight into the tuned circuit and gives good aerial coil gain when correctly aligned. However image rejection is poor and the detuning effect when different aerials are connected to the receiver is considerable.

Improved image rejection is obtained from the circuit of Fig. 11.5B but sensitivity is lost because much of the voltage developed across the tuned circuit is not applied between grid and cathode of the valve.

Fig. 11.5C gives a more satisfactory solution (Ref. A24). There is no inductive coupling between primary and permeability tuned secondary and the coupling between primary and coupling coil is unaffected by the core position. A constant gain of about three times over the band can be obtained from a coil with average effective Q of 100, with satisfactory image ratios across the band and reasonable freedom from detuning effects with different aerials.

The maintenance of correct calibrations in production receivers is a problem which concerns the designer of the iron dust core, but cores have been produced with permeability consistent enough for station names for the whole broadcast band to be marked on the dial and used.

Iron cores are available with sufficient variation in permeability for the complete broadcast band to be tuned. However if the police band is required and space for mounting the tuning unit is restricted (resulting in appreciable damping on the coil) the permeability requirements for the core are severe.

The Colpitts oscillator circuit is suitable for use in permeability tuning units, and padding can be obtained by using a suitably shaped core for the oscillator coil. Alternatively the oscillator coil can be wound in two series-connected sections, one with fixed inductance (or pre-tuned for alignment purposes) and the other with inductance varied by the moving core. Many receivers have been built with complete tracking i.e. a series inductor corresponding to the usual (parallel) trimmer, and a parallel inductor corresponding to the usual (series) paddler.

The rate of change of inductance with core movement does not give a linear relationship between tuning control and the frequency tuned unless special precautions are taken. Linearity, if required, can be obtained in two ways. The drive between tuning spindle and cores can include some type of worm or cam arranged to vary the speed of the drive in suitable parts of the tuning range, or the coils themselves can be progressive universal windings to give the same effect. Progressive universal coils lend themselves very well to this form of winding because the progression is provided by a screw thread and this can be cut with the pitch varied over the length of the winding to give the required tuning rate.

An important drawback to permeability tuning is the difficulty involved in providing coverage of a number of wavebands without complications which outweigh the saving of a tuning condenser.

One simple method of adding short wave ranges to a broadcast band permeability tuner is to connect the broadcast coil in parallel with a short wave coil which is to be tuned. This gives satisfactory tuning but restricted bands. It is suitable for a band-spreading circuit but when every international short wave broadcasting band is to be covered, a large number of ranges is required. By designing a special short wave permeability tuner it is possible to cover the 6 to 18 Mc/s band in two ranges (Ref. A24).

For more restricted ranges such as the F-M broadcasting band, permeability tuning is satisfactory provided that a suitable type of iron is available. Cores have been made which can be used in tuned circuits at 150 Mc/s without introducing undue loss.

References A11, A16, A20, A22, A23, A24, A34.

(iv) Matching

Methods of coil matching depend on the type of coil and to a certain extent upon the subsequent alignment procedure.

Air-cored solenoids can be wound with a spacing towards the end of the winding equivalent to one turn. The inductance is then increased by sliding turns across the gap from the small end section to the main body of the coil, or decreased by sliding turns in the opposite direction.

Air-cored pie-wound coils can be matched by pushing pies together to increase inductance, but the method has disadvantages. Firstly, the coils are liable to be damaged, even to the extent of collapsing completely, and secondly coils which are rigid enough to withstand the pushing without damage may have enough elasticity to return towards their original positions over a period of time, thus destroying the matching. If coils matched in this way are to be impregnated it is necessary to re-check (and readjust in many cases) after impregnation, and recheck again after flash dipping, if a reasonable degree of matching accuracy is to be maintained.

Another method which has been used with air-cored coils is to wind each coil with slightly too much inductance, bake, impregnate and flash-dip the coil and then seal it in an aluminium can. A groove is then run in the can above the appropriate coil and the depth of the groove is increased until the inductance of the coil inside the

can is reduced to that of a standard. All production inductance variations can be absorbed in the matching process with insignificant Q loss.

When iron cores are used, matching problems are much simplified. Even when the core is not threaded it can be pushed through a winding for inductance adjustment. With threaded cores the adjustment is so simple that in many cases the coils are not matched. Given correct calibrations and close tolerance padders in a complete receiver, the oscillator coil trimming and padding can be adjusted to suit the calibration and the aerial coil trimming and padding to suit the oscillator with results which may even be (from the user's point of view) superior to those obtained from more complicated matching and alignment methods.

When matching individual windings on formers containing two or more coils it is possible for errors to occur due to variations in windings other than the one being matched. For example an aerial coil secondary may be matched to the same inductance as a standard secondary but may be coupled to a primary with an inductance different from that used on the standard coil. Under operating conditions in a receiver the two effective secondary inductances would be different.

This difficulty can be overcome by suitable connection of associated coils during matching. Normally the best procedure is to short-circuit and earth coils which are not being matched, but on occasion it may be better to earth the cold end only.

SECTION 5 : SHORT-WAVE COILS

(i) *Design* (ii) *Miscellaneous features.*

(i) Design*

Much has been written on the subject of designing coils suitable for use on short waves. A number of references will be found at the end of this chapter. The work by Pollack, Harris and Siemens, and Barden and Grimes is very complete from the practical design viewpoint. The papers by Butterworth, Palermo and Grover, and Terman are basically theoretical. Austin has provided an excellent summary and practical interpretation of Butterworth's four papers. Medhurst's paper gives the results of measurements which in some cases disagree with Butterworth's theoretical values. For coils whose turns are widely spaced the measurements of high-frequency resistance are in good agreement but for closely-spaced coils the measured values are very considerably below those of Butterworth. Theoretical reasons are given for these differences.

(A) Pollack (Ref. G4) summarizes the procedure for the optimum design of coils for frequencies from 4 to 25 Mc/s as follows :—

1. Coil diameter and length of winding : Make as large as is consistent with the shield being used. The shield diameter should be twice the coil diameter, and the ends of the coil should not come within one diameter of the ends of the shield.

2. A bakelite coil form with a shallow groove for the wire, and enamelled wire may be used with little loss in Q . The groove should not be any deeper than is necessary to give the requisite rigidity. The use of special coil form constructions and special materials does not appear to be justified (except for the reduction of frequency drift due to temperature changes).

3. Number of turns : Calculate from

$$N = \sqrt{L(102S + 45)}/D$$

where S = ratio of length to diameter of coil,

D = diameter of coil in centimetres,

and L = inductance in microhenrys.

4. Wire size : Calculate from

$$d_0 = b/N\sqrt{2} = \text{optimum diameter in centimetres.}$$

where b = winding length in centimetres.

*This is a revision and expansion of the chapter on this subject in the previous edition by L. G. Dobbie.

That is, the optimum wire diameter is $1/\sqrt{2}$ times the winding pitch, measured from centre to centre of adjacent turns.

(B) **Barden and Grimes** (Ref. G16) recommend for coils working near 15 Mc/s. that No. 14 or No. 16 A.W.G. enamelled wire on a form not less than one inch diameter at a winding pitch equal to twice the wire diameter is desirable. The screen diameter should be not less than twice the coil diameter. A comparison of coils of equal inductance on 0.5 in. and 1 in. forms in screens double the coil diameter indicates that the value of Q is twice as great for the larger diameter coil. No. 24 A.W.G. wire was used for the small diameter coil.

(C) **Harris and Siemens** (Ref. G21) quote the following conclusions :—

(1) Q increases with coil diameter.

(2) Q increases with coil length, rapidly when the ratio of length to diameter is small, and very slowly when the length is equal to or greater than the diameter.

(3) Optimum ratio of wire diameter to pitch is approximately 0.6 for any coil shape. Variation of Q with wire diameter is small in the vicinity of the optimum ratio ; hence, selection of the nearest standard gauge is satisfactory for practical purposes.

(D) **The shape of a coil necessary for minimum copper loss** (from Butterworth's paper) is stated by **Austin** (Ref. D7) as follows :—

(1) Single layer solenoids : Winding length equal to one-third of the diameter.

(2) Single layer discs (pancake) : Winding depth equal to one-quarter of the external diameter.

(E) Butterworth's paper (Ref. D1) deals with the copper loss resistance only, and insulation losses must be taken into account separately. **Insulation losses** are minimized by winding coils on low loss forms, using a form or shape factor which provides the smallest possible self-capacitance with the lowest losses. Thus air is the best separating medium for the individual turns, and the form should provide only the very minimum of mechanical support. Multilayer windings in one pie have high self-capacitance due to proximity of the high and low potential ends of the winding. The same inductance obtained by several pies close together in series greatly reduces the self-capacitance and associated insulation losses. Heavy coatings of poor quality wax of high dielectric constant may introduce considerable losses.

(F) In the section of **Medhurst's paper** (Ref. D6) dealing with h.f. resistance he states that so long as the wire diameter is less than one half of the distance between wire centres, Butterworth's values are applicable. An increasing error occurs as the ratio of wire diameter to distance between centres increases, the values being 190% too high when the ratio is 0.9.

A graph is presented giving variation in optimum wire spacing with variation in the ratio of coil length to coil diameter (Fig. 11.6A).

It is shown that a good approximation to the high frequency Q of coils of the type measured is given by the simple expression

$$Q = 0.15R\psi\sqrt{f}$$

where R = mean radius of coil (cm),

f = frequency (c/s)

and ψ depends on the length/diameter and spacing ratios.

A comprehensive table of ψ values is presented.

(G) **M. V. Callender** (Ref. D9) points out that Medhurst's formula for Q can be approximated within a few per cent by the equation

$$Q = \sqrt{f}/(6.9/R + 5.4/l)$$

where R = radius of coil (cm)

and l = length of coil (cm).

An even simpler expression

$$Q = 0.15\sqrt{f}/(1/R + 1/l)$$

follows the data to a few per cent provided $l > R$.

The range of conditions under which this formula applies is the same as that to which Medhurst's data refer : in particular—

(a) The ratio of wire diameter to wire spacing must approximate to the optimum shown in Fig. 11.6A.

(b) The formulae apply only for very high frequencies because of skin effect considerations. However the following table, giving the thinnest wire for which the formula applies within $\pm 10\%$, shows that most practical solenoids will be covered—

f (Mc/s)	1.0	4.0	16
wire	22 S.W.G.	28 S.W.G.	37 S.W.G.

(c) The formulae do not hold for coils of very few turns (or extremely short coils).

(d) Dielectric loss is not allowed for. This is unlikely to be serious except where the coil has a rather poor dielectric (bakelite or worse) and is used in a circuit having a low parallel tuning capacitance.

Fig. 11.6A. Variation of optimum spacing ratio with length/diameter (Ref. D6).

(H) Meyerson (Refs. G3 and G11) gives the results of measurements on a large number of coils tuned over a range between 25 and 60 Mc/s. The following information is obtained from his work:—

(a) Q at any frequency within the band, and the frequency for maximum Q , both increase with an increase in wire size for a given coil diameter. 10 A.W.G. wire (the largest used) was nearly 10% better over the range than 12 A.W.G. wire on a one inch diameter former.

(b) Maximum Q increases, and the frequency for maximum Q decreases, with an increase in coil diameter for a given wire size, number of turns and number of turns per inch.

(c) The coil diameter required for highest Q throughout the tuning range decreases with increasing frequency for a given wire size, number of turns and number of turns per inch.

(d) Maximum Q is obtained with a spacing between adjacent wires which is slightly greater than the bare wire diameter.

(e) No variation in Q was detected between coils wound with bare wire, enamelled wire or silver plated wire.

On the other hand, cotton covering decreased Q by as much as 5% at 50 Mc/s and annealing of the copper wire increased Q by less than one per cent.

(I) In Refs. G10 and G12 Meyerson gives details of work with frequency ranges between 60 and 120 Mc/s on the Q and frequency stability of inductors made of wire, tubing and strip in various shapes e.g. disc, hairpin, folded lines, etc.

(J) Other points taken from various references are given below. **Dielectric losses** present in the self capacitance of the coil are reduced by altering the shape to separate the high potential end from all low potential parts of the circuit. These losses become relatively more important the higher the frequency. Thus, the shape of a solenoid for minimum total losses may need to be increased beyond what would otherwise be the optimum length.

The high frequency alternating field of a coil produces **eddy currents** in the metal of the wire, which are superimposed upon the desired flow of current. The first effect is for the current to concentrate at the outside surface of the conductor, leaving the interior relatively idle. In a coil where there are numbers of adjacent turns carrying current, each has a further influence upon its neighbour.

In turns near the centre of a solenoid the current concentrates on the surface of each turn where it is in contact with the form, i.e. at the minimum diameter. In turns at either end of a solenoid the maximum current density occurs near the minimum diameter of the conductor, but is displaced away from the centre of the coil.

Thus most of the conductor is going to waste. Multi-strand or litz (litzendraht) wires have been developed to meet this difficulty. Several strands (5, 7, 9, 15 being common) are woven together, each being of small cross section and completely insulated by enamel and silk covering from its neighbours. Owing to the weaving of the strands, each wire carries a nearly similar share of the total current, which is now forced to flow through a larger effective cross section of copper. The former tendency towards concentration at one side of a solid conductor is decreased and the copper losses are correspondingly reduced.

Litz wire is most effective at frequencies between 0.3 and 3 Mc/s. Outside of this range comparable results are usually possible with round wire of solid section, because at low frequencies "skin effect" steadily disappears while at high frequencies it is large even in the fine strands forming the litz wire, and is augmented by the use of strands having increased diameter.

Screens placed around coils of all types at radio frequencies should be of non-magnetic good-conducting material to introduce the least losses. In other words, the Q of the screen considered as a single turn coil should be as high as possible. In addition, the coupling to the coil inside it should be low to minimize the screen losses reflected into the tuned circuit. For this reason the screen diameter should, if possible, be at least double the outside diameter of the coil. A ratio smaller than 1.6 to 1 causes a large increase in losses due to the presence of the screen.

The design of coils for use with iron core materials depends mainly upon the type of core material and the shape of the magnetic circuit proposed. Nearly closed core systems are sometimes used with high permeability low loss material. More commonly, however, the core is in the form of a small cylindrical plug which may be moved by screw action along the axis of the coil and fills the space within the inside diameter of the form. The main function of the core in the latter case may be only to provide a means of tuning the circuit rather than of improving its Q . When improvement in Q is possible with a suitable material, the maximum benefit is obtained by ensuring that the largest possible percentage of the total magnetic flux links with the core over as much of its path as possible; the ultimate limit in this direction is of course the closed core.

An excellent series of charts for the design of single-layer solenoids for a required inductance and Q is presented by A. I. Forbes Simpson in Ref. G17. These charts and the instructions for their use are reprinted by permission of "Electronic Engineering" and the author (Figs. 11.7 to 11.13 inclusive).

The use of the charts is simple and gives direct answers. As so many unascertainable factors govern the final inductance of a coil in position, no attempt has been made to achieve an accuracy better than 1 per cent. The inductances indicated by the charts assume that the leads to the coil are of the same wire as the coil and perpendicular to it, and are each a coil diameter long.

Coils of this form have a low self-capacitance which is largely independent of all save the coil diameter and to a lesser extent the wire gauge.

The capacitance may be expressed as

$$C = D(0.47 + a) \mu\mu F$$

where D is coil former diameter in cms. and a is a constant depending on the gauge of wire, lying between 0.065 for 42 S.W.G. and 0.11 for 12 S.W.G. wire, where one lead of the coil is connected to chassis.

Use of charts

The charts shown may be used as follows:

If the desired Q is known, then reference to Fig. 11.8 will suggest a suitable diameter of former.

If, however, as great a Q as possible is required, then the largest possible former should be used unless the coil is to be sited in a can, in which case the diameter of the former should be less than one half of the internal diameter of the can and spaced from the end by the same amount or more.

When the diameter of the former is determined, reference should be made to the appropriate chart, and as shown in Fig. 11.7 the inductance intercept A corresponds to C which gives the wire gauge (D) which gives the number of turns per inch for that gauge, and E the number of turns required.

Diagram to illustrate use of Charts

FIG. 11.7

Fig. 11.7. Diagram to illustrate use of charts (Ref. G17).

FIG. 11.6B

Fig. 11.6B. Dimensions of coil referred to in text.

It will be seen that "even" gauges of wire have been used. If it is desired to use an "odd" gauge, a little simple geometry will soon give the result.

The Q in air of a coil wound to this information, when tuned by capacitances between 45 and 500 μF may be read directly from Fig. 11.8.

The Q values shown in the chart have been corrected for coil capacitance and are somewhat higher than those indicated by the usual Q meter. The accuracy of these curves is rather less than that of the inductance charts, but various values have been checked by several methods which have given substantial agreement.

Example

As an example* of the use of the curves, suppose we have a variable condenser of 450 μF swing and desire to find a coil with which it will tune from 12 Mc/s to 4 Mc/s. If the total capacitance at 12 Mc/s. be C μF then

$$(C + 450)/C = 12^2/4^2 = 9 \text{ and } C = 56.25 \mu\text{F}$$

$$L = 1/4\pi^2 f^2 C$$

$$= \frac{10^{12} \cdot 10^6}{4\pi^2 \times 12^2 \times 10^{12} \times 56.25} \mu\text{H} = 3.15 \mu\text{H}.$$

Inspecting Fig. 11.8 we see that the Q at 4 Mc/s. will lie between 116 for $\frac{1}{8}$ in. and 168 for a $\frac{3}{8}$ in. former, while that at 12 Mc/s. will lie between 182 for a $\frac{1}{8}$ in. and 265 for $\frac{3}{8}$ in. former.

If we choose a $\frac{3}{8}$ in. former we find that the line corresponding to this in Fig. 11.10 cuts the L line at a wire diameter of 0.025 in. This line intersects T.P.I. at 23.8 and the "No. of turns" is 18.5 with a wire gauge of 22 S.W.G.

Referring to Fig. 11.8—we find for $L = 3.15 \mu\text{H}$:

C μF	45	100	200	400	500
Q	212	195	175	150	142

Z_o is readily obtained by writing $Z_o = Q\sqrt{L/C}$.

*This example is presented in a different form from that in the original article.

If, however, we had used the $\frac{1}{2}$ in. former we would find that 18 turns of 26 S.W.G. at 37 T.P.I. would give

$C \mu\mu F$	45	100	200	400	500
Q	181	165	147	123	117

(ii) Miscellaneous features

(A) Matching

Short wave coils are frequently matched by altering the position of the last few turns on the former. This sometimes leads to damage to the coil, particularly if there is an interwound primary.

An alternative method, which is applicable to coils terminated by passing the wire diametrically through the former, is to push sideways this terminating wire in the

Fig. 11.8. Q/L chart for obtaining suitable size of former (Ref. G17).

middle of the coil. In this way the last half turn of the coil can be increased almost to a complete turn or decreased to a small fraction of a turn. Both the first and last half turns on the coil can be treated in this way, thereby providing a possible inductance adjustment equivalent to approximately one complete turn of the winding. When matching short wave coils it is essential that associated primaries, and any other coils on the same former, be connected in a similar manner to their ultimate connection in the receiver, i.e. earthed ends of coils should be earthed, and hot ends either earthed or left open depending on which is more suitable.

FIG. 11.9

Fig. 11.9. Optimum Q, $\frac{1}{4}$ in. former (Ref. G17).

Iron cores are widely used for adjusting the inductance of short wave coils. Because at higher frequencies increased losses in cores offset the advantage of increased permeability, the cores in some cases do not increase the Q of a coil, but provide a convenient method of inductance adjustment.

In shortwave oscillator coils an iron core also has the advantage of increasing the coupling between primary and secondary for a given winding. Thus increased grid current may be obtained although Q is not increased.

Fig. 11.10. Optimum Q , $\frac{1}{2}$ in. former (Ref. G17).

At frequencies of the order of 100 Mc/s the difficulties of manufacturing suitable iron cores are greater although they are made and used (Ref. A22) but it is comparatively simple to wind air cored coils with a Q of say 300. Because of this, inductance adjustment can also be carried out by means of copper slugs which are adjusted in the field of the coil in the same way as are iron cores at lower frequencies. The slugs are sometimes silver plated to minimize losses, but on the other hand brass slugs are also used, apparently without undue losses.

FIG. 11.11

Fig. 11.11. Optimum Q , $\frac{1}{4}$ in. former (Ref. G17).

(B) Self-capacitance

To reduce capacitances in a coil with an interwound primary winding without noticeably decreasing the coupling, it is possible—if the spacing factor of the secondary winding allows it—to wind the primary against the wire on the low potential side of each space between secondary wires. A definite advantage is gained from this method of winding and at the same time the cause of appreciable random deviations in coil capacitance is removed.

It is usually advisable to start an interwound primary winding just outside a tuned secondary winding for a desired coupling with minimum secondary capacitance. Best results will probably be obtained with the primary started between one half

Fig. 11.12. Optimum Q, $\frac{1}{8}$ in. former (Ref. G17).

FIG. 11.12

FIG. 11.13

Fig. 11.13. Effect of circular and square screening cans on inductance (Ref. G17).

and one and one half turns outside the cold end of the secondary, close spacing being used for parts of the primary outside the secondary and the external primary turns being wound as close to the last secondary turn as possible

(C) Aerial primary windings

On the 6 to 18 Mc/s short wave bands both interwound and external high impedance primaries are used. External primaries have the advantage of reducing the capacitive coupling between the aerial and the grid of the first valve with the result that oscillator re-radiation from superheterodyne receivers is noticeably reduced. In addition, impulse interference is apparently decreased. The gain obtainable over a band of frequencies is at least as good as that with low impedance interwound primaries and the tracking troubles experienced when a particular aerial resonates an interwound primary within the band are not so likely to occur.

A satisfactory method of winding for an external primary is to use a universal winding (perhaps 36 or 38 A.W.G. S.S.C.) with a small cam (1/10 inch or 1/16 inch) and space the primary as closely as possible to the cold end of the secondary. About 25 turns on a 3/8 inch former would be suitable for the range from 6 to 18 Mc/s but final details must be determined in a receiver. Additional capacitance coupling will sometimes provide increased gain at the high frequency end of the band, although with the loss of some of the advantages outlined above.

(D) Direction of windings

For interwound oscillator coils the method of connection is the same as that previously described—considering primary and secondary as one continuous tapped winding in the one direction, the grid is connected to the end of the secondary further from the primary (for a tuned grid oscillator) and the plate is connected to the other extreme, i.e. the end of the primary further from the grid connection.

Interwound aerial and r-f coils are connected in the opposite sense, i.e. grid to end of secondary further from primary, and plate (or aerial) to end of primary closer to grid.

External primaries are connected in the same sense as oscillator coils i.e. aerial and grid at extremes of the two windings when considered as one tapped winding in the same direction. Care is needed with short wave coil connections because secondary and external primary are wound on different types of machines and may be wound in opposite directions. This necessitates reversing the connections to the primary winding. Examination of a coil will show that if the primary is moved from one end of the secondary to the other it will also be necessary to reverse the connections to the primary.

SECTION 6 : RADIO-FREQUENCY CHOKES

(i) *Pie-wound chokes* (ii) *Other types.*

(i) Pie-wound chokes

Radio frequency chokes are of two main types, those used above their main self-resonant frequency and those used below it. In either case the choke is normally required to have, over a range of frequencies, an impedance higher than some minimum value and a high reactance which does not have sudden changes in its value. The need for high impedance is obvious, and a constant value of reactance is necessary if the choke is in parallel with a ganged tuned circuit.

At frequencies below its natural resonance the impedance of a choke is due to its inductive reactance, modified by the self-capacitance as shown in Sect. 2(i) of this chapter, and so increases with frequency until self-resonance is reached. The choke may have one or more resonances, series as well as parallel, as explained below, but above some high frequency its impedance is approximately equal to the reactance

of its self-capacitance, i.e. the impedance is inversely proportional to frequency and eventually reaches values low enough to render the choke useless.

Thus to obtain high impedance over a wide band of frequencies a choke requires maximum inductance and minimum self-capacitance. For lower frequencies universal windings are used, usually split into two or more spaced pies with each pie as thin as possible for minimum self-capacitance.

To keep the impedance high over a band of frequencies it is necessary to avoid any tuning of sections of the choke by other sections. A typical case of such tuning would occur in a r-f-c consisting of two pies of different sizes. The impedance-frequency curve of such a choke would show two maxima at the self-resonant frequencies of the two sections, but between these peaks there would be a serious drop in impedance at the frequency at which the inductive reactance of one pie became series resonant with the capacitive reactance of the other. At such a frequency there would also be a sudden change in the effective reactance of the choke which would give tracking errors.

Series resonance of the type described occurs whenever pies with different self-resonant frequencies are connected together. To eliminate them it is not sufficient to wind several pies with the same numbers of turns because the effects of mutual inductance in different sections of the coil still give different self-resonant frequencies to adjacent pies. To avoid this, Miller (Ref. H6) recommends winding progressively smaller pies towards the centre of a multi-pie r-f-c to make the self resonant frequency of each pie the same. He gives figures which show a considerable increase in uniformity of impedance over a range of frequencies when this method is adopted.

In addition to the need for individual pies to be resonant at the same frequency, Wheeler (Ref. H5) gives the requirement (for two-pie chokes) that the pies should be connected so that mutual inductance opposes the self-inductance of the pies. This almost entirely removes minor resonances which occur at approximately harmonically related frequencies, and gives a very smooth curve of apparent capacitance for the r-f-c. The spacing between pies and the number of turns on the pies should be experimentally adjusted for best results with the choke located in the position in which it is to be used.

(ii) Other types

At high frequencies (above 10 Mc/s) self resonant chokes can be wound to give a high impedance over a reasonably wide band of frequencies. The winding length of such chokes for a given former diameter and wire size can be obtained from Ref. H1 for frequencies between 10 and 100 Mc/s.

In other cases it is necessary to design chokes for maximum impedance, i.e. maximum inductance and minimum self-capacitance with a minimum of resistance. Such an application occurs in the battery input circuit of a vibrator unit. Solenoids have been used for this purpose but higher impedance can be obtained with pyramid winding (say eight turns on the first layer, seven on the second and finishing with a top layer of one turn).

Even better results are obtainable by using an iron core as a former, although the winding must be arranged in such a way that the iron core does not increase the self-capacitance unduly.

Another application requiring a minimum-resistance r-f-c is a mains filter. Universal windings of, say, 26 A.W.G. wire are used in some cases, but where better performance is required a wooden former of perhaps 2 inches diameter is used, and slots in the former are filled with jumble windings of heavy wire.

SECTION 7 : TROPIC PROOFING

- (i) *General considerations* (ii) *Baking* (iii) *Impregnation* (iv) *Flash dipping*
(v) *Materials.*

(i) General considerations

The use of a suitable wax or varnish is not the only way in which the moisture resisting properties of a coil can be improved. The higher the impedance of a circuit, the greater the effect of a certain resistance in parallel with it. Thus a leakage between coil terminals (or other appropriate parts of the circuit) due to moisture will have a greater effect on a high Q circuit than on a low Q one. Depending upon the importance attached to maintenance of performance in humid conditions, it may be desirable to use low impedance (low Q and low L) circuits even at the expense of an additional stage in a receiver.

Another aspect of the question is that the moisture absorption of a coil is governed by its surface area. High Q coils usually have a larger surface (due to the use of pie-winding for instance) and thus are more liable to deteriorate rapidly under humid conditions.

This has been demonstrated in a test in which two sets of coils were used. The first set consisted of 1 mH coils wound in a single pie with a 3/8 in. cam, giving an initial Q of 75, the second set of 1 mH coils were wound with three pies and a 1/10 in. cam giving a Q of 145. Both sets of coils were baked, impregnated and flash dipped and then exposed to conditions of high humidity. At the end of one week the single pie windings had an average Q of 65, and the three pie windings an average Q of about 60. As the test continued the improved performance of the single pie windings became even more marked. In addition the variations between individual coils were much less in the single pie windings, which may have been due to the more variable nature of the flash-dip on the three-pie windings.

No coating or impregnating treatment for coils prevents moisture penetration if the exposure to high humidity is prolonged. On the other hand, some treatments will delay the ingress of moisture much longer than others—for instance the Q of a coil with a single flash-dip will fall much more rapidly than that of a coil which has been vacuum impregnated and flash-dipped twice. The corollary should not be overlooked; after prolonged exposure to humidity the coil with a single flash dip will return to its original performance when the humidity is decreased more rapidly than will the other. Conditions of use determine requirements, but it cannot be taken for granted that the treatment which gives the slowest deterioration in Q is the best for all types of operation.

Apart from maintaining Q , moisture proofing is also required to maintain insulation resistance between different windings or between windings and earth. This is particularly important in the case of interwound coils (e.g. an oscillator coil) in which one winding is earthed and the other is of fine wire with a d.c. potential applied to it. Leakage between the two windings in the presence of moisture can produce electrolysis and a consequent open-circuit in the fine wire.

(ii) Baking

Irrespective of the moisture proofing treatment which is to be applied to a coil, the first requirement is to remove all moisture. This is done most conveniently by baking at a temperature above the boiling point of water. Materials used in coil winding are liable to be damaged at temperatures greatly in excess of 100°C and a satisfactory oven temperature is from 105° to 110°C.

The time required depends on the components being treated, and it is essential for all parts of a coil to be raised to oven temperature and maintained at that temperature at least for a short time. Baking for a quarter of an hour is a minimum for simple coils, and half an hour is a more satisfactory time.

One detail of oven design which must not be overlooked is that provision must be made for removing the water vapour as it is expelled from the coils. A current of fresh air passing through the oven is satisfactory for this purpose.

Whether the baking is followed by impregnation or flash-dipping only, the next process should begin before the coils have cooled.

(iii) Impregnation

Although vacuum impregnation gives the best penetration of the impregnant and best removal of moisture vapour and gas, a "soaking" treatment is often used and gives satisfactory results for commercial requirements.

A typical soaking treatment calls for the coils to be immersed in wax which is maintained at 105° to 110°C for a period of from one quarter to one half hour, depending on the type of winding, e.g. a thick universal winding needs more time than a spaced solenoid. In any case the coil should be left in the wax until no more bubbles are given off.

The temperature of the wax-tank needs accurate adjustment as apart from damage to coils which may result if it is too high, the characteristics of the wax may be altered by excessive heating.

Soaking in varnish (air-drying or oven-drying) is also possible but it is necessary to keep a close check on the viscosity.

(iv) Flash-dipping

Flash-dipping is commonly practised without impregnation and properly carried out it can be a satisfactory commercial treatment. The flash-dip should be of the same type of material as normally used for impregnation.

A wax-tank for flash-dipping can conveniently be maintained at a lower temperature than one for soaking, and a suitable temperature is one at which a skin of wax just develops on the surface of the tank on exposure to air. By keeping the top of the tank covered when not in use the skin will not be troublesome and it can readily be cleared away when necessary.

With the wax temperature low, a thicker coating is obtained on the coil when dipped and the tendency for "blow-holes" to develop is minimized. This is partly due to the thicker coating and partly because the coil itself is heated less by the wax and so has less tendency to expel air through the coating of wax as it is setting.

Once a hole has developed it is desirable to seal it with a hot instrument. To attempt to seal it with a second flash-dip usually results in failure as air is expelled through the hole in the first coat as the coil is warmed up and this punctures the second coating in the same place.

If flash-dipping alone is used for moisture proofing a minimum treatment might be, first flash-dip, seal all blow-holes with wax, then second flash dip.

Similar troubles are experienced with holes when varnish sealing is used.

(v) Materials

The first requirement for an impregnating compound is good moisture resistance. It is also important that its losses be low at the frequencies concerned, and it is quite possible to obtain impregnants which can be used without noticeably affecting the Q of the impregnated winding.

Because it is usually desirable to have minimum self-capacitance in a coil, the dielectric constant should be low, and the temperature coefficient should also be known. Waxes can be obtained with dielectric constants having a negative temperature coefficient and this is useful in offsetting the temperature coefficient of the coil itself, which is positive in all usual cases.

Apart from the resistance of a moisture proofing compound to moisture absorption, its surface properties are important. A compound which does not wet easily is desirable and tests on moisture proofing should be designed to separate the effects of surface leakage from those of absorption.

Where flash-dipping only is carried out, some of the properties mentioned above are not of such importance but they cannot be ignored completely.

Other points which must be considered when choosing a moisture-proofing compound are that it must be capable of maintaining its properties over the range of temperatures to which it is liable to be subjected. Melting of waxes is the trouble most likely to be encountered, but crazing (and the consequent admission of moisture) may be experienced at low temperatures.

Waxes and varnishes do not themselves support **fungus growth**, but they are liable to collect coatings of dust which may do so. Suitable precautions to avoid this may be desirable. More important is the avoidance in coils as far as possible of materials which are subject to fungus attack. Some types of flexible tubing fall in this category and should not be used, and the same applies to some cheap coil former materials. The fabric covering of wires also may support fungi and should be completely coated with the wax or varnish to avoid this occurrence.

SECTION 1 : INTRODUCTION

(i) Voltage amplifiers

A voltage amplifier is one in which the voltage gain is the criterion of performance. To be strictly correct it is not possible to have voltage without power since infinite impedance does not exist in amplifiers, but for all ordinary purposes a "voltage amplifier" is one in which a "voltage" output is required. Voltage amplifiers generally work into high impedances of the order of 1 megohm, but in certain cases lower load impedances are used and there is no sharp demarcation between "voltage" and "power" amplifiers. In cases where transformer coupling is used between stages, the secondary of the transformer may be loaded only by the grid input impedance of the following stage and the numerical value of the impedance may not be known. In such cases the transformer is usually designed to operate into an infinite impedance, and the effect of normal grid input impedances on the transformer is very slight compared with the primary loading.

It is important to bear in mind the reversal in polarity which occurs in any valve when used as an amplifier with a load in the plate circuit. As a consequence, the a-f voltage from grid to plate is

$$E_{gp} = E_{gk} + E_{kp} = E_{gk}(1 + A) \quad (1)$$

where A is the voltage gain from grid to plate.

SECTION 2 : RESISTANCE-CAPACITANCE COUPLED TRIODES

(i) Choice of operating conditions (ii) Coupling condenser (iii) Cathode bias
(iv) Fixed bias (v) Grid leak bias (vi) Plate voltage and current (vii) Gain and distortion at the mid-frequency (viii) Dynamic characteristics (ix) Maximum voltage output and distortion (x) Conversion factors with r.c.c. triodes (xi) Input impedance and Miller Effect (xii) Equivalent circuit of r.c.c. triode (xiii) Voltage gain and phase shift (xiv) Comments on tabulated characteristics of resistance-coupled triodes.

(i) Choice of operating conditions* (Fig. 12.1)

Any triode may be used as a r.c.c. amplifier, but for most purposes the valves specially suitable for this application may be grouped :

1. **General purpose triodes** with μ from 15 to 50, and plate resistance from 6000 to 10 000 ohms (with battery types somewhat inferior). These are also called "medium mu" triodes.

2. **High- μ triodes** with μ from 50 to 100, and plate resistances say from 50 000 to 100 000 ohms.

The load resistance (R_L) may be any value from a few ohms to many megohms, but for normal operation R_L should never be less than twice the plate resistance at the operating point, with a higher value preferred. The load resistance should never be greater than the following grid resistance (R_{g2}) and should preferably be not more than one quarter of R_{g2} . The following table is a good general guide, but capable of modification in special circumstances.

Valve type—	General purpose	High- μ		
Following grid resistor—	0.22 to 1	0.22	0.47	1 M Ω
Load resistance	0.1	0.22	0.22	0.22 M Ω
		or 0.47	or 0.47	M Ω

The optimum combination of R_L and R_{g2} for maximum output voltage is covered in Sect. 2(ix).

The **plate supply voltage** (E_{bb}) should generally be as high as practicable provided that the maximum ratings are not exceeded. Plate supply voltages up to 300 volts are safe for use with all types of indirectly-heated valves unless otherwise stated. Somewhat higher supply voltages may be used with triodes provided that the designer ensures that, other than momentarily when switching on, the maximum plate voltage rating is not exceeded under any possible conditions.

The **input grid resistor** (R_{g1}) should not normally exceed 1 megohm with indirectly-heated valves, although higher resistances are satisfactory with 1.4 volt battery valves. Higher grid resistances will not do damage to a r.c.c. triode, provided that the plate load resistance is not less than, say, 0.1 megohm with 300 volts plate supply, but the reverse grid current may be sufficient to shift the operating point into the region of distortion and lower gain. For this reason cathode bias is to be preferred to fixed bias and the input grid resistor should not be higher than necessary, particularly with high- μ triodes—see (iv) below. For example, little is gained by using a grid resistor having more than four times the resistance of the plate load resistor of the preceding stage.

Values of input grid resistor in excess of 1 megohm may only be used satisfactorily in low-level pre-amplifier operation where the valve is one specially manufactured or tested for this class of service, under a specification which ensures that the reverse grid current is very low. With a maximum reverse grid current of 0.2 μ A and with

Fig. 12.1. Triode valve (V_1) resistance-capacitance coupled to V_2 .

*See Chapter 3 Sect. 1(iv) for valve ratings and their limiting effect on operation ; also (v) Recommended practice and operation.

μ not greater than 40, a grid resistor up to 5 megohms may be used, provided that the total resistance of the plate load resistor and the plate decoupling resistor is not less than 0.1 megohm.

If grid-leak bias is used, R_g may be from 5 to 10 megohms.

The output grid resistor (R_{og}) may be the **maximum recommended** for the following stage by the valve manufacturers—usually 0.5 megohm for power valves with cathode bias—or as determined by eqn. (6) or (7) in Chapter 3 Sect. 1(v)d. Lower values are desirable to reduce the effects of reverse grid current in the following stage, and there is no appreciable advantage in either gain or distortion through the use of a resistance greater than $4 R_L$. Calculation of the maximum grid resistance for use with power valves is covered in Chapter 13 Sect. 10(i).

(ii) Coupling condenser

The coupling condenser (C) may be selected to give the desired low frequency response. The loss of voltage due to C may be calculated by the use of a vector diagram or by the following equation, which applies to the circuit of Fig. 12.1 provided that the input resistance of V_2 is very high.

$$E_o/E = R/|Z| \quad (1a)$$

where E_o = signal voltage on grid of V_2

E = signal voltage across R_L

$R = R_{o2} + r_p R_L / (r_p + R_L)$

or as an approximation, $R \approx R_{o2}$ if the plate resistance of V_1 is small compared with R_{o2} ,

$|Z|$ = magnitude of series impedance of R and C

$$= \sqrt{R^2 + X_c^2}$$

and $X_c = 1/\omega C = 1/2\pi f C$.

For example, if $R = 1$ megohm and $f = 50$ c/s, the following results will be obtained—

db loss	E_o/E	X_c/R	X_c	C
1	0.891	0.51	0.51 megohm	0.006 24 μF
2	0.794	0.76	0.76 megohm	0.004 19 μF
3	0.708	1.00	1.0 megohm	0.003 18 μF

The phase angle shift is given by

$$\phi = \tan^{-1} 1/\omega CR = \tan^{-1} 1/2\pi f CR \quad (1b)$$

In certain cases a low value of C is adopted intentionally to reduce the response to hum arising from preceding stages. However, the use of a low coupling capacitance, when the following grid resistor is 0.5 megohm or more, increases the hum contributed by the following valve through the a.c. operation of its heater. A low coupling capacitance should therefore not be used on a low-level stage. In high fidelity amplifiers a fairly large value of C is generally adopted, thus not only improving the low frequency response but also reducing phase shift and possibly also improving the response to transients. However, excessively large values of C are undesirable.

The following table gives the approximate values of C for certain selected conditions. Note that R must be as defined below eqn. (1a).

COUPLING CONDENSER

Attenuation	1 db at	12.5	25	50	100	200 c/s
	2 db at	8.5	17	34	67	134 c/s
	3 db at	6.5	13	26	51	102 c/s
$R =$	10 000 ohms	2.5	1.25	0.62	0.31	0.15 μF
	50 000 ohms	0.5	0.25	0.12	0.06	0.03 μF
	100 000 ohms	0.25	0.12	0.06	0.03	0.015 μF
	0.25 megohm	0.1	0.05	0.025	0.012	0.006 μF
	0.5 megohm	0.05	0.025	0.012	0.006	0.003 μF
	1.0 megohm	0.025	0.012	0.006	0.003	0.001 5 μF
	2 megohms	0.012	0.006	0.003	0.001 5	0.000 8 μF
	5 megohms	0.005	0.002 5	0.001 2	0.000 6	0.000 3 μF

C_k = capacitance of by-pass condenser in farads

R_k = resistance of self bias resistor in ohms

μ = valve amplification factor at the operating point

r_p = valve plate resistance in ohms at the operating point

R_L = resistance of plate load resistor in ohms

R_{g2} = resistance of following grid resistor in ohms

and $R' = R_L R_{g2} / (R_L + R_{g2})$.

The derivation of eqn. (2) is given in Ref. B11 ; see also Refs. A11, A13.

The **attenuation characteristics** of a typical general-purpose triode with cathode bias are given in graphical form in Fig. 12.3A. It will be seen that all curves have the same shape, but are shifted bodily sideways depending on the value of C_k . The maximum slope of the curves in Fig. 12.3A is 1.4 db/octave ; the slope does not normally exceed 3 db/octave when R_k is the optimum value to provide bias.

The **limiting loss of gain at zero frequency** due to R_k is given by

$$\left| \frac{A'}{A} \right| = \frac{R' + r_p}{R' + r_p + (\mu + 1)R_k} \quad (3)$$

Examples of limiting loss of gain at zero frequency (based on equation 3)

Type	R_L	R_{g2}	R'	R_k	μ^*	r_p^*	A'/A	loss
6J5	0.1M Ω	0.5M Ω	0.08M Ω	2700	18	17 000	0.65	3.7 db
6Q7	0.25M Ω	0.5M Ω	0.17M Ω	3000	68	70 000	0.53	5.5 db
6SQ7	0.25M Ω	0.5M Ω	0.17M Ω	3900	100	100 000	0.40	8.0 db

*At operating point.

FIG. 12.3B

Fig. 12.3B. Universal attenuation curves with cathode bias (Ref. A11 Part 4).

Universal attenuation curves are given in Fig. 12.3B (Ref. A11 Part 4) in which

$$B = 1 + \frac{R_k(\mu + 1)}{r_p + R'}$$

$$R' = R_L R_{g2} / (R_L + R_{g2})$$

and $X_k = 1/(\omega C_k)$.

(B) The **phase angle shift** is a maximum at the frequency where the slope of the attenuation characteristic is a maximum, and drops towards zero at zero frequency

and at higher audio frequencies. The maximum value for any normal r.c.c. amplifier does not exceed about 30° .

Universal curves showing phase angle shift are given in Fig. 12.3C in which the symbols have the same meaning as in Fig. 12.3B.

(C) Choice of cathode bias resistor

The best method is to determine the grid voltage as for fixed bias—see (iv) below—and then to calculate R_k . A fairly satisfactory approximation is to select R_k by the following table.

μ	R_L M Ω	Low level	Inter- mediate level	High level	
				$R_g = R_L$	$R_g = 2R_L$
12 to 25	any	$R_k = 0.25R_L/\mu$	$0.5R_L/\mu$	$0.6R_L/\mu$	$0.8R_L/\mu$
30 to 50	any	$R_k = 0.5R_L/\mu$	$0.7R_L/\mu$	$0.7R_L/\mu$	$0.9R_L/\mu$
70 to 100	0.1	$R_k = 1.0R_L/\mu$	$1.2R_L/\mu$	$1.2R_L/\mu$	$1.6R_L/\mu$
	0.22	$R_k = 0.8R_L/\mu$	$1.0R_L/\mu$	$0.9R_L/\mu$	$1.2R_L/\mu$
	0.47	$R_k = 0.65R_L/\mu$	$0.8R_L/\mu$	$0.75R_L/\mu$	$1.0R_L/\mu$

Conditions : Plate supply voltage 200 to 300 volts. Values of μ are the published values.

Fig. 12.3C. Universal phase angle shift curves with cathode bias (Ref. A11 Part 4).

(D) Cathode bias loadlines

Cathode bias loadlines may be drawn on the plate characteristics as on the mutual characteristics [Chapter 2 Sect. 4(v) and Fig. 2.27] but they will no longer be straight lines. Fig. 12.4 shows the loadline and plate characteristics for a high- μ triode. The cathode bias loadline may very easily be plotted for any selected value of R_k , e.g. 10 000 ohms. In Fig. 12.4 each curve applies to increments of 0.5 volt in E_g so that (with $R_k = 10\,000$ ohms) the successive increments of I_b are 0.05 mA—

$E_g = 0$	-0.5	-1	-1.5	-2	-2.5	-3 volts
$I_b = 0$	0.05	0.1	0.15	0.2	0.25	0.3 mA

The intersection of the selected R_k loadline with the R_L loadline gives the operating point (Fig. 12.4).

Alternatively, the intersection of the R_L loadline with each grid curve may be marked with the corresponding value of R_k ; e.g. in Fig. 12.4 at point A, $E_g = -1.5$ V and $I_b = 0.47$ mA, therefore $R_k = (1.5/0.47) \times 1000 = 3200$ ohms. Similarly at point B, $R_k = 7800$ ohms. If greater accuracy is required in determining an in-

dividual point, the values of R_k may be plotted against E_c , and the desired value may be selected.

For greater accuracy, particularly with relatively high values of cathode resistance, the slope of the loadline in Fig. 12.4 should be that corresponding to $(R_L + R_k)$.

(E) Maximum grid resistance with cathode bias

It may be shown that the maximum permissible grid resistance with cathode bias is greater than that with fixed bias, as indicated by the approximation :

$$\frac{R_g \text{ with cathode bias}}{R_g \text{ with fixed bias}} \approx 1 + g_m R_k \quad (3a)$$

where g_m = slope of dynamic characteristic at operating point

$$\approx \frac{g_m r_p}{(r_p + R_L)} \approx \frac{\mu}{(r_p + R_L)}$$

g_m = mutual conductance at operating point

μ = amplification factor at operating point

r_p = plate resistance at operating point

and R_k = cathode bias resistor.

This ratio (eqn. 3a) is usually between 1.2 and 2.

Fig. 12.4. Plate characteristics of high- μ triode (6SQ7) with $E_{bb} = 400$ volts and $R_L = 0.5$ megohm. Cathode bias loadlines for selected values of cathode bias resistance (R_k) have been drawn in.

FIG. 12.5

Fig. 12.5. Resistance-capacitance coupled triode with fixed bias from voltage divider.

(iv) Fixed bias

(A) It is sometimes desired to operate the valve with fixed bias, either from a separate bias supply (battery or rectifier/filter combination) or from a voltage divider across the plate supply. Fig. 12.5 is an example of the latter, with R_1 and R_2 forming a voltage divider. Here

$$E_{c1} = \frac{R_2 E_{bb} + R_1 R_2 I_b}{R_1 + R_2} \text{ and } R_2 = \frac{E_{c1}}{I_b + (E_{bb} - E_{c1})/R_1} \quad (4)$$

Condenser C_k is for by-passing R_2 , but as R_2 may have a fairly low value, thus necessitating a large capacitance for C_k , it is frequently economical to add R_3 and so permit a smaller value of C_k . In addition, $C_k R_3$ forms a useful hum filter for the bias voltage.

(B) The optimum grid bias ($-E_c$) is a function of the input voltage; the bias should be the minimum (k_1) which can be used without running into damping due to positive grid current, with a margin for differences between valves, together with a further margin (k_2) to allow for the effects of reverse grid current in the grid resistor.

If the input voltage is known,

$$E_c = 1.41 E_i + k_1 + k_2 \text{ volts} \quad (5a)$$

If the output voltage is known,

$$E_c = (1.41 E_o/A) + k_1 + k_2 \text{ volts} \quad (5b)$$

where E_i = r.m.s. input voltage

E_o = r.m.s. output voltage, from plate to cathode

A = voltage gain of stage

k_1 = 0.75 to 1.0 for high- μ indirectly heated valves*

= 0.6 (approx.) for general purpose indirectly heated valves*

= 0.25 (approx.) for battery valves*

$$k_2 \approx \frac{7.5 R_{g1}}{100 R_L} \text{ for high-}\mu \text{ valves}$$

$$\approx \frac{3 R_{g1}}{100 R_L} \text{ for general purpose valves.}$$

R_{g1} = resistance of grid resistor (upper limit)

and R_L = resistance of plate load resistor (lower limit).

These approximate values of k_2 are based on typical American manufacturing specifications for maximum grid current (limiting values), and on the assumption that the reverse grid current is proportional† to the plate current.

Values of k_2 are tabulated below for three typical conditions for a plate supply voltage of 250 volts.

Case 1: $R_{g1} = 1$ megohm

	General purpose triode	High- μ triode
$R_L = 0.1$ megohm	$k_2 = 0.31$	$k_2 = 0.75$ volt
$R_L = 0.22$ megohm	$k_2 = 0.14$	$k_2 = 0.34$ volt
$R_L = 0.47$ megohm	$k_2 = 0.07$	$k_2 = 0.16$ volt

The additional bias (k_2) provided to allow for the effect of reverse grid current is of no great consequence with general purpose triodes, but it is very serious with high- μ triodes

Case 2: $R_{g1} = 2R_L$

$k_2 = 0.15$ volt for high- μ triodes

$k_2 = 0.06$ volt for general purpose triodes.

Case 3: $R_{g1} = 4R_L$

$k_2 = 0.3$ volt for high- μ triodes

$k_2 = 0.12$ volt for general purpose triodes.

Thus with **general purpose triodes operated as fixed bias r.c.c. amplifiers**, a grid resistor having a resistance of 1 megohm or even higher may be used without serious effects. However, it is always desirable to keep the resistance as low as practicable—not more than four times the resistance of the preceding plate load resistor, and not exceeding 1 megohm.

If the effect of reverse grid current on the operating point is to be kept small in **fixed-bias high- μ triodes**, it is essential to use a grid resistor R_{g1} (that is, its own grid resistor) having a resistance not more than twice that of its plate load resistor. This will restrict the maximum change of bias to 0.15 volt (i.e. $k_2 = 0.15$ volt). For example a load resistance of 0.47 megohm will permit the use of a grid resistor of 1 megohm, while a load resistance of 0.22 megohm will permit the use of a grid resistor of 0.47 megohm.

(C) **Cathode bias is preferable to fixed bias** in that the shift of operating point due to reverse grid current is minimized. With general purpose triodes employing cathode bias there is no advantage in making any adjustment to the bias voltage as calculated for fixed bias (eqns. 5a, 5b) but with high- μ triodes employing cathode bias the value of k_2 may be taken as approximately

$$k_2 \approx \frac{5 R_{g1}}{100 R_L} \text{ for high-}\mu \text{ valves with cathode bias.}$$

Consequently, with high- μ triodes, the resistance of the grid resistor R_{g1} may be made 1.5 times that with fixed bias for the same effect on the operating-point.

*These values of k_1 are only typical, and are likely to be exceeded by some valves. In each case, a value should be determined for the valves being used.

†This is approximately true when the reverse grid current is nearly all due to ionization—see Ref. G1, Fig. 1.

(D) Damping due to positive grid current

It is shown in Chapter 2 Sect. 2(iii) that damping on the positive peaks of grid input voltage may be quite serious, even when the peak grid voltage does not reach the grid current "cross-over point." This damping on positive peaks introduces an objectionable form of distortion which is particularly important when the preceding stage has high effective impedance (looking backwards from the grid of the stage being considered) as, for example, with a high- μ triode or pentode. The damping at the positive peak of the input voltage is proportional to the grid conductance at this point, which value increases rapidly as soon as electrons commence to flow from cathode to grid, and even while the resultant grid current is still negative.

If grid current damping is to be avoided, the grid bias must be increased sufficiently to avoid this region.

(v) Grid leak bias

If a grid resistor of 5 or 10 megohms is used, it is possible to obtain the grid bias for a high- μ triode by means of the voltage drop in R_g [see Chapter 2 Sect. 2(iii)]. This imposes damping on the input circuit due to the grid current, and the average input resistance is approximately $R_g/2$. The distortion is approximately the same as with the optimum fixed bias, but the great advantage is that it accommodates itself to variations from valve to valve, while fixed bias is critical.

It may also be used with general purpose triodes operating with input voltages not exceeding, say, 1 volt peak.

Grid leak bias is not very suitable for use with low-level (pre-amplifier) stages owing to hum.

(vi) Plate voltage and current

As discussed in Chapter 2 Sect. 3(i), the voltage on the plate is less than the supply voltage by the voltage drop in the load resistor. This is illustrated in Fig. 12.6 in which the loadline is fixed by the plate supply voltage E_{bb} and the load resistance R_L . The quiescent operating point Q is fixed by the intersection of the loadline and the grid curve for E_{c1} , the bias voltage having been previously determined. Alternatively, the cathode bias loadline may be drawn by the method described above, thus determining the operating point.

Having fixed Q , the quiescent plate current I_{b0} and plate voltage E_{b0} will automatically be fixed. If

$I_{b0} = KI_m$, where K is a constant less than 1 and $I_m = E_{bb}/R_L$, then

$E_{b0} = (1 - K)E_{bb}$. If $K = 0.5$, for example, then

$I_{b0} = \frac{1}{2}I_m = \frac{1}{2}E_{bb}/R_L$ and $E_{b0} = \frac{1}{2}E_{bb}$; in this case the voltage across the valve is equal to the voltage across the load resistor. In practice, K may have values between about 0.25 and 0.85.

Typical values of K are tabulated below

	Intermediate			
	Low level	level	High level*	
General purpose triodes	0.75 - 0.85	0.6 - 0.75	0.5 - 0.6	
High- μ triodes	0.6 - 0.65	0.5 - 0.6	0.45 - 0.55 ($R_L = 0.5M\Omega$)	
			0.4 - 0.5 ($R_L = 0.25M\Omega$)	

*If R_{g2} is less than $2R_L$, then the values of K for high level operation should be decreased.

Fig. 12.6. Plate characteristics of r.c.c. triode with normal loadline AB, operating point Q , and working loadline EQF due to grid resistor shunting.

Relation between K and cathode bias resistor

Knowing K , it is possible to calculate R_k or vice-versa :

$$R_k \approx \frac{R_L - K(R_L + r_p)}{\mu K} \quad (6a)$$

$$K \approx \frac{R_L}{R_L + r_p + \mu R_k} \quad (6b)$$

Relation between K and grid voltage

$$E_c \approx [R_L - K(R_L + r_p)](E_{bb}/\mu R_L). \quad (6c)$$

Eqns. (6a), (6b) and (6c) are exact for linear characteristics, but only approximate in practice.

Example : $\mu = 20$, $r_p = 10\,000$ ohms, $R_L = 0.1$ megohm, $E_{bb} = 250$ volts

$K =$	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
$E_c =$	-12.5	-11.1	-9.7	-8.4	-7.0	-5.6	-4.3	-2.9	-1.5	-0.1	+1.25

(vii) Gain and distortion at the mid-frequency

The voltage gain at the mid-frequency is

$$A_0 = \frac{\mu R_L}{R_L + r_p} = \frac{g_m}{(1/r_p) + (1/R_L)} \quad (6d)$$

where there is no a.c. shunt load, and where μ , g_m and r_p are the values at the operating point, that is at the operating plate current. Alternatively this may be calculated from the loadline (Fig. 12.6) :

$$A_0 = \frac{E_{b2} - E_{b1}}{2E_{c1}} \quad (6e)$$

where E_{b2} is plate voltage corresponding to negative peak grid signal voltage

E_{b1} is plate voltage corresponding to positive peak grid signal voltage
and E_{c1} is peak grid signal voltage.

When there is a following grid resistor R_{g2} , the loadline must be rotated about Q to a new position EQF with a slope of $-(1/R_L + 1/R_{g2})$. The voltage gain for the same input voltage is then

$$A' = \frac{E_{b2}' - E_{b1}'}{2E_{c1}} \quad (6f)$$

which may be shown by the equivalent circuit [see (xii) below] to be

$$A' = \frac{g_m}{1/r_p + 1/R_L + 1/R_{g2}} \quad (7)$$

$$\text{also } A'/A = R_{g2}/(R + R_{g2}) \quad (8)$$

where $R = R_L r_p / (R_L + r_p)$

and g_m and r_p are the values at the operating point.

In practice, the new loadline EQF extends downwards with point F in the region of increasing distortion, and in the extreme case plate current cut-off may occur. This effect may be avoided by reducing the input voltage so that the output voltage will be

$$R_{g2}/(R_L + R_{g2}) \times \text{output voltage without shunting} \quad (9)$$

Gain in terms of g_m and g_p

Equation (6d) may be put into the alternative form

$$A_0 = \frac{g_m R_L}{1 + g_p R_L} \quad (9a)$$

where g_p = plate conductance at the operating point = $1/r_p$.

When there is a following grid resistor R_{g2} the gain is given by

$$A_0 = \frac{g_m R}{1 + g_p R} \quad (9b)$$

where $R = R_L R_{g2} / (R_L + R_{g2})$.

The values of g_m and g_p may be derived from "G" curves (e.g. see Fig. 13.9B). By this means the actual values of g_m and g_p at the operating point may be determined with a good degree of accuracy without any assumptions or manipulations (Ref. A15).

Distortion

The percentage second harmonic distortion—see Chapter 13 Sect. 2(i)—is given by

$$H_2\% = \frac{EQ - QF}{2(EQ + QF)} \times 100 \quad (10)$$

(viii) Dynamic characteristics

The dynamic characteristic of a resistance-loaded triode is described in Chapter 2 Sect. 3(i) and Fig. 2.19. In shape it closely resembles the dynamic characteristic of a resistance-loaded pentode, and a comparison between the two is made in Sect. 3(viii) below and Fig. 12.15. With the triode dynamic characteristic the greater part or the whole of the “top bend” is in the grid current region and therefore cannot be used. The most nearly straight portion is therefore that of minimum bias.

An “ideal” (linear) dynamic characteristic of a general purpose triode is shown in Fig. 12.7A. It is limited at the lower end by plate-current cut-off at A, while the other end is in the grid current region. The usable part extends from A to G, but in reality the lower part is curved, and is avoided as far as possible. The upper end (GB) is also curved, but as this is in the grid current region it cannot be used in any case. The curves are to scale for $\mu = 20$, $r_p = 10\,000$ ohms, $R_L = 0.1$ megohm and $E_{bb} = 250$ volts.

FIG. 12.7

Fig. 12.7. “Ideal” linear dynamic characteristics (A) for general purpose triode with $\mu = 20$, $r_p = 10\,000$ ohms, $R_L = 0.1$ megohm and $E_{bb} = 250$ volts; (B) for high- μ triode with $\mu = 100$, $r_p = 0.1$ megohm, $R_L = 0.25$ megohm and $E_{bb} = 250$ volts.

Point C at $E_c = 0$ has a plate current $I_{b1} = E_{bb}/(R_L + r_p)$ which in this case is $0.91 E_{bb}/R_L$. This point and point A may be used as the two basic points for plotting the loadline. Alternatively, point B may be plotted, since $FB = E_{bb}/g_m R_L$. Point G is the commencement of grid current ($E_c = -0.5$ volt) and in this case its $I_{b2} = 0.86 E_{bb}/R_L$. The highest operating point cannot exceed $0.85 E_{bb}/R_L$, and this is only possible for extremely small input voltages. The lowest useful operating point (for high-level operation) is D, which is the mid point of AG, with $I_{b3} = 0.43 E_{bb}/R_L$. Thus the operating point must be within the limits 0.43 and $0.85 \times E_{bb}/R_L$.

The dynamic characteristic in Fig. 12.7B applies to a high μ triode with $\mu = 100$, $r_p = 0.1$ megohm, $R_L = 0.25$ megohm and $E_{bb} = 250$ volts. The grid current is taken as commencing at $E_c = -0.75$ volt. The usable part of the characteristic extends from A to G, and the operating point must be within the limits 0.25 and 0.5 multiplied by E_{bb}/R_L . The upper limit would be somewhat extended if the load resistance were increased to 0.5 megohm.

(ix) Maximum output voltage and distortion

It is difficult to lay down any limit to the maximum voltage output, since overloading occurs very gradually. It is assumed that in all cases the grid bias is sufficient to avoid positive grid current.

For lower values of I.M. distortion, the preceding values of maximum output voltage should be multiplied by:

I.M.	$R_L = 0.1$ megohm	$R_L = 0.25$ megohm
10%	Factor = 0.8	Factor = 0.72
5%	0.48	0.36
2.5%	0.26	0.18

With a high- μ triode the voltage output for 14% intermodulation distortion is only about 0.17 E_{bb} to 0.21 E_{bb} for $R_L = 0.25$ and $R_{g2} = 0.5$ megohm.

Note that with intermodulation distortion the output voltage is taken as the arithmetical sum of the component voltages—see Chapter 14 Sect. 3(ii).

The intermodulation distortion of a triode and a pentode are compared in Fig. 12.16A [Sect. 3(ix)]. At low output voltages the pentode gives less distortion while at high output voltages the triode gives less distortion. The triode is, however, less critical than the pentode, and the distortion increases at a lower rate than with the pentode when the bias is made more negative than the optimum value.

(x) Conversion factors with r.c.c. triodes

Some valve manufacturers publish values of μ , g_m and r_p plotted against plate current. These may be used fairly accurately under any conditions of plate or grid voltage.

If these are not available:

1. The **amplification factor** is nearly constant. In most high- μ triodes it drops about 5% to 10% (15% for types 6SL7-GT and 5691) as I_b is reduced to 0.25 mA, while in general purpose triodes it drops about 15% as I_b is reduced to 1 mA.

2. The **mutual conductance** is largely a function of the plate current and is given by the approximate equation

$$g_m \approx F g_{m0} \quad (11a)$$

where g_m = desired mutual conductance at any operating point with plate current I_b

g_{m0} = published mutual conductance at plate current I_{b0}
and F is given by the following table based on the equation

$$F = \sqrt[3]{F_i} = \sqrt[3]{I_b/I_{b0}}$$

I_b/I_{b0}	1.0	0.9	0.8	0.7	0.6	0.5	0.4	0.3	0.2	0.1
F	1.0	0.97	0.93	0.89	0.84	0.79	0.74	0.67	0.58	0.46

Alternatively, if the gain with resistance-coupled operation is known, the mutual conductance at the operating point may be calculated from

$$g_m = \frac{\mu \times \text{voltage gain}}{R(\mu - \text{voltage gain})} \quad (11b)$$

where $R = R_L R_g / (R_L + R_g)$,

and μ = amplification factor at the operating point.

3. The **plate resistance** may be calculated from $r_p = \mu/g_m$. It is approximately equal to $r_{p0} \sqrt[3]{I_{b0}/I_b}$.

(xi) Input impedance and Miller Effect

In the amplifier of Fig. 12.1 the grid to plate capacitance C_{gp} has impressed across it a voltage $(A + 1)E_i$ where A is the voltage gain of V_1 . The current flowing through C_{gp} is therefore $(A + 1)$ times the current which would flow through the same capacitance when connected from grid to cathode. This is one example of the Miller Effect which occurs in all amplifiers. For example take type 6SQ7 high- μ triode with $C_{gp} = 1.6 \mu\text{F}$ and $A = 62$. The effective input capacitance due to C_{gp} alone is therefore $63 \times 1.6 = 101 \mu\text{F}$.

The total input capacitance also includes the capacitance from grid to cathode plus $(A + 1)$ times any stray capacitance from grid to plate.

If the plate load is partially reactive the input impedance is equivalent to a capacitance C' and a resistance R' in parallel from grid to cathode,

where $C' = C_{gk} + (1 + A \cos \phi) C_{gp}$ (12)

$$R' = -1/(2\pi f C_{gp} A \sin \phi) \quad (13)$$

and ϕ = angle by which the voltage across the load impedance leads the equivalent voltage acting in the plate circuit (ϕ will be positive for an inductive load and negative for a capacitive load)

When the load is capacitive, as usually with a r.c.c. amplifier, R' is positive and there is some slight additional loading of the input circuit. When the load is inductive, R' is negative and self oscillation may occur in an extreme case.

(xii) Equivalent circuit of r.c.c. triode

The exact a.c. equivalent circuit of a r.c.c. triode is given in Fig. 12.8 where the valve V_1 is replaced by a generator of voltage μE_i in series with r_p . The plate load resistor R_L is shunted by C_0 , which includes the valve output capacitance plus stray capacitance. The grid resistor of V_2 is shunted by C_i which includes the input capacitance of V_2 (including the Miller Effect capacitance from the plate) plus stray capacitance. Any additional condenser connected from plate or grid to earth should be added to C_0 or C_i respectively.

Fig. 12.8. Exact equivalent circuit of r.c.c. triode.

The cathode bias resistor is here assumed to be adequately by-passed at all signal frequencies.

This equivalent circuit is the basis of the calculations of gain and phase angle shift at all frequencies.

(xiii) Voltage gain and phase shift

It has been shown by Luck and others that the voltage gain/frequency characteristic of a r.c.c. amplifier has the same mathematical form as a tuned circuit except that the Q is very low (never greater than 0.5). There is a mid-frequency at which the gain is a maximum (A_0) and the phase shift zero. At both lower and higher frequencies the gain falls off, and when the gain is $A_0/\sqrt{2}$ the absolute values of the resistive and reactive components are equal. These two reference frequencies, which correspond approximately to 3 db attenuation, are the basic points on the attenuation characteristics, and, with the mid-frequency gain A_0 , are sufficient to determine the whole frequency characteristic. The value of Q is given by

$$Q = f_0/(f_b - f_a) \quad (14)$$

where f_0 = mid-frequency (at which voltage gain is A_0)

f_b = (high) reference frequency at which voltage gain is $0.707 A_0$

and f_a = (low) reference frequency at which voltage gain is $0.707 A_0$.

The low reference frequency f_a is given by

$$f_a = 1/2\pi CR' \quad (15)$$

where $R' = R_g + r_p R_L/(r_p + R_L)$

and the constants are as in Fig. 12.8.

The high reference frequency (f_b) is given by

$$f_b = 1/2\pi(C_0 + C_i)R'' \quad (16)$$

where $R'' = r_p R_L R_g/(r_p R_L + r_p R_g + R_L R_g)$.

When f_a and f_b have been determined, the attenuation at any other frequency may be found by reference to Fig. 12.9A.

The phase shift at any frequency may be determined from Fig. 12.9B; the phase shift at f_a and f_b is 45° leading and lagging respectively.

Alternatively, if the low reference frequency is known, the gain at any frequency f is given by (Ref. F1):

Fig. 12.9(A). Attenuation in decibels for r.c.c. triode at low and high frequencies (B) Phase shift at low and high frequencies. Values of phase shift for frequencies beyond the limits of the curves may be estimated with reasonable accuracy by taking the angle as proportional or inversely proportional to the frequency.

$$\frac{\text{gain at frequency } f}{\text{gain at mid-frequency}} = \cos \tan^{-1} \frac{f_a}{f} \quad (17)$$

while the phase angle shift is given by

$$\tan \phi = f_a/f \quad (18)$$

where f_a = low reference frequency (3 db attenuation).

Similarly if the high reference frequency is known, the gain at any frequency f is given by

$$\frac{\text{gain at frequency } f}{\text{gain at mid-frequency}} = \cos \tan^{-1} \frac{f}{f_b} \quad (19)$$

while the phase angle shift is given by

$$\tan \phi = f/f_b \quad (20)$$

where f_b = high reference frequency (3 db attenuation).

(xiv) Comments on tabulated characteristics of resistance-coupled triodes

Published operating characteristics of resistance-coupled triodes (unless the test conditions are specified) appear to be taken under test conditions with a low source impedance, a low d.c. resistance between grid and cathode, and a small value of positive grid current. When this is so, they cannot be applied directly to the normal practical case where there is a high resistance d.c. path between grid and cathode, and where the source impedance may be high. The usual value of total harmonic distortion, unless otherwise specified, appears to be about 5% under the conditions of test (Ref. A17).

In a practical resistance-coupled amplifier the maximum output voltage for 5% total harmonic distortion will be less than the tabulated value, depending on the source impedance and the d.c. resistance from grid to cathode, in the presence of grid-circuit damping. This damping is caused, not only by positive grid current, but also by the grid input conductance which, on the extreme tip of the positive peaks, may be appreciable. See page 20 under Grid variational conductance and page 489 under Damping due to positive grid current.

Thus, for any practical amplifier, the tabulated maximum output voltage is misleading, and a lower value should be used for design purposes. In addition, there will be a slight effect on the gain.

SECTION 3 : RESISTANCE-CAPACITANCE COUPLED PENTODES

(i) Choice of operating conditions (ii) Coupling condenser (iii) Screen by-pass (iv) Cathode bias (v) Fixed bias (vi) Dynamic characteristics of pentodes (vii) Gain at the mid-frequency (viii) Dynamic characteristics of pentodes and comparison with triodes (ix) Maximum voltage output and distortion (x) Conversion factors with r.c.c. pentodes (xi) Equivalent circuit of r.c.c. pentode (xii) Voltage gain and phase shift (xiii) Screen loadlines (xiv) Combined screen and cathode load-lines and the effect of tolerances (xv) Remote cut-off pentodes as r.c.c. amplifiers (xvi) Multigrid valves as r.c.c. amplifiers (xvii) Special applications (xviii) Comments on tabulated characteristics of resistance-coupled pentodes.

(i) Choice of operating conditions

A r.c.c. pentode may be treated as a special case of a r.c.c. triode, and many features are common to both provided that the necessary adjustments are made for the differences in μ , g_m and r_p .

The load resistance (R_L) may be any value from a few ohms to many megohms, but for normal operation it is generally from 0.1 to 0.5 megohm. Lower values are used when a reduction in gain or an extended high frequency response is desirable, or when some form of tone correction is intended. Higher values are occasionally used for special applications, but the frequency response is seriously limited unless negative voltage feedback is used. The load resistance should never be greater than the following grid resistor (R_{g2}) and should preferably be not more than one quarter of R_{g2} . The choice of load resistance has only a small effect on the distortion, lower values of R_L (of the order of 0.1 megohm) being somewhat better in this respect.

Plate supply voltage : As for triodes.

Screen supply : A series resistor from the plate supply voltage is generally preferred. Valves in which the screen current has wide tolerances (e.g. some remote cut-off types and most tetrodes) should be supplied from a voltage divider.

Following grid resistor : As for triodes.

Input grid resistor : As for triodes.

(ii) Coupling condenser

The triode formulae and curves in Sect. 2(ii) may be used except that R may be taken as being approximately equal to $R_{g2} + R_L$. See Sect. 3(x) below for more accurate calculations involving r_p .

(iii) Screen by-pass

For normal performance it is necessary for the screen to be adequately by-passed to the cathode. In practice this is usually obtained by by-passing from screen to earth and also from earth to cathode, the value of C_k being normally much larger than C_s (Fig. 12.10).

Fig. 12.10. Circuit of resistance-capacitance coupled pentode with screen dropping resistor and cathode bias.

The effect of incomplete screen by-passing on gain is given by eqn. (1) on the assumption of complete cathode by-passing (Fig. 12.10), the derivation being given in Ref. B3 (see also Refs. A11, A12, A13, B2).

$$\left| \frac{A'}{A} \right| \approx \sqrt{\frac{1 + R_s^2 \omega^2 C_s^2}{B^2 + R_s^2 \omega^2 C_s^2}} \quad (1)$$

where A' = stage voltage gain at frequency f with screen resistor R_s by-passed by condenser C_s

A = stage voltage gain with R_s completely by-passed

= mid-frequency voltage gain

$\omega = 2\pi f$

$$B \approx 1 + \frac{R_s g_m}{m \mu_t (1 + R_L/r_p)} = 1 + \frac{R_s g_{md}}{m \mu_t} \quad (1a)$$

$m = I_b/I_{c2}$ (assumed constant)

g_m = mutual conductance at operating plate current [see Sect. 3(vii)]

g_{md} = slope of dynamic characteristic at operating plate current

and μ_t = triode mu (with screen tied to plate).

If the screen voltage is obtained from a voltage divider (R_1, R_2) then R_s should be taken as $R_1 R_2 / (R_1 + R_2)$.

Fig. 12.11A. Curves for the frequency response of a resistance-coupled pentode with screen dropping resistor R_s and screen by-pass reactance $X_s (= 1/\omega C_s)$. The value of B is given by eqn. (1a). The frequency for $R_s/X_s = 1$ is given by $f = 1/2\pi R_s C_s$. The frequency scale should be traced and the tracing moved horizontally until f corresponds to $R_s/X_s = 1$ (method after Sturley).

Eqn. (1) is plotted in Fig. 12.11A for selected values of B versus R_s/X_s which is equal to $2\pi f R_s C_s$ and therefore proportional to the frequency.

For most purposes it is sufficient to use the **approximation**, for a loss not exceeding 1 db at a frequency f :

$$C_s \approx B/\pi f R_s, \quad (2)$$

where $B \approx 1 + R_s g_m/m \mu_t$

and $m = I_b/I_{c2}$.

For example, type 6J7 with $R_L = 0.25$, $R_s = 1.5$ megohms, $g_m = 850 \mu\text{mhos}$, $\mu_t = 20$ and $m = 4$ has $B \approx 16.5$. For 1 db attenuation at $f = 50$ c/s, $C_s \approx 0.07 \mu\text{F}$.

The **limiting loss of voltage gain** at very low frequencies is $1/B$; in the example above this is 0.06 (i.e. 24.3 db). If the screen had been supplied from a voltage divider, the loss of gain at very low frequencies would have been much less.

An unbypassed screen resistor of $g_m r_s$ ohms gives the same degree of degeneration as a 1 ohm cathode resistor

where r_s = dynamic screen resistance ($\partial e_s / \partial i_s$)

\approx triode plate resistance.

For example, when $g_m = 2000$ micromhos and $r_s = 10\,000$ ohms, an unbypassed

Fig. 12.11B. Phase angle displacement corresponding to Fig. 12.11A.

Fig. 12.11C. Magnitude and phase of factor for use in Fig. 12.11D (Ref. A12). Reprinted by permission from RADIO ENGINEERS' HANDBOOK by F. E. Terman, copyrighted in 1943, McGraw-Hill Book Company Inc.

screen resistor of 20 ohms will give the same degree of degeneration as a 1 ohm cathode resistor.

The effect of the screen by-pass capacitance on **phase shift** is indicated by Fig. 12.11B. Under normal conditions with a high resistance dropping resistor, the angle does not exceed 65° . This angle may be considerably reduced by reducing the effective value of R_s , as for example with a voltage divider. Such action is normally only necessary with negative feedback.

(iv) Cathode bias

(A) Effect of incomplete by-passing on gain

Provided that the screen is adequately by-passed at all frequencies of operation, the procedure is as for triodes (Sect. 2) except that the d.c. current flowing through

FIG. 12.11D

Fig. 12.11D. Curves from which the loss in gain and phase shift of output at low frequencies resulting from resistance-condenser bias impedance $R_f C$, can be calculated in a resistance-coupled amplifier for the general case where both screen and bias impedances are of importance (Ref. A12). Reprinted by permission from **RADIO ENGINEERS' HANDBOOK** by F. E. Terman, copyrighted in 1943, McGraw-Hill Book Company Inc.

R_k is now $I_k = I_b + I_{c2}$. The effect of R_k and C_k on the voltage gain at any frequency is given by the approximation (derived from Sect. 2 Eqn. 2)

$$\left| \frac{A'}{A} \right| \approx \sqrt{\frac{1 + (\omega C_k R_k)^2}{(1 + g_m R_k)^2 + (\omega C_k R_k)^2}} \quad (3a)$$

on the assumption that the screen is completely by-passed.

When the screen is not completely by-passed, so that both cathode and screen circuits are attenuating simultaneously, the cathode attenuation characteristic is affected by the screen circuit. Under these circumstances it is possible to use the method due to Terman (Refs. A12, B2) whose curves are reproduced in Figs. 12.11C and 12.11D.

Terman expresses the relationship in the form

$$\frac{\text{Actual output voltage}}{\text{Output voltage with zero bias impedance}} = \frac{1}{1 + R_f g_m \eta \beta} \quad (3b)$$

where g_m = mutual conductance of valve in mhos, at operating point
 R_f = cathode bias resistance in ohms

$$\eta = \frac{1}{1 + j(f/f_4)}$$

f = actual frequency in c/s

$f_4 = 1/2\pi C_f R_f$ = frequency at which the reactance of C_f equals bias resistance R_f

and $\beta = \left| \frac{A'}{A} \right|$ contributed by the screen circuit at frequency f as given by eqn.

(1). (Note that $\beta = 1$ for complete by-passing).

The procedure in a practical case is

1. Determine $\beta = |A'/A|$ from equation (1).
2. Knowing f and f_4 , calculate f/f_4 .
3. Apply this value of f/f_4 to Fig. 12.11C, thus determining the magnitude of η in db, and also its phase angle.
4. Calculate the value of $R_f g_m \eta \beta$, in db above unity.
5. Apply the value of $R_f g_m \eta \beta$ and the phase angle of η to Fig. 12.11D to determine the loss in gain (in decibels).

It will be seen that incomplete screen by-passing results in a smaller value of attenuation by the cathode impedance than would occur with complete screen by-passing.

Attenuation curves for a typical r.c.c. pentode are given in Fig. 12.12 for complete screen by-passing.

As a useful **rule of thumb**, sufficient for most design purposes other than for amplifiers incorporating negative feedback over 2 or 3 stages,

$$fC_k \approx 0.55g_m \text{ for 1 db attenuation} \quad (4a)$$

$$fC_k \approx 0.35g_m \text{ for 2 db attenuation} \quad (4b)$$

where C_k is in microfarads,

and g_m = mutual conductance in micromhos at the operating plate current.

The effect of incomplete cathode by-passing on phase angle displacement is approximately the same as for a triode, and the curves of Fig. 12.3C may be used, but the value of B may be taken as roughly

$$B \approx 1 + g_m R_k$$

on the assumption that μ is very large and that R' is small compared with r_p , where $R' = R_L R_{g2}/(R_L + R_{g2})$.

The combined effect of incomplete cathode and screen by-passing and of a grid coupling condenser on gain and on phase angle displacement may be determined by adding the attenuations in decibels and the phase angles in degrees, provided that eqn. (3b) is used for calculating the attenuation due to the cathode impedance.

(B) Cathode bias resistance

The cathode bias resistance should preferably be the smallest value which can be used without any danger of grid current on the maximum signal. Fortunately, however, the resistance is not critical and a higher value has very little deleterious

Fig. 12.12. Attenuation characteristics for selected values of cathode by-pass condenser with valve type 6J7 and $E_{hb} = 250$ volts, $R_L = 0.25$, $R_p = 0.5$, $R_s = 1.5$ megohms, $R_k = 2000$ ohms : screen adequately by-passed.

effect under normal operation, provided that the screen voltage is adjusted to give the correct operating plate current.

Optimum values may be calculated for any specific case by first finding the fixed bias and then calculating $R_k = E_{c1}/(I_b + I_{c2})$.

Alternatively, the value of R_k may be determined by eqn. (5f) below.

The procedure for the calculation of the cathode bias resistor when a series screen resistor is also used, is given in Sect. 3(vi)C, while the graphical method is described in Sect. 3(xiii) and (xiv).

(C) Effect of reverse grid current with cathode bias

When the screen voltage is maintained constant from a low impedance source, the following approximate relationship may be derived from Chapter 3 Sect. 1 eqn (6) :

$$\frac{R_{g1} \text{ for cathode bias}}{R_{g1} \text{ for fixed bias}} \approx 1 + R_{kgk} \approx 1 + R_{kgm} I_k / I_b \quad (4c)$$

For a typical pentode, type 6J7, the ratio is approximately 1.7, 2.1 and 2.6 for $R_L = 0.1, 0.22$ and 0.47 megohm respectively. Now the value of R_{g1} for fixed bias is derived in (v)a below for a reverse grid current of $1 \mu A_s$, so that for type 6J7 the maximum grid resistor under this condition with cathode bias and fixed screen voltage is approximately

$$\begin{aligned} 0.56 \text{ megohm for } R_L &= 0.1 \text{ megohm,} \\ 0.91 \text{ megohm for } R_L &= 0.22 \text{ megohm,} \\ 1.5 \text{ megohms for } R_L &= 0.47 \text{ megohm.} \end{aligned}$$

With a series screen resistor the following approximate relationship may be derived from Chapter 3 Sect. 1 eqn. (6).

$$\frac{R_{g1} \text{ for cathode bias}}{R_{g1} \text{ for fixed bias}} \approx 1 + R_{kgk} + \frac{P_{g1} R_{g2}}{\mu_{v1} e^2} \quad (4d)$$

The first two terms are the same as in eqn. (4c), while the third term is the same as the second term of eqn. (5b) below, so that the ratio in eqn. (4d) will normally exceed 7 : 1, for $R_L = 0.1$ megohm and will be considerably greater than this value for $R_L = 0.22$ megohm or higher.

However, it is generally advisable to limit the grid resistor to 2.2 megohms maximum for amplifiers having a reduced frequency range and 1 megohm or less for amplifiers having a maximum frequency of 10 000 c/s or more.

(v) Fixed bias

The optimum bias is the smallest which can be used without danger of positive grid current, provided that the screen voltage is adjusted to give the correct operating plate current.

If the input voltage is known,

$$E_{c1} = 1.41 E_i + k_1 + k_2 \quad (4c)$$

If the output voltage is known,

$$E_{c1} = (1.41 E_o / A) + k_1 + k_2 \quad (4f)$$

where E_i = r.m.s. input voltage

E_o = r.m.s. output voltage from plate to cathode

A = voltage gain of stage

k_1 = bias voltage to avoid damping due to positive grid current—a value of 1.0 volt maximum would cover all normal indirectly heated valves*

and k_2 = increment of bias voltage to allow for the effects of reverse grid current in the grid resistor (see below).

If a fixed screen voltage is used, and the grid resistor has the maximum value determined in (a) below, then the value of k_2 may be taken as 0.1 volt for high slope valves (e.g. 6AU6) with R_L not less than 0.1 megohm, and the same value for low slope valves with R_L not less than 0.22 megohm. The value of k_2 may be taken as 0.2 volt for low slope valves having R_L less than 0.22 but not less than 0.1 megohm.

If a series screen resistor is used, and if the grid resistor does not exceed 1 megohm, k_2 may be taken as 0.1 volt maximum.

With some valves, as the screen voltage is decreased, the grid current commencement (or cross-over) point may tend to move to a more negative value in indirectly-heated types, and to a less positive value (possibly even negative) in directly-heated battery pentodes. **Low screen voltages should therefore be avoided with zero-bias operation of battery pentodes, particularly when a high plate load resistance is used.**

The effect of reverse grid current with fixed grid bias

(a) With fixed screen voltage

The position of the operating point in pentodes, for minimum distortion, is fairly critical. Thus when the correct screen and grid bias voltages have been applied, any reverse grid current that may flow through the grid resistor R_{g1} will cause a change in bias and hence a change in plate current to a value less than the optimum. The writer considers a change of $0.1 E_{bb}/R_L$ as being the maximum permissible change in plate current due to the flow of grid current. On this basis, the maximum permissible grid resistance with fixed bias and fixed screen voltage can be shown to be given approximately by

$$R_{g1} \approx K_p \left(\frac{R_L}{1000} \right)^{0.32} \quad (5a)$$

where R_{g1} = maximum grid resistance in ohms,

R_L = load resistance in ohms,

$$K_p = \frac{8I_{b0}}{g_{m0}E_{bb}I_{c1}}$$

I_{b0} = plate current in amperes at which both g_{m0} and I_{c1} are measured,

g_{m0} = mutual conductance in mhos at plate current I_{b0} ,

E_{bb} = plate supply voltage,

and I_{c1} = maximum rated reverse grid current in amperes at plate current I_{b0} .

In this calculation the assumption was made that the ionization current is proportional to the cathode current, which relationship only holds approximately and then only when the grid leakage current is small compared with the ionization current and provided that the latter does not increase during operation.

Values of K_p have been derived for three valve types—

$$\left. \begin{array}{l} \text{Type 6J7 } K_p = 5.2 \times 10^4 \\ \text{Type 6SJ7 } K_p = 5.8 \times 10^4 \\ \text{Type 6AU6 } K_p = 5.7 \times 10^4 \end{array} \right\} \begin{array}{l} \text{for } E_{bb} = 250 \text{ volts} \\ \text{and } I_{c1} = 1 \mu\text{A.} \end{array}$$

Values of the function of R_L are given below—

*Higher values may occur in a few cases, but are not typical. See also comments on triodes in Sect. 2(iv)B. For grid damping see Sect. 2(iv)D.

R_L	$\left(\frac{R_L}{1000}\right)^{0.38}$
100 000	5.75
220 000	7.8
470 000	10.4

From which the following values may be calculated :

Type	$R_L = 0.1$	0.22	0.47 megohm
6J7	$R_{g1} = 0.3$ max.	0.4 max.	0.54 max. megohm
6SJ7	$R_{g1} = 0.33$ max.	0.45 max.	0.6 max. megohm
6AU6	$R_{g1} = 0.33$ max.	0.44 max.	0.59 max. megohm

We may therefore conclude that, for a maximum reverse grid current of $1 \mu\text{A}$, the value of R_{g1} with fixed bias and fixed screen voltage should not exceed

- 0.33 megohm for $R_L = 0.1$ megohm,
- 0.43 megohm for $R_L = 0.22$ megohm,
- 0.56 megohm for $R_L = 0.47$ megohm.

Where the variations of reverse grid currents are such that the large majority of valves would have values below half the maximum value—i.e. in this case below $0.5 \mu\text{A}$ —double these values of R_{g1} would be satisfactory. This would also apply in any cases where the maximum value of reverse grid current is specified as $0.5 \mu\text{A}$.

(b) With series screen resistor

When fixed bias is used in conjunction with a series screen resistor supplied from the plate voltage source, it may be shown from eqn. (9) of Chapter 3 Sect. 1 that

$$\frac{R_{g1} \text{ for series screen resistor}}{R_{g1} \text{ for fixed screen voltage}} \approx 1 + \frac{P_{gk} R_{g2}}{\mu_{g1g2}} \quad (5b)$$

where $P = I_{c2}/I_k$

$g_k = g_m(I_k/I_b)$ at the operating point,

R_{g2} = resistance of series screen resistor in ohms,

and μ_{g1g2} = "triode" amplification factor.

Ratios calculated from eqn. (4c) for typical valves, with a load resistance of 0.1 megohm or more, exceed 6 times, so that when a high-resistance series screen resistor is used, the grid resistor may be at least 6 times the value quoted above for fixed screen voltage.

However, it is generally advisable to limit the grid resistor to 2.2 megohms maximum for amplifiers having a reduced frequency range and 1 megohm or less for amplifiers having a maximum frequency of 10 000 c/s or more.

Fig. 12.13. Dynamic characteristic of r.c.c. pentode for fixed screen voltage (b) compared with mutual characteristic (a).

(vi) Dynamic characteristics of pentodes

(A) General description

A single dynamic characteristic of a pentode, together with the equivalent mutual characteristic, are shown in Fig. 12.13. The slope of the dynamic characteristic at any point is given by

$$g_{md} = g_m \frac{r_p}{r_p + R_L} = \frac{g_m}{1 + (R_L/r_p)} \quad (5c)$$

The values of g_m and g_{md} are normally within 10% provided that the operating plate current does not exceed $0.8 E_{bb}/R_L$. Values of g_m and g_{md} for valve types 6J7 and 6SJ7 are given in (vii) below.

Pentodes differ from triodes in that there is an unlimited number of dynamic characteristics for any selected plate voltage and load resistance, there being one characteristic for each value of screen voltage. Some typical dynamic characteristics are shown in Fig. 12.14A from which it will be seen that these have much the same general form, but that they are moved bodily sideways. Careful examination will show that the curves for lower screen voltages are less curved than those for higher screen voltages. As a general rule, the screen voltage should therefore be as low as possible, provided that the correct operating point can be maintained and that positive grid current does not flow.

Fig. 12.14A. Family of dynamic characteristics for typical r.c.c. pentode (type 6J7 with $E_{bb} = 250$ volts, $R_L = 0.25$ megohm).

(B) Optimum operating conditions

A very complete investigation (Ref. B8) has shown that all pentodes normally used with r.c. coupling may be adjusted for **maximum gain and minimum non-linear distortion** merely by ensuring that the plate current is a certain fraction (K) of E_{bb}/R_L . This plate current may be achieved either by fixing the grid bias (or cathode bias resistor) and varying the screen voltage (or series screen resistor) or vice versa. The effect of reverse grid current in the grid resistor is to decrease the effective grid bias by an amount which may be appreciable with fixed screen voltage, but may usually be neglected when a high-resistance series screen resistor is used. In the former case, with fixed screen voltage, it is suggested that the design be based on a value of half the maximum specified reverse grid current flowing through the grid resistor.

The optimum value of K is not appreciably affected by either the following grid resistor or the electrode voltages, provided only that the screen voltage is kept reasonably low. The optimum value of K for minimum distortion is, however, a function of the output voltage as indicated below.

Output voltage (r.m.s.) =	$0.04E_{bb}$	$0.08E_{bb}$	$0.16E_{bb}$	$0.24E_{bb}$
Output voltage (r.m.s.)* =	10	20	40	60
Optimum K =	0.78	0.76	0.70	0.62

*For $E_{bb} = 250$ volts.

where $K = I_b/I_{bm}$ and $I_{bm} = E_{bb}/R_L$, and $R_g = 2R_L$.

For example, with $E_{bb} = 250$ volts and $R_L = 0.25$ megohm, $I_{bm} = 1$ mA.

The voltage between plate and cathode is a function of K : $E_b = (1 - K)E_{bb}$.

When $K = 0.78$ 0.76 0.70 0.62

Then $E_b = 0.22E_{bb}$ $0.24E_{bb}$ $0.3E_{bb}$ $0.38E_{bb}$

(C) Determination of series screen and cathode bias resistors when plate and screen current curves are available

If curves of both plate and screen currents versus grid voltage under resistance loaded conditions (e.g. Figs. 12.14A and 12.18) are available, the procedure is—

1. Determine E_{c1} —see (v) above.
 2. Determine the optimum value of K —see (vi)B above.
 3. From the I_b curves, determine E_{c2} to give the required values of E_{c1} and K ; also determine I_b at the operating point.
 4. From the I_{c2} curves, determine I_{c2} at the operating point.
 5. Then $R_k = E_{c1}/(I_b + I_{c2})$ (5d)
- and $R_s = (E_{c2} - E_{c1})/I_{c2}$ (5e)

(D) Calculation of series screen and cathode bias resistors

The procedure for calculating R_s and R_k is—

1. Determine E_{c1} as for fixed bias—see (v) above.
2. Determine the optimum value of K —see (vi)B above.

$$3. \text{ Then } R_k \approx \frac{E_{c1} R_L m}{K E_{bb} (m + 1)} \quad (5f)$$

where E_{c1} = control grid voltage (taken as positive)

and $m = I_b/I_{c2}$.

Typical values of m at normal voltages are :

Type	6J7	6SJ7	6SF7	6SH7	6AC7	6AU6	1S5	1U5
m	4.0	3.75	3.75	2.63	4.0	2.54	4.0	4.0

Equation (5f) is perfectly general, and may be used with any screen voltage source.

The only approximation is the assumption that m is constant.

$$4. \text{ Then } E_{c2} \approx E_{c1} \mu_t + E_s - \frac{K E_{bb} \mu_t}{R_L g_{md}} \left(1 - \frac{R_L}{R_L} \right) \quad (5g)$$

where E_{c2} = screen voltage

μ_t = triode mu

E_s = screen voltage at which $I_b = 2$ mA for $E_{c1} = 0$

≈ 22 (for 6AU6), 25 (for 6SJ7), 39 (for 6J7)

$R_L = 0.1$ M Ω

and g_{md} = max. slope of dynamic characteristic with $R_L = 0.1$ M Ω .

Equation (5g) may also be used with fixed bias E_{c1} .

$$5. \text{ Then } R_s \approx \frac{m R_L}{K E_{bb}} (E_{bb} - E_{c2}) \quad (5h)$$

Note : This procedure is based on several approximations (e.g. that m , g_{md} and E_s are constant) but is sufficiently accurate for all practical purposes for any pentode.

It will be seen that a single operating condition is incapable of giving optimum performance for both low and high levels. For low level operation, E_{c1} may be taken as -1.3 volts, while for high level operation E_o may arbitrarily be taken as $0.24E_{bb}$ volts r.m.s. unless it is desired to determine some intermediate condition.

It will be seen from eqn. (5g) that the optimum screen voltage is a function, not only of E_{c1} , but also of R_L —a higher value of load resistance permits a lower screen voltage.

(E) Screen supply from voltage divider

Although a series screen resistor is normally preferable, the screen may be supplied in certain applications from a voltage divider. The procedure is straight forward, but the voltage should be adjusted manually or else the two resistors should have $\pm 5\%$ tolerances.

When a screen voltage divider is used, the equivalent series screen resistance is given by the resultant of the two sections of the voltage divider in parallel. This value may be used as R_{s2} in eqn. (6) of Chapter 3 Sect. 1, although if R_{s2} is less than 50 000 ohms, its effect is small.

If the equivalent series screen resistance is less than 50 000 ohms, the screen voltage may be considered as fixed, and it is then necessary to increase the grid bias to allow for the effect of reverse grid current.

The increase in grid bias is

$$\Delta E_{c1} = R_{s1} I_{c1} I_{b0} / I_{b0} \quad (6a)$$

where I_{b0} = plate current at which the reverse grid current is measured, and I_{c1} may be taken as half the maximum specified reverse grid current (say 1 μA); i.e. (say) $I_{c1} = 0.5 \mu A$.

The increased value of cathode bias resistor is given by

$$R_k' = R_k + \Delta R_k \quad (6b)$$

$$\text{where } \Delta R_k = \frac{\Delta E_{c1}}{I_b + I_{c2}} = \frac{\Delta E_{c1}}{I_b} \cdot \frac{m}{m+1}$$

and E_{c1} is given by equation (6a).

Using the suggested value of I_{c1} , we have

$$R_k' = R_k + \frac{R_{s1} \times 0.5 \times 10^{-6}}{I_{b0}} \cdot \frac{m}{m+1} \quad (6c)$$

For example, if $R_{s1} = 1$ megohm, $I_{b0} = 2$ mA, and $m = 4$, then

$$R_k' = R_k + 200 \text{ ohms.}$$

(vii) Gain at the mid-frequency

(A) The voltage gain at the mid frequency (for small input voltages) is given by

$$A_0 = \frac{g_m}{(1/r_p) + (1/R_L) + (1/R_g)} \quad (7)$$

where g_m = mutual conductance at operating plate current,

r_p = plate resistance at operating point,

and R_g = resistance of following grid resistor.

The mutual conductance at the working plate current is often an unknown factor, and methods for determining it are given below (E).

(B) Alternatively, the gain may be calculated from the slope of the dynamic characteristic :

$$A_0 = g_{md} R \left(\frac{r_p + R_L}{r_p + R} \right) \approx g_{md} R \quad (8)$$

where g_{md} = slope of dynamic characteristic at the operating point—see (E) below, and $R = R_L R_g / (R_L + R_g)$.

(C) The gain may also be calculated graphically from the dynamic characteristic (Fig. 12.13). If the peak-to-peak grid input voltage is CD, then the instantaneous plate current will swing between the extreme limits M and P, giving a peak-to-peak output voltage EF measured on the plate voltage scale. To allow for the effect of R_g , the output voltage must be multiplied by the factor $R_g / (R_g + R')$ where $R' = r_p R_L / (r_p + R_L) \approx R_L$.

Typical voltage gains are :

R_L	R_g	6J7	6SJ7	6AU6
0.1 megohm	0.5 megohm	94	104	168
0.25 megohm	0.5 megohm	140	167	230*
0.5 megohm	2.0 megohms	230	263	371**

* $R_L = 0.22$ megohm. ** $R_L = 0.47$ megohm.

If the resistance of the following grid resistor R_g is limited, the **maximum gain on low input voltages** is obtained when the load resistance is approximately equal to the following grid resistance, i.e. $R_L \approx R_g$.

(D) Gain in terms of g_m and g_p

Eqn. (7) may be put into the alternative form

$$A_0 = \frac{g_m R}{1 + g_p R} \quad (9a)$$

where $R = R_L R_g / (R_L + R_g)$

and g_p = plate conductance = $1/r_p$.

Unfortunately "G," curves for pentodes hold only for a fixed screen voltage and are not flexible (g_m curves for type 7E7 are shown in Ref. A15).

(E) The determination of g_m , g_{ma} , and r_p

The values of g_m , g_{ma} and r_p for use in equations (7), (8) and (9) are difficult to calculate with any precision, but may be measured on an average valve.

Curves of constant g_{ma} could, with advantage, be plotted on the family of dynamic characteristics such as Fig. 12.14A, although this has not yet been done.

Mutual conductance

For the general case see (x)A below. Fig. 12.14B gives an approximation to the maximum value of g_m with any load resistance for two typical pentodes. This value is believed to be accurate within $\pm 10\%$ for an average valve.

Slope of dynamic characteristic

The value of the slope of the dynamic characteristic at any point is given by

$$g_{ma} = g_m / (1 + R_L / r_p) \quad (9b)$$

where g_{ma} = slope of dynamic characteristic at operating point

g_m = mutual conductance at operating point

and r_p = plate resistance at operating point.

FIG. 12.14B

Fig. 12.14B. Mutual conductance of resistance-capacitance coupled pentodes types 6J7 and 6SJ7 plotted against load resistance. In each case the value of K is taken as being adjusted to give maximum mutual conductance.

Plate resistance

The value of plate resistance r_p at the operating point may be estimated from Sect. 3(x) below.

Data for types 6J7 and 6SJ7

Detailed values of mutual conductance (g_m), slope of the dynamic characteristic (g_{ma}) and plate resistance (r_p) for types 6J7 and 6SJ7 are tabulated below. It is emphasized that there are considerable variations between valves, particularly with the plate resistance.

Valve type Plate supply voltage Published g_m^*		6J7 250 1225			6SJ7 250 1650			volts μmhos
R_L M Ω	K	g_m μmhos	$g_{m a}$ μmhos	r_p M Ω	g_m μmhos	$g_{m a}$ μmhos	r_p M Ω	
0.1	0.78	1065	980	0.6	1390	1280	0.7	
	0.76	1080	1010	0.67	1380	1290	0.9	
	0.70	1130	1080	1.1	1370	1310	1.3

	0.62	595	575	5.2	590	580	5.0	
	0.55	550	540	6.0	519	495	5.4	

*With $E_b = 250$ volts, $E_{c2} = 100$ volts, $E_{c1} = -3$ volts.

(viii) Dynamic characteristics of pentodes and comparison with triodes

A family of dynamic characteristics for a typical pentode is shown in Fig. 12.14A. There is one curve for every possible value of screen voltage, but it is obvious that those for lower screen voltages (e.g. 30 volts) are less curved than those for higher voltages. In actual operation the quiescent operating point is fixed, and the signal voltage on the grid causes the plate current to swing along the dynamic curve. This only holds strictly when there is no following grid resistor or other shunt load, but it is sufficient for design purposes since allowance can readily be made for the effect of R_g in reducing both the voltage gain (eqn. 8) and the output voltage.

The voltage drop in R_L is proportional to the plate current, and therefore a plate voltage scale may be added to Fig. 12.14A. The general treatment and the calculation of gain are identical with those for ideal linear dynamic characteristics as applied to triodes in Sect. 2(viii). In the case of pentodes the operation can be kept outside the grid current region, without any other loss, by selecting a suitable screen voltage.

A single pentode dynamic characteristic (that is one for a fixed screen voltage) is drawn as curve b in Fig. 12.13. For comparison, curve a has also been included, this being the ordinary mutual characteristic for the same screen voltage. At low plate currents the two are practically identical but they diverge steadily up to the point of inflexion* P, beyond which the dynamic characteristic forms the "top bend."

The line XY is at a plate current $I_{bm} = E_{bb}/R_L$ at which the factor $K = 1$. This curve is typical of the shape of all pentode dynamic characteristics which differ mainly in the slope and the horizontal displacement of the curve. The effects of changes in R_L are largely overcome by the use of the factor K in place of the actual plate current.

Comparison between triode and pentode dynamic characteristics

Both triode and pentode dynamic characteristics are shown in Fig. 12.15 in such a way as to enable a comparison to be made between them. Over the region from $K = 0.4$ to $K = 0.6$ they appear to be very similar, but in the region from $K = 0.15$ to 0.4 the pentode characteristic appears less curved than the triode, while in the region from $K = 0.6$ to 0.8 the triode characteristic appears less curved than the pentode.

*The point of inflexion is the point at which the curvature changes from one direction to the other, and is the point of greatest slope.

Fig. 12.15. Comparison between pentode and triode dynamic characteristics of the same valve (6SJ7 with $E_{bb} = 250$ volts, $R_L = 0.25$ megohm, $E_{c2} = 22.5$ volts for pentode, E_{c2} connected to plate for triode characteristics; triode characteristics divided by slope factor 0.0813 and superimposed so that points for $I_b = 0.5$ mA coincide).

(ix) Maximum voltage output and distortion

The maximum voltage output, with any specified limit of distortion, is obtained when R_p is much greater than R_L . If R_p is limited, the maximum voltage output is obtained when R_L is much less than R_p . The following table is typical of r.c.c. pentodes such as types 6J7 and 6SJ7, and also enables a comparison to be made with triodes. The optimum value of K has been used throughout.

Intermodulation distortion* with $E_{bb} = 250$ volts

Output voltage†	10	19	37	63
Valve type 6J7	Intermodulation distortion %			
$R_L = 0.1 \text{ M}\Omega$ $R_p = 0.1 \text{ M}\Omega$	0.35	2.2	8.6	—
0.2	0.3	1.5	4.6	14.0
0.4	0.26	0.85	3.9	12.5
$R_L = 0.25 \text{ M}\Omega$ $R_p = 0.25 \text{ M}\Omega$	0.65	1.9	7.4	37
0.5	0.5	1.6	4.4	17
1	0.35	1.4	3.5	15
$R_L = 0.5 \text{ M}\Omega$ $R_p = 0.5 \text{ M}\Omega$	1.0	3.7	14.0	54
1	0.8	2.6	9.5	32
2	0.5	2.0	6.5	19
Valve type 6SJ7				
$R_L = 0.1 \text{ M}\Omega$ $R_p = 0.1 \text{ M}\Omega$	1.0	2.9	12.0	—
0.2	0.9	2.2	8.3	24
0.4	0.8	1.5	5.9	20
$R_L = 0.25 \text{ M}\Omega$ $R_p = 0.25 \text{ M}\Omega$	2.1	6.0	16.0	67
0.5	1.1	3.8	13.0	38
1	1.0	3.0	11.0	23
$R_L = 0.5 \text{ M}\Omega$ $R_p = 0.5 \text{ M}\Omega$	3.0	8.3	18.0	76
1	2.1	6.6	15.0	42
2	1.5	4.4	12.5	28

The maximum output voltage for limited intermodulation distortion (r.m.s. sum) is indicated below for type 6SJ7 pentode with $R_p = 4R_L$.

R_L	$E_{0(r.m.s.)}/E_{bb}$			
	I.M. = 2.5%	5%	10%	20%
0.1 M Ω	0.09	0.13	0.18	0.25
0.25	0.08	0.11	0.16	0.22
0.5	0.07	0.09	0.13	0.20

When $R_p = 2R_L$, the factors above should be multiplied by 0.87. When $R_p = R_L$, the factors above should be multiplied by 0.7. The values are for $E_{bb} = 250$ volts, but hold closely over the range from 200 to 300 volts. Optimum operating conditions are assumed.

Harmonic distortion

Type 6SJ7 with $E_{bb} = 250$ volts, $R_L = 0.25 \text{ M}\Omega$, $R_p = 0.5 \text{ M}\Omega$

$K =$	0.8	0.76	0.72	0.65	0.6	0.56
$E_{0(r.m.s.)}$ volts	8	16	30	52	62	78

*Modulation method—r.m.s. sum. For details and for relation between intermodulation and harmonic distortion see Chapter 14 Sect. 3.

†The arithmetical sum of the r.m.s. values of the two component waves.

Comments

1. Type 6J7 (with published $g_m = 1225 \mu\text{mhos}$) has less distortion than type 6SJ7 (with published $g_m = 1650 \mu\text{mhos}$) under the same conditions.

The distortion for a given output voltage increases when a valve is replaced by another having higher mutual conductance, although there are also differences between valve types having approximately the same mutual conductance.

2. Load resistance $R_L = 0.1$ megohm provides lower distortion than higher values of load resistance.

3. The distortion under any given conditions decreases when the resistance of the following grid resistor is increased.

Comparison between triode and pentode

[Refer Sect. 2(ix)]

The comparison is based on intermodulation distortion with type 6SJ7 as both triode and pentode, having $R_L = 0.25$ and $R_p = 1.0$ megohm (Fig. 12.16A). Generally similar results are obtained with type 6J7 and with other load resistances (Ref. B8).

1. At the level used in the first a-f stage in a typical receiver ($E_0 = 10$ volts r.m.s.) the pentode gives only about one eighth of the intermodulation distortion given by a triode, when both are adjusted for minimum distortion.

2. The two curves in Fig. 12.16A cross, and the intermodulation distortion is therefore the same for both triode and pentode, at about 31 r.m.s. volts output.

3. At higher output voltages the pentode gives the greater intermodulation distortion, the ratio being 2.3 : 1 at 63 r.m.s. volts output.

4. The pentode, to give the minimum value of distortion, requires fairly critical adjustment. Under the working conditions recommended in this section, however, the distortion with a pentode is likely to be less than with a general-purpose triode at output voltages up to about 20 volts r.m.s.

Fig. 12.16A. Intermodulation distortion for type 6SJ7 with $E_b = 250$ volts, $R_L = 0.25 M\Omega$, $R_p = 1.0 M\Omega$, in both triode and pentode operation.

(x) Conversion factors with r.c.c. pentodes

(A) The mutual conductance may be derived from published data (generally plotted against E_{c1}) or if these are not available then it may be calculated as for triodes, Sect. 2(x). See also values quoted for 6J7 and 6SJ7 in (vii) above.

(B) The plate resistance may be estimated by the following method from published data. The usual data are for either equal plate and screen voltages (e.g. 100 V) or for 250 V and 100 V respectively. Unfortunately there is no general rule for calculating the effect of a change of plate voltage on the plate resistance, and the accuracy obtainable by graphical means is very poor. However, as some sort of guide, the plate resistance of type 6SJ7 is increased about twice, and of type 6J7 about 2.75 times, for a change from 100 to 250 volts on the plate, with 100 volts on the screen and -3 volts grid bias.

The plate resistance of a r.c.c. pentode may vary from slightly below the published value at $E_b = E_{c2} = 100$ volts, to 6 or 8 times this value, depending on the load resistance and value of K . Typical values for types 6J7 and 6SJ7 are given below [see also table in (vii) above] :

$R_L = 0.1$ megohm

$R_L = 0.25$ megohm

$R_L = 0.5$ megohm

$r_p = 0.6$ to 2.1 megohms

$r_p = 1.6$ to 3.7 megohms

$r_p = 3.0$ to 6.0 megohms

for $K = 0.78$ to 0.55 respectively.

There are considerable variations between different valves, and some may have plate resistances less than half these values, while others may have higher plate resistances.

(C) Conversion factors applied to whole amplifiers

If one set of operating conditions is available, it is possible to calculate others.

Given:

E_{bb}	R_L	R_k	R_s	R_g	A	E_o
300 V	0.1 MΩ	450 Ω	0.5 MΩ	0.25 MΩ	82	81 V

Example:

(1) To calculate conditions for $R_L = 0.25$ megohm,

$E_{bb} = 300$ volts:—

$F_r = 2.5$ (i.e. resistance conversion factor).

$R_k = 2.5 \times 450 = 1130$ ohms.

$R_s = 2.5 \times 0.5 = 1.25$ megohms.

$R_g = 2.5 \times 0.25 = 0.75$ megohm.

E_o will be approximately the same for the same distortion.

A is affected both by the load and the mutual conductance.

The load resistance factor is 2.5; the mutual conductance factor is $\sqrt[3]{I_{b2}/I_{b1}} = \sqrt[3]{1/2.5} = 0.74$. Therefore $A = 82 \times 2.5 \times 0.74 = 152$.

Note: If E_{bb} had been altered, the mutual conductance factor would have been $\sqrt[3]{E_{bb2}R_{L1}/E_{bb1}R_{L2}}$.

(2) If all resistors are multiplied by a factor F_r , leaving E_{bb} unchanged, the voltage gain will be increased approximately as tabulated:

F_r	0.4	0.5	0.75	1.0	1.5	2	2.5
-------	-----	-----	------	-----	-----	---	-----

Voltage

gain	0.54A	0.63A	0.83A	A	1.43A	1.58A	1.85A approx.
------	-------	-------	-------	---	-------	-------	---------------

In practice these may vary $\pm 10\%$ or even more.

(xi) Equivalent circuit of r.c.c. pentode

The exact a.c. equivalent plate circuit of a r.c.c. pentode is given in Fig. 12.16B where the "constant current generator" circuit has been adopted. This could equally be applied to the triode case (Fig. 12.8) or vice versa. In other respects the triode and pentode equivalent circuits are identical [see Sect. 2(xii)]. Both the cathode and screen circuits are assumed to be adequately by-passed at all signal frequencies, or the effects to be separately calculated.

Fig. 12.16B. Exact a.c. equivalent plate circuit of a r.c.c. pentode.

(xii) Voltage gain and phase shift

Provided that the cathode and screen circuits are adequately by-passed at all signal frequencies, or that their voltages are obtained from low impedance sources, the voltage gain and phase shift will be the same as for the triode case [Sect. 2(xiii)]. In the case of a pentode it is usually possible to neglect the "Miller Effect" capacitance from the plate circuit.

The low frequency response [Sect. 2(xiii); eqn. (15)] will be slightly higher than for a triode with the same values of C_1 , R_L and R_g owing to the higher value of r_p .

The high frequency response [Sect. 2(xiii), eqn. (16)] will normally be lower than that for a triode, owing to the higher value of R'' due again to the higher plate resistance. The valve output capacitance is usually greater for a pentode than for a triode, this being a further contributing factor. The high frequency response may be extended to higher frequencies by reducing the resistance of the plate load resistor, although at the cost of gain. A similar result may be achieved by the use of negative voltage feedback.

The effect of the screen and cathode by-passing has been covered in (iii) and (iv) above.

(xiii) Screen loadlines

(A) Exact method using I_{c2} versus E_{c2} characteristics

These characteristics (Fig. 12.17) only apply to a single value of supply voltage and plate load resistance. The screen loadline is a straight line drawn from A to B.

Point A : $E_{c2} = E_{cc2}$ (here 250 volts), $I_{c2} = 0$

Point B : $E_{c2} = 0$, $I_{c2} = E_{cc2}/R_s$ (here $250/1.5 = 167 \mu\text{A}$).

It is then necessary to transfer the values of E_{c2} at the intersections of the E_{c1} curves and the loadline, to a second curve in which E_{c1} is plotted against E_{c2} . From the latter, the values of E_{c1} corresponding to the screen voltages of the dynamic characteristics (Fig. 12.14A) are determined, and transferred directly to the plate dynamic characteristics, and the screen loadline drawn as a smooth curve (Fig. 12.19).

Fig. 12.17. Screen I_{c2} versus E_{c2} characteristic for type 6J7; $E_{bb} = 250$ volts, $R_L = 0.25 \text{ M}\Omega$. A screen loadline is shown.

(B) Exact method using I_{c2} versus E_{c1} characteristics

This is an alternative method illustrated by Fig. 12.18 on which the screen loadline (which in this case is slightly curved) may be plotted. On each E_{c2} curve plot the corresponding value of I_{c2} derived from the equation

$$I_{c2} = (E_{cc2} - E_{c2})/R_s \quad (10)$$

Then draw a smooth curve (CD in Fig. 12.18) through the plotted points. The values of E_{c1} corresponding to the points of intersection are then transferred directly to the plate dynamic characteristic, and the loadline drawn as a smooth curve (Fig. 12.19).

Fig. 12.18. Screen I_{c2} versus E_{c1} characteristics for type 6J7; static curves are for $E_{bb} = 250$ volts, $R_L = 0.25 \text{ M}\Omega$. A screen loadline is shown.

(C) Approximate method*

This is based on the assumption that the ratio of plate and screen currents is constant, such being only a rough approximation; it is, however, good enough for many purposes. Using the conditions for Fig. 12.19 and assuming $I_b/I_{c2} = 4.0$ (as for type 6J7) and $R_s = 1$ megohm, we can draw up the table:

E_{c2}	$(E_{c2} - E_{c1})$	I_{c2}	$I_b = 4I_{c2}$
100 V	150 V	0.15 mA	0.60 mA
80	170	0.17	0.68
60	190	0.19	0.76
40	210	0.21	0.84
20	230	0.23	0.92

The values of I_b are then plotted on the characteristics corresponding to the respective screen voltages (E_{c2}). The screen loadline (Fig. 12.19) is almost a straight line which may be extended to cut the horizontal axis at approximately

$$E_{c1} \approx -E_{c2}/\mu_t \quad (11)$$

and which may be shown to have a slope of approximately

$$m\mu_t g_{md}/(R_s g_{md} + m\mu_t) \quad (12)$$

where μ_t = valve triode mu,

g_{md} = slope of plate dynamic characteristic at point of interest,

and m = ratio of plate to screen currents.

Alternatively, the point of intersection of the screen loadline with the horizontal axis may be determined by the point of cathode current cut-off on the "triode" characteristics (if available) where $E_b = E_{c2}$.

The plate current at $E_{c1} = 0$ is given approximately by

$$I_{b0} \approx m g_{md} E_{c2}/R_s g_{md} + m\mu_t \quad (13)$$

The value of screen resistor to provide a plate current $I_b = KE_{cb}/R_L$ at a fixed grid voltage E_{c1} when $E_{c2} = E_{cb}$ is given approximately by

$$R_s \approx \frac{m}{K} \left\{ R_L - \frac{\mu_t R_L E_{c1}}{E_{cb}} - \frac{K\mu_t}{g_{md}} \right\} \quad (14)$$

Fig. 12.19. Plate dynamic characteristics for type 6J7 with screen loadline.

Variations in ratio between plate and screen currents

Although considerable variations exist, particularly in the region of high plate current, there is a comparatively large region within which the ratio is constant within $\pm 5\%$, this being fortunately in the region most generally useful for amplification (e.g. shaded area in Fig. 12.20).

The variations which occur are mainly caused by the variations in the ratio of plate to screen voltages. It is clear that they will be serious for E_b less than E_{c2} (above broken line in Fig. 12.20) but the variations become greater as E_b approaches E_{c2} . If it is desired to make accurate calculations involving an assumed constant value of $m (= I_b/I_{c2})$ it is desirable to maintain E_b/E_{c2} nearly constant. The use

*A further approximate method is described in Ref. B12.

of a series screen resistor with a resistance equal to mR_s (or slightly above this value) assists in maintaining the constant current ratio.

(xiv) Combined screen and cathode loadlines and the effect of tolerances

(A) Cathode loadlines

The method normally adopted is an approximate one but very convenient, since it may be used directly with the plate dynamic characteristics. Provided that $I_b/I_{c2} = m = \text{constant}$, the current through R_k will be $(m+1)I_b$, so that it is necessary to use a "conversion factor" of $m/(m+1)$ in respect to both the current and slope of the loadline. For example if $m = 4$, the loadline for a cathode bias resistor of 2000 ohms would have a slope of $-1/2500$ mhos. The effect of any error in the value of m is minimized through the screen current being only a small fraction of the cathode current.

Fig. 12.20. Plate dynamic characteristics for type 6J7 with curves of constant plate to screen current ratio. The shaded area has m within $\pm 5\%$.

Fig. 12.21. Cathode loadline (OF) with single plate dynamic characteristic for type 6J7. The broken lines show the limits of $\pm 10\%$ tolerances in R_k .

The method is illustrated in Fig. 12.21 where only one plate dynamic characteristic is shown, with a cathode bias loadline OF having a slope of $-m/(m+1)R_k$. The static operating point is at P, the intersection of OF with the dynamic characteristic. Owing to the very large plate load resistors commonly employed, there is very little rise in plate current due to rectification effects, so that P may be regarded as the dynamic operating point.

The effect of $\pm 10\%$ variation in R_k is illustrated by lines OF'' and OF' respectively in Fig. 12.21.

It may readily be shown geometrically that $\pm 10\%$ variation in R_k has less effect on I_b than $\pm 10\%$ variation in E_{c1} .

(B) Cathode and screen loadlines and tolerances

When both cathode and screen resistors are used, the point of operation is the intersection of the two loadlines (Fig. 12.22). In this diagram it has been assumed that the screen loadline is a straight line, this being closely correct except at very low and high values of I_b . However, any practicable method for determining the screen loadline may be used—see (xiii) above.

The effect of $\pm 10\%$ variation in the resistance of R_s is indicated by the broken lines, and the combined effect with $\pm 10\%$ variation of both R_s and R_k is indicated by the region shown shaded. It is on account of these inevitable variations, together with valve variations, that it is inadvisable to operate with too low a nominal screen voltage and consequently very close to the grid current point.

(C) Tolerances in general

All three resistors R_L , R_s , and R_k have partially self-compensating effects which enable fairly satisfactory results to be obtained with ordinary 10% tolerances in the resistors. If operation is required for minimum harmonic distortion at low level or

Fig. 12.22. Plate dynamic characteristics of type 6J7 with screen and cathode loadlines, showing the effect of $\pm 10\%$ tolerances in both R_s and R_k .

for a high output voltage, the resistors may beneficially have closer tolerances or be selected so that high R_L , high R_s and high R_k go together, and similarly with low values.

The supply voltage may be varied by a ratio up to 2 : 1 in either direction without very serious effects in normal operation and without necessarily making any change in R_L , R_s or R_k .

(xv) Remote cut-off pentodes as r.c.c. amplifiers

Remote cut-off ("variable- μ ") pentodes may be also used satisfactorily as r.c.c. amplifiers, although they give higher distortion for the same voltage output, and should therefore be restricted to low level operation. However, they are quite satisfactory in ordinary radio receivers for the first a-f stage driving an output pentode. Operation is slightly more critical than with sharp cut-off pentodes, but a value of $K = 0.78$ is reasonably close for low level operation.

As a typical example, intermodulation distortion on type 6SF7 is tabulated for $E_{bb} = 250$ volts.

R_L	R_g	$E_g = 10$	19	37	63 volts r.m.s.
0.25 M Ω	0.25 M Ω	1.8%	5.5%	17%	—
	0.5	1.5%	4.0%	13.5%	52%
	1.0	1.2%	3.0%	10.5%	34%
	Optimum value of K				
0.25 M Ω		0.8	0.78	0.73	0.63

(xvi) Multigrid valves as r.c.c. amplifiers

All types of multigrid valves may be used as r.c.c. amplifiers, and behave effectively the same as pentodes provided that the unused grids are connected to suitable fixed voltages. Operating conditions, including suitable values of K , are the same as for pentodes.

(xvii) Special applications

1. An article giving useful information on 28 volt operation is Ref. B4.
2. An article describing a special pentode operating as two triodes in cascade, giving gains up to 500 with a 45 volt plate supply, is Ref. B6.

(xviii) Comments on tabulated characteristics of resistance-coupled pentodes

Comments are as for triodes—Sect. 2(xiv). See Sect. 3(v), (vi)B and E for optimum operating conditions.

SECTION 4: TRANSFORMER-COUPLED VOLTAGE AMPLIFIERS

(i) *Introduction* (ii) *Gain at the mid-frequency* (iii) *Gain at low frequencies* (iv) *Desirable valve characteristics* (v) *Equivalent circuits* (vi) *Gain and phase shift at all frequencies* (vii) *Transformer characteristics* (viii) *Fidelity* (ix) *Valve load-lines* (x) *Maximum peak output voltage* (xi) *Transformer loading* (xii) *Parallel feed* (xiii) *Auto-transformer coupling* (xiv) *Applications* (xv) *Special applications.*

(i) Introduction

Transformer-coupled voltage amplifiers usually employ general purpose triode valves with plate resistances about 6 000 to 10 000 ohms. Valves having higher plate resistance require excessively large transformer inductances, while valves having lower plate resistances are only used in special applications, with transformers designed to handle the higher plate currents.

A typical transformer-coupled amplifier stage is shown in Fig. 12.23 where V_1 is the valve under consideration, with transformer T coupling it to the grid of the following valve (V_2). The stage gain is the voltage gain from the grid of V_1 to the grid of V_2 . Push-pull transformers are covered in Section 6. Read also Chapter 5 Sections 1, 2 and 3.

Fig. 12.23. Circuit diagram of transformer-coupled voltage amplifier

(ii) Gain at the mid-frequency

An unloaded transformer with high inductance and low losses has a very high impedance at the mid-frequency; an input impedance of 1 megohm at 1000 c/s is not uncommon.

With the circuit of Fig. 12.23, the voltage gain at the mid-frequency is very nearly

$$A_0 = \mu T \quad (1)$$

where μ = amplification factor of valve

T = turns ratio = N_2/N_1

N_1 = primary turns

and N_2 = secondary turns.

The gain with loaded transformers is dealt with in (xi) below.

(iii) Gain at low frequencies

At low frequencies the gain is reduced by the shunting effect of the primary inductance. The gain relative to that at the mid-frequency (A_0) is given in Chapter 5 Sect. 3(iii)a particularly eqn. (1).

(iv) Desirable valve characteristics

- (a) Low plate resistance—gives better bass response.
- (b) High amplification factor—gives higher gain.

- (c) Low operating plate current—reduces the direct current through the transformer primary and thus increases the effective inductance compared with a valve having a higher plate current. If necessary, any valve may be over-biased so as to bring the plate current to a suitable value—5 mA is quite usual.
- (d) High maximum plate voltage—only desirable if a high input voltage is required by the following stage (e.g. push-pull low μ triodes, or cathode follower).

(v) Equivalent circuits

See Chapter 5 Sect. 2, particularly Fig. 5.9, the input terminals of which are to be understood as being connected to a generator μe_g in series with r_p .

(vi) Gain and phase shift at all frequencies

A transformer tends to produce a peak in the gain/frequency characteristic due to the series resonance between the total leakage inductance and the distributed capacitance of the secondary. This peak may be made negligible by ensuring that

$$Q_s = \omega_1 L' / [r_1 + (r_2/T^2) + r_p] \leq 0.8 \quad (2)$$

where $Q_s = Q$ of resonant circuit in secondary

$$\omega_1 = 2\pi \times \text{frequency of resonance} = \sqrt{1/L'C_sT^2}$$

L' = leakage inductance referred to primary

C_s = secondary equivalent shunt capacitance

r_1 = d.c. resistance of primary

r_2 = d.c. resistance of secondary

and T = turns ratio = N_2/N_1 .

Irrespective of the value of Q_s , there is a 90° phase angle shift (lagging) at the frequency of resonance which extends asymptotically to 180° at infinite frequency. The rate of change is more gradual for lower values of Q_s . It is on account of this phase shift that transformer coupling is avoided as far as possible with negative feedback, and that (when unavoidable) the secondary is heavily damped to give a low Q_s .

At low frequencies a transformer-coupled amplifier has the same attenuation and phase angle shift (leading) characteristics as a r.c.c. amplifier due to its grid coupling condenser alone (see Fig. 12.9).

See Refs. A12 (pp. 366-371 and curves Fig. 13) ; A13 (pp. 28-38).

(vii) Transformer characteristics

See Chapter 5 Section 3.

(viii) Fidelity

Distortion caused by the valve is usually very low in the vicinity of the mid-frequency with unloaded transformers of high impedance—about 1% to 2% second harmonic with maximum grid swing—but it increases as the transformer is loaded, up to about 5% second harmonic and 2% or 3% third harmonic. At frequencies below 1000 c/s the impedance steadily falls, while the loadline opens out into a broad ellipse at low frequencies. The valve distortion may be considerable at high output levels under these conditions [see Chapter 2 Sect. 4(vi)].

The transformer (core) distortion is usually quite appreciable and may cause serious intermodulation distortion [see Chapter 5 Sect. 3(iii)].

(ix) Valve loadlines

The loadline for the mid-frequency approximates to a resistive loadline [see Chapter 2 Sect. 4(i) and (ii)]. The procedure is identical to that for Fig. 2.23 except that the loadline AQB is at a smaller angle to the horizontal.

(x) Maximum peak output voltage

To determine the maximum peak output voltage for the mid-frequency, refer to the published curves (say type 6J5), determine I_b (say 5 mA) and E_b (say 250 V) ; mark Q at $E_b = 250$, $I_b = 5$ mA ; draw a horizontal loadline through Q ; determine E_{b0} for the grid current point ($E_c = -0.5$ V) on the loadline—here $E_{b0} = 65$ volts.

The maximum peak output voltage in this example is $(E_b - E_{b0})T = (250 - 65)T = 185T$ volts $= 0.74 E_b T$. This is reduced as the load becomes less, and a value of about $0.65 E_b T$ is fairly typical.

(xi) Transformer loading

A resistor shunted across the secondary reduces the value of Q_s , thereby giving more uniform high frequency response, and also extends the low frequency response. A resistor shunted across the primary extends the low frequency response. If f_1 is the low frequency giving a specified attenuation with an unloaded transformer, then the same attenuation is reached at $0.5 f_1$ when the total shunt load effective across the primary is equal to r_p , and at $(2/3) f_1$ with a shunt load of $2r_p$.

Loading results in higher valve distortion and secondary loading also results in higher transformer distortion. Loading is generally undesirable, although unavoidable in some applications; it reduces the maximum peak output voltage and the gain.

The effective load on the valve is given by $R_L = R_1 + R_2/T^2$

where R_1 = resistance shunted across the primary

R_2 = resistance shunted across the secondary

and $T = N_2/N_1$ = turns ratio.

(xii) Parallel feed

Parallel feed (Fig. 12.24) avoids the direct plate current passing through the transformer primary and thereby increases its effective inductance, and decreases transformer distortion. Owing to the drop in R_L the average plate voltage will be con-

Fig. 12.24. Circuit diagram of parallel-fed transformer-coupled voltage amplifier.

siderably less than the supply voltage and this may restrict the maximum output voltage. If a high output voltage is required, the supply voltage may be increased up to the maximum rating. It is generally desirable to make R_L a resistance of 3 or 4 times the plate resistance of the valve. Higher values of R_L result in increased distortion at low frequencies due to the elliptical load-line. Lower values of R_L result in lower gain and increased distortion at all frequencies.

The optimum value of C is dependent upon the transformer primary inductance, and the following values are suggested—

$L =$	10	20	30	50	100	150
$C =$	4.0	2.0	2.0	1.0	0.5	0.5 μF .

These values of capacitance are sufficiently high to avoid resonance at an audible frequency. Use is sometimes made of the resonance between C and the inductance of the primary to give a certain degree of bass boosting. By this means a transformer may be enabled to give uniform response down to a lower frequency than would otherwise be the case. It should be noted that the plate resistance of the valve, in parallel with R_L , forms a series resistance in the resonant circuit. The lower the plate resistance, the more pronounced should be the effect [see Chapter 15 Sect. 2(iii)C].

It is frequently so arranged that the resonant frequency is sufficiently low to produce a peak which is approximately level with the response at middle frequencies, thereby avoiding any obvious bass boosting while extending the frequency range to a maximum.

For mathematical analysis see Ref. A13 pp. 38-41.

In all cases when making use of any resonance effects involving the inductance of the transformer primary, it is important to remember that this is a variable quantity.

Not only are there considerable variations from one transformer to another, but there are large variations of inductance caused by the a.c. input voltage (see Chapter 5).

The series resonant circuit presents a low impedance to the valve at the resonant frequency, thus tending to cause serious distortion, particularly when the valve is being operated at a fairly high level. For these reasons the resonance method is not used in good design.

(xiii) Auto-transformer coupling

An "auto-transformer" is a single tapped inductance which is used in place of a transformer. Fig. 12.25 shows a parallel-fed auto-transformer coupled amplifier. The auto-transformer may be treated as a double-wound transformer (i.e. with separate primary and secondary) having primary turns equal to those between the tap and earth, and secondary turns equal to the total turns on the inductance. A step-up or step-down ratio may thus be arranged. An ordinary double-wound transformer may be connected with primary and secondary in series (with sections aiding) and used as an auto-transformer, but capacitance effects between windings may affect the high-frequency response of certain types of windings.

The inductance between the tapping point and earth should be the same as for a normal transformer primary. With the parallel-fed arrangement of Fig. 12.25 the plate current does not flow through the inductance, but an alternative arrangement is to omit the parallel-feed and to add a grid coupling condenser and grid resistor for V_2 .

Fig. 12.25. Circuit diagram of parallel-fed auto-transformer coupled voltage amplifier.

Fig. 12.26. Choke-capacitance coupled voltage amplifier.

(xiv) Applications

The cost of a transformer having linear response over a wide frequency range is considerable and, since equally good response may generally be obtained by a very simple resistance-coupled amplifier, the transformer is only used under circumstances where its particular advantages are of value. Some of these are—

- (1) High output voltage for limited supply voltage,
- (2) Stepping up from, or down to, low-impedance lines,
- (3) When used with split or centre-tapped secondary for the operation of a push-pull stage, and
- (4) When a low d.c. resistance is essential in the grid circuit of the following stage.

(xv) Special applications

(a) **Cathode loading** : V_1 in Fig. 12.25 may be connected as a cathode follower either with the transformer primary in the cathode circuit or with parallel feed (see Chapter 7 Sect. 2(i)G).

(b) **28 volt operation** : see Reference B4.

SECTION 5 : CHOKE-COUPLED AMPLIFIERS

(i) *Performance* (ii) *Application.*

(i) Performance

A typical choke-capacitance coupled amplifier is shown in Fig. 12.26. The operation and design are similar to those of a transformer-coupled amplifier (Fig. 12.23) with a transformer ratio 1 : 1 except that C must be designed as in a r.c.c. amplifier to avoid additional low frequency attenuation. An amplifier of this type produces a higher maximum output voltage than a r.c.c. amplifier but less than that with a step-up transformer.

(ii) Application

It is occasionally used with valves having rather high plate current, for which a suitable transformer may not be available. It was also used with tetrode valves of old design, the inductance being several hundred henries, shunted by a resistance of about 0.25 megohm.

SECTION 6 : METHODS OF EXCITING PUSH-PULL AMPLIFIERS

(i) *Methods involving iron-cored inductors* (ii) *Phase splitter* (iii) *Phase inverter* (iv) *Self-balancing phase inverter* (v) *Self-balancing paraphase inverter* (vi) *Common cathode impedance self-balancing inverters* (vii) *Balanced output amplifiers with highly accurate balance* (viii) *Cross coupled phase inverter.*

Normally we begin with a single-sided amplifier, and then at some suitable level a stage may be inserted having a single input and a push-pull output. In a radio receiver such a stage usually immediately precedes the output stage, but in more ambitious amplifiers there may be several intermediate push-pull stages. In this section we consider the methods of exciting push-pull amplifiers.

(i) Methods involving iron-cored inductors

(A) Tapped secondary transformer (Fig. 12.27A)

This needs little explanation except that the input transformer step-up ratio (primary to half secondary) does not usually exceed 1 : 2. The fidelity is largely dependent upon the quality of the transformer. This method may be used with almost any type of amplifier, and the arrangement illustrated is merely typical. For example, fixed bias operation, or operation with triodes in place of pentodes could equally well be adopted.

Fig. 12.27. (A) Triode valve (V_1) followed by transformer (T) having centre-tapped secondary and exciting the grids of the push-pull stage (V_2, V_3). (B) Modified form with non-centre-tapped transformer, using two resistors to provide an equivalent centre-tap.

(B) Centre-tapped resistor across secondary (Fig. 12.27B)

This is an alternative arrangement which does not require centre-tapping of the transformer secondary. In this case an ordinary transformer with a single secondary winding is used, and a centre-tapped resistor ($R_1 = R_2$) is connected across the secondary. The resistors cause a load to be reflected into the plate circuit of V_1 which is equal to $(R_1 + R_2)/T^2$ where $T = N_2/N_1$. For example if $R_1 = R_2 = 0.1$ megohm, and $T = 3$, the load reflected into the plate circuit will be $200\,000/9 = 22\,000$ ohms. This load is lower than some triodes are capable of handling without noticeable distortion, and it might be necessary to increase R_1 and R_2 , the limit being set by the maximum grid circuit resistance permitted with valves V_2 and V_3 . In addition, this arrangement gives greater distortion than the centre-tapped transformer when the valves are slightly over-driven and pass grid current.

(C) Centre-tapped choke (Fig. 12.28)

This is an alternative method sometimes used, involving parallel feed. The effective voltage gain from primary to half secondary is $1/0.5$, indicating a loss as compared with a transformer. It is difficult to obtain perfect balance between the two sides.

(D) Choke-coupled phase inverter—see page 355.**(ii) Phase splitter**

(A) This is an excellent method which is also self-balancing. Its principal characteristics are given in Chapter 7 Sect. 2(ii)B and Fig. 7.25. Perfect balance* is obtained at low frequencies if the plate and cathode load resistors are equal, while commercial tolerances in the following grid resistors have only a small effect on the balance. General purpose triode valves are normally used, and the gain is about 0.9 to each side of the output. The input resistance is of the order of 10 megohms, and the harmonic distortion is extremely low.

FIG. 12.28

FIG. 12.29 A

Fig. 12.28. Triode valve (V_1) with parallel feed and centre-tapped choke exciting the grids of the push-pull stage.

Fig. 12.29A. Modified form of phase splitter giving full gain without degeneration. The input is from grid to cathode and cannot be earthed. The cathode resistor is by-passed to provide full gain.

An analysis of the balance with equal load resistors and shunt capacitors is given in Ref. C27, indicating that under these conditions the balance is perfect at all frequencies. However, in practice, the total shunt capacitances across the two channels differ slightly and there is a slight (and generally negligible) unbalance at high frequencies; see also page 330.

If a high gain amplifier is placed between the phase splitter and the output stage, hum may be troublesome. Part of the hum is due to the difference of potential between the heater and cathode. This may be reduced by operating the heater of the phase splitter from a separate transformer winding which may be connected to a suitable point in the circuit at a potential approximating that of the cathode.

It is normal practice to assume a maximum r.m.s. output voltage (grid-to-grid)

*In an experimental test it is important to reverse the phase of the input from the B.F.O. when the valve voltmeter is moved from one output to the other.

of $0.18E_{bb}$, for less than 2% total harmonic distortion, equivalent to $0.25 E_{bb}$ peak-to-peak output. The distortion drops rapidly as the output voltage is decreased. With a plate supply voltage of 400 volts to the phase splitter, the output is sufficient to excite push-pull Class A 2A3 valves operating with 250 volts on their plates and -45 volts bias.

A complete circuit with 3 stages incorporating a phase splitter and negative feedback is shown in Fig. 7.42.

(B) **A modified form of phase splitter** (Fig. 12.29A) gives the full gain without degeneration, but the input is floating and cannot be earthed. For this reason it cannot generally be used with a pickup, although it may be applied to a radio receiver. In the latter application, the valve may be a duo-diode triode performing detection and 1st a-f stage amplification; a.v.c. may be operated with some complication. This circuit is particularly prone to suffer from hum, owing to the high impedance from cathode to earth and the high gain. The hum may be minimized by adjusting the potential on the heater to approximately that of the cathode.

References (C) 1, 3, 7, 11, 12.

(C) **It is possible to apply positive feedback** from a tapping on the cathode resistor, through a coupling resistor to the unbypassed cathode of the preceding r.c. pentode, and thus increase the gain. A direct-coupled version is shown in Fig. 7.51A. See Chapter 7 Sect. 2(xi).

(D) **Another modification** (Fig. 12.29B) also gives high gain not from the phase splitter itself but from the preceding stage. It makes use of the high input resistance of the phase splitter as the dynamic load on V_1 , thereby increasing its gain. The full analysis of its operation is given in Reference C18 and the following is a summary.

The effective cathode load on V_2 (apart from the cathode resistor R_8) is R_2 and R_5 in parallel, i.e. 20 000 ohms, which is the same as R_4 . The cathode resistor R_8 is by-passed in order to increase the input resistance.

Fig. 12.29B. Phase splitter (V_2) using high input impedance to increase the gain of the preceding stage (V_1) by about six times.

Fig. 12.29C. Phase splitter using pentode with unbypassed screen and suppressor grid.

The d.c. load resistance in the plate circuit of V_1 is $R_1 + R_2 = 0.29$ megohm, while the dynamic load is the input resistance of V_2 , i.e. [see Chapter 7 Sect. 2(ii)B]

$r_i' = R_g/(1 - A')$
 where $R_g = R_1R_3/(R_1 + R_3) = 167\ 000$ ohms
 and $A' \approx 0.9$,
 so that in this example, $r_i' = 1.67$ megohms.

The gain of V_1 is given by

$$A_1 = \frac{g_m}{(1/r_p) + (1/r_i')} = \frac{950}{1/4 + 1/1.67} = 1120,$$

which is about 6 times the gain under normal conditions.

The circuit is nearly balanced if $R_4 = R_c$ and

$$\frac{E_{o1}}{E_{o2}} = \frac{\mu_2 R_g - R_c}{\mu_2 R_g + r_{p2} + R_c}$$

where $R_c = R_2R_5/(R_2 + R_5)$.

The out-of-balance, being about 1.2% in this example, is negligible.

(E) A further type makes use of a heptode (mixer) valve in which unequal load resistors are placed in both plate and screen circuits, the push-pull output being taken from plate and screen. The input is taken to grid No. 3.

Ref. C20.

(F) A further modification makes use of a pentode with an unbypassed screen. The two output voltages are taken from plate and screen, and the suppressor grid is maintained at a negative potential with respect to the cathode (Fig. 12.29C and Ref. C23).

(iii) Phase inverter (Fig. 12.30A)

This is a popular arrangement with twin triode valves, either general purpose or high- μ . It is not self-balancing, and requires individual adjustment for accurate balance both during manufacture and after the valve has been replaced. It is slightly out of balance at very low frequencies owing to the two coupling condensers operating in the lower channel, but C_2 may be made larger than C_1 if desired. It gives a gain (to each channel) equal to the normal gain of one valve.

If it is preferred to avoid individual balancing, the value of R_2 is given by $R_2 = (R_1 + R_2)/A$ where A is the voltage gain of valve V_2 . If R_1 and R_2 both have $\pm 10\%$ tolerances, the maximum possible out of balance will be nearly 20% due to the resistors alone, plus valve voltage gain tolerances.

Separate cathode resistors, each by-passed, are helpful in reducing valve gain tolerances, but require independent cathodes. If a common cathode resistor is used, it may be unbypassed, thus introducing negative feedback for out-of-balance voltages. The hum level is quite low.

N.B. This circuit was originally named Paraphase, but the latter name covers a large number of different circuit arrangements and cannot therefore be used to distinguish one from another.

References C1, C3, C7, C11, C14.

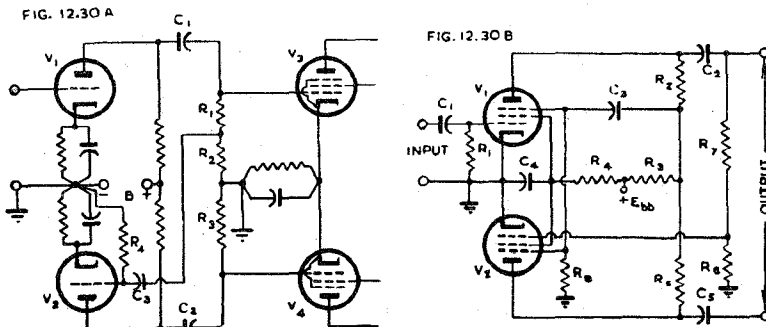

Fig. 12.30A. Conventional form of phase inverter in which V_1 excites V_3 , and V_2 excites V_4 , the grid of V_2 being connected to a tapping on the grid resistor of V_3 .

Fig. 12.30B. Phase inverter with pentodes using the suppressor grids for self-balancing (Ref. C19).

(iv) Self-balancing phase inverter (Fig. 12.30B)

In this circuit V_1 and V_2 are pentodes, and any unbalanced voltage appears across the common plate resistance R_3 and is fed to both suppressors through the blocking condenser C_3 , thus causing degeneration in the valve producing the larger signal output, and regeneration in the other. Ref. C19.

(v) Self-balancing paraphase inverter

(A) Floating paraphase (Fig. 12.31)

This circuit is, to a considerable extent, self-balancing thereby avoiding any necessity for individual adjustment except in cases where a very high accuracy in balancing is required.

In order to visualize the operation of this circuit consider firstly the situation with V_2 removed. Resistors R_5 and R_9 in series form the load on valve V_1 , and the voltage at the point X will be in proportion to the voltage at the grid of V_3 . When V_2 is replaced, the voltage initially at point X will cause an amplified opposing voltage to be applied to resistors R_7 and R_9 . If resistor R_7 is slightly greater than R_5 , it will be found that the point X is nearly at earth potential. If the amplification of V_2 is high, then R_7 may be made equal to R_5 and point X will still be nearly at earth potential. The point X is therefore floating, and the circuit a true Paraphase; the derivation of the name "Floating Paraphase" is obvious.

FIG. 12.31

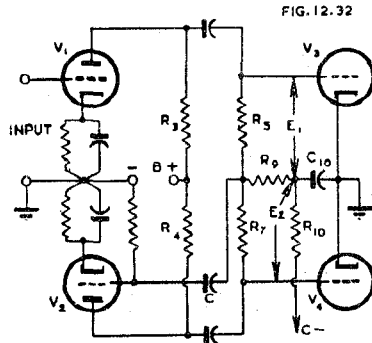

FIG. 12.32

Fig. 12.31. The Floating Paraphase self-balancing phase inverter with cathode bias.
Fig. 12.32. The Floating Paraphase circuit with fixed bias in the following stage.

The degree of balance is given by

$$\frac{E_1}{E_2} \approx \frac{R_5}{R_7} + \frac{1}{A_2} \left(1 + \frac{R_5}{R_7} + \frac{R_6}{R_9} \right) \quad (1)$$

where A_2 = voltage gain of V_2 into plate load resistor R_4 and following grid resistor R_7 .

If $R_6 = R_7 = R_9$, then $E_1/E_2 = 1 + 3/A_2$ (2)

If V_2 is type 6J5 (or half type 6SN7-GT) $R_4 = 0.1$, $R_5 = R_7 = R_9 = 0.25$ megohm, then $A_2 = 14$ and $E_1/E_2 = 1.21$ which is too high to be acceptable. In such a case R_7 may be increased to, say, 0.3 megohm giving $E_1/E_2 = 1.03$.

If V_2 is type 6SQ7 with $R_4 = R_5 = R_7 = R_9 = 0.25$ megohm, then $A_2 = 48$ and $E_1/E_2 = 1.06$ which is generally acceptable.

If V_2 is a pentode (e.g. type 6J7) with $R_4 = R_5 = R_7 = R_9 = 0.25$ megohm, then $A_2 = 104$ and $E_1/E_2 = 1.03$, which is very close.

The gain from the grid of V_1 to the grid of V_3 is slightly greater than the gain with $R_9 = 0$.

FIG. 12.33

Fig. 12.33. Common plate impedance self-balancing phase inverter.

If fixed or partially-fixed bias is employed, it is necessary to couple the grid of V_2 to point X through a suitable condenser (C in Fig. 12.32). In addition, a hum filter (R_{10} , C_{10}) may be required, because most partially-fixed bias sources contain appreciable hum voltage; any hum voltage appearing across the grid resistor of V_2 is amplified by V_2 and V_4 . References C12, C14, C16.

(B) Common plate impedance (Fig. 12.33)

This follows the same principle as the Floating Paraphase, except that the common impedance is in the d.c. plate circuit instead of in the shunt a.c. (following grid) circuit. Here similarly

Fig. 12.34. "See-saw" self-balancing phase inverter (Ref. C9).

$$\frac{E_1}{E_2} = \frac{R_3}{R_4} + \frac{1}{A_2} \left(1 + \frac{R_3}{R_4} + \frac{R_4}{R_6} \right) \quad (3)$$

while if $R_3 = R_4 = R_6$, then $E_1/E_2 = 1 + 3/A_2$ (4) where A_2 = voltage gain of V_2 into plate load resistance R_4 . Ref. C12.

(C) See-saw self-balancing phase inverter (Fig. 12.34)

This is merely another form of the common plate impedance circuit, with two separate resistors.

When $R_3 = R_4 = R_6$, then $E_1/E_2 = 1 + 3/(A_2 + 3)$ (5)

For perfect balance, $R_4 = R_3 [1 + 6/(2A_2 - 3)]$. (6)

It is desirable for A_2 to be greater than 40, thereby giving an out-of-balance less than 7%. References C9, C10, C17.

(D) Modified see-saw self-balancing phase inverter (Fig. 12.35)

This is very similar to the original form, except that it eliminates the loading of the grid resistor R_5 (Fig. 12.34). As a result the balance is improved:

When $R_3 = R_4$, then $E_1/E_2 = 1 + 2/(M + 2)$ (7)

while for perfect balance, $R_4 = R_3 [1 + 2/(A_2 - 1)]$ (8)

References C9, C10.

(vi) Common cathode impedance self-balancing inverters

(A) The Schmitt phase inverter

This circuit has been described in Chapter 7 Sect. 2(viii)A. It is very useful with twin triode valves, and exact balance may be obtained by suitably proportioning the two load resistors. A slightly modified practical form is shown in Fig. 12.36. The gain with this type of circuit is only about half the normal amplification. References C7, C12.

Fig. 12.35. Modified "see-saw" self-balancing phase inverter (Ref. C10).

Fig. 12.36. Practical "Schmitt" common cathode impedance self-balancing inverter using type 6C8-G twin triode ($\mu = 36$). C_1 and C_2 should have high insulation resistance.

(B) Two stage circuit (Fig. 12.37)

This circuit includes a normal push-pull triode stage V_1V_2 with the input applied to V_1 grid only. The grid of V_2 is excited from the common cathodes of the following stage (V_3V_4) through blocking condenser C . Thus the out-of-balance voltage across R excites V_2 . No analysis appears to have been published.

(vii) Balanced output amplifiers with highly accurate balance

For certain specialized applications it is necessary to have highly stable and accurate balance. This may be achieved in various ways including

- the use of two or more inverters in cascade, the later ones operating with push-pull input.
- the use of an additional valve to amplify the out-of-balance voltage before applying it for correction (Ref. C13).
- the use of the so-called "phase compressor" following the inverter—see Sect. 7(v).

Fig. 12.37. Two stage self-balancing phase inverter with common cathode impedance.

(viii) Cross coupled phase inverter

The cross coupled phase inverter (Ref. C25) employs two twin triodes, the circuit being that of the second and third stages of Fig. 15.43A. In this application the single input may be connected between either of the two grids and earth, the other being connected to earth. The hum level from the plate supply is low because hum voltages balance out.

SECTION 7 : PUSH-PULL VOLTAGE AMPLIFIERS

(i) Introduction (ii) Cathode resistors (iii) Output circuit (iv) Push-pull impedance-coupled amplifiers—mathematical treatment (v) Phase compressor.

(i) Introduction

A push-pull voltage amplifier stage is one having push-pull (3 terminal) input and push-pull output. Two separate valves (or one twin valve) are required. The two valves are each treated as for a single-ended amplifier, whether resistance- or transformer-coupled.

(ii) Cathode resistors

A common cathode resistor may generally be used and should not normally be bypassed. Separate cathode resistors are beneficial in that they aid in the correct adjustment of the operating point when this is at all critical, such as

- r.c.c. pentodes when extremely low distortion is required*,
- any r.c.c. valves operating near to the overload point,
- transformer-coupled triodes when it is desired to reduce to a minimum the out-of-balance direct current.

(iii) Output circuit

The voltage from plate to plate does not include any appreciable even harmonic distortion owing to the cancellation between the two valves, but it does include odd harmonics. The voltage from either plate to earth, however, includes even harmonics. If such a stage is r.c. coupled directly to the grids of a following similar push-pull stage, there is no benefit obtained in the form of reduced distortion. For the latter achievement it is necessary to use either a push-pull transformer with a

*Alternatively a similar result may be achieved by adjusting the screen resistors.

centre-tapped primary, or the so-called "phase compressor"—see (v) below. The same also holds true when feeding into a single-ended stage.

Many push-pull transformers are designed to operate with an out-of-balance plate current not exceeding about 1 or 2 mA, thus necessitating matched valves, or adjusted bias, or parallel feed.

(iv) Push-pull impedance-coupled amplifiers—mathematical treatment (Fig. 12.38)

Such a 6 terminal amplifier involves four gain factors

$$A = e_2/e_1 \quad \text{for} \quad e_1' = 0 \quad (1)$$

$$A' = e_2'/e_1' \quad \text{for} \quad e_1 = 0 \quad (2)$$

$$\gamma = -e_2'/e_1 \quad \text{for} \quad e_1' = 0 \quad (3)$$

$$\gamma' = -e_2/e_1' \quad \text{for} \quad e_1 = 0 \quad (4)$$

In a perfectly balanced amplifier $A = A'$ and $\gamma = \gamma'$.

Fig. 12.38. 6 terminal push-pull amplifier.

If there is no cross-coupling (e.g. from a cathode resistor common to both sides) $\gamma = \gamma' = 0$.

In a linear amplifier—

$$e_2 = Ae_1 - \gamma'e_1' \quad (5)$$

$$e_2' = A'e_1' - \gamma e_1 \quad (6)$$

$$\text{Differential gain} = (e_2 - e_2')/(e_1 - e_1') \quad (7)$$

$$= \frac{1}{2}(A + A' + \gamma + \gamma') \quad (8)$$

$$\text{In-phase gain} = (e_2 + e_2')/(e_1 + e_1') \quad (9)$$

$$= \frac{1}{2}(A + A' - \gamma - \gamma') \quad (10)$$

$$\text{Inversion gain} = (e_2 - e_2')/\frac{1}{2}(e_1 + e_1') \quad (11)$$

$$= A - A' + \gamma - \gamma' \quad (12)$$

$$\text{Differential unbalance} = (e_2 + e_2')/(e_1 - e_1') \quad (13)$$

$$= \frac{1}{2}(A - A' - \gamma + \gamma') \quad (14)$$

In an amplifier without cross-coupling, $\gamma = \gamma' = 0$:

Differential gain $= \frac{1}{2}(A + A')$ = average gain of two sides.

In-phase gain = differential gain.

Inversion gain $= A - A'$ = difference between gains of two sides.

Differential unbalance $= \frac{1}{2}(A - A')$.

See also pages 573-574 for the theory of push-pull amplification based on the expansion of the valve characteristic into an infinite series.

(v) Phase compressor

The so-called "phase compressor" is rather a misnomer since its function is to eliminate the in-phase components (e.g. even harmonics) from a nominally push-pull output. In this application it operates in very much the same manner as a transformer. The circuit is given in Fig. 12.39 and is a push-pull phase splitter with the addition of capacitances C_1 and C_2 from each plate to the opposite output terminal. It is these condensers which attenuate in-phase components. The gain for push-pull input is approximately 0.9 from input to output.

Even if the input signal is imperfectly balanced, the output is still balanced. This circuit, unlike a transformer, does not remove hum from the B+ line, but reduces it to about half at the output terminals. Ref. C8.

Fig. 12.39. Circuit of the "phase compressor" for eliminating in-phase components and passing on a pure push-pull output voltage (Ref. C8).

SECTION 8 : IN-PHASE AMPLIFIERS

(i) Cathode-coupled amplifiers (ii) Grounded-grid amplifiers (iii) Inverted input amplifiers (iv) Other forms of in-phase amplifiers.

(i) Cathode-coupled amplifiers

These are described in Chapter 7 Sect. 2(viii)B and have many forms for special applications. In Fig. 7.46 the output from terminal B is in phase with the input. See references Chapter 7 Sect. 6(G).

(ii) Grounded-grid amplifiers

In these, the input voltage is applied to the cathode, the grid is earthed, and the output is taken from the plate, being in phase with the input. Driving power is required, so that it is not strictly a voltage amplifier.

(iii) Inverted input amplifiers

In Fig. 7.18 the input is from grid to plate and the output voltage is in phase with the input.

(iv) Other forms of in-phase amplifiers

There are many other forms too numerous to mention.

SECTION 9 : DIRECT-COUPLED AMPLIFIERS

(i) Elementary d-c amplifiers (ii) Bridge circuit (iii) Cathode-coupled (iv) Cathode follower (v) Phase inverter (vi) Screen coupled (vii) Gas tube coupled (viii) Modulation systems (ix) Compensated d.c. amplifiers (x) Bridge-balanced direct current amplifiers (xi) Cascode amplifiers.

(i) Elementary d-c* amplifiers

A direct-coupled amplifier is one in which the plate of one stage is connected to the grid of the next stage directly, or through a biasing battery or equivalent. It usually receives the plate, screen and grid voltages from sources which do not include any reactances such as filter or by-pass condensers. If this condition is fulfilled, it may amplify down to zero frequency without attenuation or phase shift ; it may also be used to amplify direct voltages.

Fig. 12.40. Elementary direct-coupled amplifier.

Fig. 12.41. Direct-coupled amplifiers without "hot" grid bias battery.

The most elementary form is Fig. 12.40 in which the plate of V_1 is coupled to the grid of V_2 through a bias battery to provide the correct grid bias. As it stands it is of little practical use, owing to the "hot" bias battery.

A more practical circuit is Fig. 12.41 in which all the batteries may be at earth potential. Tapping point B has to be adjusted to give the correct bias between grid

*The abbreviation d-c amplifier is used in this Handbook to indicate a direct-coupled amplifier.

and cathode of V_2 . The voltage drop across R_{L1} will normally be more than half the voltage between A and C .

A circuit requiring only a single source of voltage is Fig. 12.42; the two dividers are desirable to avoid interaction (degeneration) between the two stages unless the bleed current is very high. The output terminal is returned to a point on the voltage divider having the same potential.

Another circuit requiring only a single source of voltage is Fig. 12.43; this has only a single voltage divider. The voltage drop across R_{k2} must equal the plate voltage of V_1 minus the grid bias of V_2 . There will be degeneration caused by the unby-passed cathode resistors, which may be avoided by a push-pull arrangement with common cathode resistors for both stages.

FIG. 12.42

FIG. 12.43

Fig. 12.42. Direct-coupled amplifier with only one source of voltage (E_{bb}).

Fig. 12.43. Direct-coupled amplifier with one source of voltage and one voltage divider.

Pentodes may be used, if desired, in all these circuits by making suitable provision for the screen voltages. In Fig. 12.43 the screen of V_1 may be taken to a tap on R_{k2} , provided that either the screen is by-passed to cathode, or R_{k2} is by-passed; the amplifier would then be limited to audio frequencies only (Ref. D40).

When the first amplifier stage is a pentode, its load resistor may be increased to values much greater than those conventionally used, provided that sufficient negative voltage feedback is applied to secure an acceptable high frequency response (e.g. Ref. D40).

A pentode may also be used with another pentode as its plate resistor. By this means a gain of several thousand times may be obtained, but this is only useful in electronic measuring instruments.

Such circuits (Figs. 12.40–12.43) are generally limited to two stages. If any increase is made, there is distinct danger of slow drift occurring in the direct plate current, due to variations in battery voltages and valve characteristics. These may be minimized by voltage regulators and controlled heater voltage or current, or may be avoided by one of the special methods described below (viii to x). See also Refs. D36, D39.

Negative feedback may be applied to any d-c amplifier in the normal manner.

(ii) Bridge circuit

The bridge circuit (Fig. 12.44) may be used with any number of stages in cascade from a single B supply. The basic design equations are :

$$R_2 = R_1(E_b + E_3)/[E_1 - E_b(1 + R_1/R_p)] \quad (1)$$

$$R_3 = R_1(E_2 - E_3)/[E_1 - E_b(1 + R_1/R_p)] \quad (2)$$

where R_p = the d.c. plate resistance of $V_1 = E_b/I_b$
and E_b = the direct plate voltage.

Typical operation with 6SJ7 pentode as V_1

$E_{bb} = 400$ volts, $E_1 = E_2 = 200$ volts, $E_b = 100$ volts, $E_3 = 0$, $R_1/R_p = 0.5$. Amplification is 71.4% of that as a r.c.c. amplifier. A two stage amplifier using type 6J7 pentodes has an amplification of 100 per stage with fixed voltages for bias and screen supplies, or with push-pull connection.

Negative feedback may be applied to this type of circuit.

References D8, D15.

Fig. 12.44. "Bridge" circuit, direct-coupled amplifier.

Fig. 12.45. Three stage d-c amplifier with V_2 and V_3 as cathode-coupled twin triodes.

(iii) Cathode-coupled

The fundamental form of a cathode-coupled amplifier is covered in Chapter 7 Sect. 2(viii)B.

Fig. 12.45 shows a conventional d-c single triode (V_1) followed by two twin triodes as d-c cathode-coupled amplifier stages. For example, V_2 has one triode as a cathode follower with its grid at a fixed voltage from the voltage divider R_1R_2 , while the other triode operates as an amplifier but sharing the common cathode resistor R_{k1} .

Fig. 12.46. Direct-coupled amplifier incorporating twin triode with relative positions opposite to those in Fig. 12.45 (extracted from Ref. D19).

Fig. 12.46 is an alternative arrangement in which the positions of the two triodes are reversed. This input circuit was primarily for use with a phototube (Ref. D19) but could be adapted to any other requirement.

In the form shown, the output circuit has a direct potential difference, being intended for coupling directly to the screen of the 6V6 following.

See also Section 6(vi).

References D1, D19; also Chapter 7 Refs. (G).

(iv) Cathode follower

The cathode follower may also be used as a d-c amplifier. One circuit is Fig. 12.47A in which the total cathode load is $R_k + R_6R_7/(R_6 + R_7)$. The value of R_7 is equal to E_c/I_b so as to eliminate the undesired direct voltage across R_6 .

References D15, D36.

Fig. 12.47A. Cathode follower used as d.c. amplifier (Ref. D15).

Fig. 12.47B. Direct-coupled amplifier with r-c pentode exciting phase inverter (Ref. D14).

(v) Phase inverter

A direct coupled amplifier having in the first stage a resistance coupled pentode, and in the second stage a twin triode phase inverter, is shown in Fig. 12.47B. The voltage gain is 67 db, with uniform gain up to 12 000 c/s.

References D14, D15.

(vi) Screen-coupled

The preceding stage may be directly-coupled to the screen of a cathode follower pentode (Fig. 12.48). This circuit has a voltage gain of 30 db with 0.5% total harmonic distortion at 0.85 volt peak output. Output terminal *A* has a d.c. potential of -1.5 volts, which may be used as bias for the following stage.

Screen-coupled cathode followers are stable, with a wide-band frequency response, but the distortion is higher than with normal operation owing to the non-constant ratio of plate to screen currents. About 85% of this distortion can be cancelled by a push-pull arrangement.

References D14, D19.

(vii) Gas tube coupled

Fig. 12.49 shows the simplest form of gas tube coupling in which a gas tube (GT) provides the desired voltage drop from the plate of V_1 to the grid of V_2 . The gas tube here must be a glow tube or neon lamp, a voltage regulator tube being unsuitable because its d.c. plate resistance is of the same order of magnitude as the plate load resistor. The values of R_{L1} and R_g must be carefully selected to meet the various limitations.

Fig. 12.48. Two stage amplifier with the plate of the first stage directly-coupled to the screen of the second stage (Ref. D14).

Fig. 12.49. Two stage amplifier with gas tube coupling from the plate of the first stage to the grid of the second stage.

Fig. 12.50 is an improved circuit in which an additional valve (6J5) is used as a cathode follower with its cathode impedance composed of the voltage regulator tube and the resistor R_g . With this arrangement there is no d.c. load on the first amplifier and the input impedance of the cathode follower is so high that it does not affect the gain of the first stage. Almost all the signal voltage drop occurs across R_g . The design of the first stage is independent of the d.c. resistance of the V.R. tube, but R_g must be much larger than the dynamic impedance of the V.R. tube. Negative feedback for improved stability is provided by R_k in the second stage.

The gas tube introduces noise, hence should not be used in low-level amplifiers. For design, see Reference D13.

(viii) Modulation systems

Although not strictly direct-coupled amplifiers, they may be used in many applications. The d.c. signal to be amplified modulates a carrier wave, and after sufficient amplification the modulated wave is detected to obtain the amplified signal. In a modified arrangement, the input signal is interrupted or "chopped."

References D2, D8, D9, D11, D20, D21, D22, D28.

Fig. 12.50. Improved two stage amplifier with gas tube coupling, in which a cathode follower is introduced for better performance.

(ix) Compensated direct current amplifiers

In these, some variable characteristic of the amplifying valve is balanced against the same variations in another valve, or against a different characteristic of the same valve.

(A) Cathode compensation

A typical circuit is Fig. 12.51A and makes use of a twin triode with common cathode resistance. This largely compensates for contact potential drift, and provides a stable amplifier provided that an accurately regulated power source is used. Valves with common cathodes are also used (e.g. 6SC7).

A diode-triode or diode-pentode valve with a common cathode may also be used (Refs. D36, D39).

Both cathode and B supply compensation may be obtained by returning the lower input terminal of Fig. 12.51A to a tapping point ($+E_b/A$) on the voltage divider (broken line) instead of to earth (Ref. D8).

Other circuits used are series balance, and cascode series balance (Ref. D39); also cathode coupled phase splitter with single ended output (Refs. D1, D39).

References D1, D4, D8, D15, D23, D24, D36, D39.

(B) Compensation for filament and plate voltages

This is used in the electrometer tube circuit, and has low drift but cannot be cascaded. Ref. D8.

(C) Compensation for emission

This can be obtained by a circuit using a pentagrid valve. Refs. D4, D8.

(D) Push-pull operation

A degree of compensation is provided by any push-pull amplifier. An alternative form is a push-pull circuit in which one half only of each stage is used as an amplifier, and the other half as a dummy to reduce drift (Ref. D25).

(x) Bridge-balanced direct current amplifiers

With this type of direct current amplifier the regulation of plate and filament supplies usually becomes unnecessary. These are normally used only in laboratory instruments. Ref. D8.

(xi) Cascode amplifiers

The cascode amplifier fundamentally consists of two triodes connected in series (Fig. 12.51B). The usual arrangement in practice is to provide a fixed positive voltage for the grid of V_1 .

FIG. 12.51A

Fig. 12.51A. Cathode-coupled twin-triode used as d.c. amplifier with cathode compensation.

A cascode amplifier may be considered as a single valve having the characteristics μ' , g_m' , r_p' . The load into which V_2 works is given by

$$\frac{r_p + R_L}{\mu + 1}$$

where μ , g_m and r_p are the characteristics of both V_1 and V_2 .

The amplification of V_2 is therefore given by

$$A' = \frac{\mu R_L}{r_p + (r_p + R_L)/(\mu + 1)} \quad (3)$$

$$= \frac{1}{\frac{\mu + 2}{g_m(\mu + 1)R_L} + \frac{1}{\mu(\mu + 1)}} \quad (4)$$

Eqn. (4) may be compared with the ordinary form for expressing amplification, namely

$$A = \frac{1}{\frac{1}{g_m R_L} + \frac{1}{\mu}}$$

and it will be seen therefore that from equation (4)

$$\mu' = \mu(\mu + 1) \quad (5)$$

$$g_m' = g_m(\mu + 1)/(\mu + 2) \quad (6)$$

$$\text{and therefore } r_p' = \frac{\mu}{g_m'} = (\mu + 2)r_p \quad (7)$$

It is preferable to make R_L very much greater than r_p in order to avoid distortion in V_2 due to the low load resistance into which it works; a value of $2\mu r_p$ is satisfactory

For example, consider a twin triode with $\mu = 20$ and $r_p = 10\,000$ ohms under resistance-coupled conditions. A suitable value for the load resistance is $2\mu \times 10\,000 = 400\,000$ ohms—say 0.5 megohm.

From eqn. (5): $\mu' = 20 \times 21 \times 500\,000 \div 510\,000 = 412$

From eqn. (6): $g_m' = \mu/r_p = 20/10\,000 = 2000 \mu\text{hos}$.

From eqn. (7): $r_p' = 21 \times 10\,000 \times 500\,000 \div 510\,000 = 206\,000$ ohms.

A high- μ triode would show even higher values of amplification factor and plate resistance, resembling those of a sharp cut-off r-f pentode.

Curves have been drawn for some typical twin triodes operating as cascode amplifiers; they resemble the curves of pentodes except that the rounded knee has been replaced by a nearly straight, sloping line (Ref. D35).

One special application is as a low-noise r-f amplifier (Refs. D33, D35).

Another application is as a voltage stabilizer (Refs. D32, D34).

The cascode amplifier has been used as a direct current amplifier responding to zero frequency (Ref. D35).

Two cascode amplifiers have been used in a "floating paraphase" push-pull amplifier operating with single-ended input, to deliver a balanced output. In this application, two high- μ twin-triode type 6SL7-GT valves were used each as a cascode amplifier, to deliver an output of about 30 volts peak, each side. Only one coupling capacitor was used in the whole stage, thus simplifying the design of the feedback circuit (Ref. D41).

References to direct-coupled amplifiers (general) Refs. (D).

Ref. D36 is particularly valuable as it gives a detailed examination of the whole subject, including all causes of "drift." See also Chapter 2 Sect. 2(vii) Drift of characteristics during life, and (viii) Effect of heater voltage variation.

Fig. 12.51B. Fundamental circuit of cascode amplifier.

SECTION 10 : STABILITY, DECOUPLING AND HUM

(i) *Effect of common impedance in power supply* (ii) *Plate supply by-passing* (iii) *Plate circuit decoupling* (iv) *Screen circuit decoupling* (v) *Grid circuit decoupling* (vi) *Hum in voltage amplifiers.*

(i) Effect of common impedance in power supply

Every form of power supply has some impedance—even a dry battery has appreciable internal resistance, particularly when partially discharged. This is represented by the resistance R_4 in Fig. 12.52.

When two circuits operating at the same frequency have an impedance common to both there is coupling between them, and the phase relationships may be such that the coupling is either regenerative or degenerative. In the former case instability may result.

A two-stage resistance coupled a-f amplifier has degenerative coupling through the common power supply since the plate currents are out of phase.

A three stage r.c.c. amplifier (Fig. 12.52) has the signal plate currents of the first and third stages in phase, and the total signal current through R_4 is $I_{p1} + I_{p3} - I_{p2}$. Since $(I_{p1} + I_{p3})$ is greater than I_{p2} , the resultant signal current through R_4 will be in the direction of I_{p3} , thus causing across R_4 a signal frequency voltage drop E_d . As a result, the signal voltage applied to the grid of V_2 through R_{L1} and C_1 will be in phase with the normal signal on the grid of V_2 , thus giving positive feedback. If the gain of the amplifier is high, there may be sufficient positive feedback to cause oscillation. This effect may be prevented by the use of decoupling.

On the subject of stability, see Chapter 7 Sect. 3 (stability with feedback), also Ref. E1 (requires a high standard of mathematics).

Fig. 12.52. Three stage amplifier demonstrating the effects of impedance (R_4) in the power supply.

Fig. 12.53. Plate circuit decoupling.

(ii) Plate supply by-passing

The simplest form of decoupling, but one having limited usefulness, is a large capacitance across the power supply (points A and B in Fig. 12.52). This reduces the effective power supply impedance to a low value except at very low frequencies, but it may not be sufficient to prevent low frequency instability ("motor-boating") and frequently requires to be supplemented by plate circuit decoupling.

This by-pass capacitance also fulfils a useful purpose in that it completes the circuit for signal frequencies without appreciable signal currents passing through the B battery or power supply.

Electrolytic condensers are generally used ; if paper condensers are used they should be of a type having low inductance. Either type of condenser may need, in certain rare cases, to be shunted by an additional condenser with a small value of capacitance.

(iii) Plate circuit decoupling

The most popular method is illustrated in Fig. 12.53 where R_d is the decoupling resistance and C the decoupling capacitance. The signal plate current I_p divides

between the path through C and the path through the B supply in the ratio

$$\frac{I_c}{I_a} = \frac{R_a + R_4}{X_c} \quad (1)$$

where R_4 = resistance of B supply
and $X_c = 1/\omega C = 1/(2\pi fC)$.

If X_c is very much less than $R_a + R_4$ then almost the whole of the signal current will pass through C , thus reducing the coupling through the B supply. If the value of R_4 is unknown, it may be neglected as an approximation, since R_a is usually much greater than R_4 .

The decoupling circuit comprising C and R_a is actually a resistance-capacitance filter [for theory see Chapter 4 Sect. 8(ii)]. The frequency at which the current divides equally between the two paths is given by

$$f_1 \approx 1/2\pi R_a C \quad (2)$$

A normal minimum value of $R_a C$ is $10\,000 \times 10^{-6}$, giving a time constant 0.01 second and $f_1 \approx 16$ c/s. Typical combinations for this value of RC are:

R_a	5000	10 000	20 000	40 000	100 000	ohms
C	2	1	0.5	0.25	0.1	μF

Higher values of C may, of course, be used if desired; these higher capacitances are often necessary in pre-amplifiers where several stages operate from the same power supply.

The total d.c. load resistance in the plate circuit is $R_L + R_a$ (+ R_4 if desired), and the quiescent operating conditions should be based on this value. On the other hand, the dynamic (a.c.) load is approximately R_L .

The dynamic operating conditions (gain, voltage output etc.) may be determined by referring to the published data for a supply voltage the same as that for point M (Fig. 12.53). The voltage from M to earth is given by

$$E_M = E_{bb} - I_b R_a \quad (3)$$

where $I_b = KE_{bb}/R_L$

and the value of K (for low level operation) may be taken as approximately

$K = 0.75$ for general purpose triodes and pentodes

$K = 0.6$ for high- μ triodes

[for more exact values see Sects. 2 (vi) for triodes and 3 (vi) for pentodes].

A good general value of R_a for most purposes is one fifth of R_L . If the stage is operating at low level, R_a may be increased up to about the same resistance as R_L to give better decoupling. If the stage is operating at high level, R_a should be reduced as much as possible provided that sufficient decoupling can be maintained. This may be assisted by increasing C , but the cost and size of paper condensers may set a limitation. Two stages of decoupling can sometimes be used to advantage. Electrolytic condensers should be used with caution, since their leakage currents are appreciable and they tend to cause noise if used in low level stages. They should never be used with values of R_a above 50 000 ohms, and very much lower values are desirable.

The plate decoupling circuit of Fig. 12.53 has the effect of increasing the bass response, since at extremely low frequencies the total plate load becomes very nearly $(R_L + R_a)$. If V_1 is a triode, and R_L is greater than $5 r_p$, then the effect is slight. If V_1 is a pentode, or a triode with R_L less than $5 r_p$, the effect may be appreciable. The increase of gain and the phase angle are both identical in form (except for the sign) with the loss of gain and phase angle caused by the cathode bias resistor and bypass condenser—see Section 2 (iii) for triodes and 3 (iv) for pentodes; also Ref. E3 for curves.

The limiting increase in gain is given by

$$\frac{|A'|}{|A|} = 1 + \frac{1}{(R_L^2/R_a)(1/r_p + 1/R_o) + R_L(1/r_p + 1/R_o + 1/R_a)} \quad (4)$$

or if $r_p \gg R_L$ as for pentodes,

$$\frac{|A'|}{|A|} \approx 1 + \frac{R_o R_a}{R_L(R_L + R_a + R_o)} \quad (5)$$

or if the effect of R_p may be neglected,

$$\left| \frac{A'}{A} \right| \approx 1 + \frac{r_p R_d}{R_L(R_L + R_d + r_p)} \quad (6)$$

Example : Pentode with $R_L = 0.25$, $R_d = 0.05$, $R_p = 1$ megohm.

$$A'/A \approx 1.15.$$

This increase of gain at low frequencies may be exactly cancelled by a suitable choice of cathode bias resistor and by-pass condenser (Refs. E3, E5) provided that R_L and R_d are small compared with r_p and R_p : for triodes—

$$R_k = R_d/R_L g_m \text{ and } C_k R_k = CR_d \quad (7)$$

$$\text{and then } A = g_m r_p R_L / (r_p + R_L). \quad (8)$$

This generally gives a value of R_d greater than R_L , and is of limited usefulness.

A special circuit giving **plate decoupling without decoupling condensers**, suitable for use at low frequencies, is shown in Fig. 12.54 (Ref. E4). The plate currents of the last two valves, which are in phase opposition, flow through separate impedances Z_1 , Z_2 , of such value that the back e.m.f.'s developed across them and the common impedance Z_3 of the plate supply balance out at the junction points J1, J2. The screens and plates of the preceding valves are supplied from J2 and J1 through pairs of resistances R , R and R_1 , R_1 in order to balance out undesirable ripple.

The need for decoupling is less when **push-pull operation** is used, although there is still the possibility of motor-boating arising from the effect on earlier stages of plate supply voltage variations caused by the final stage. The latter are small when pure Class A operation is employed.

Chokes may be employed instead of resistors for decoupling, and are frequently used when the plate currents are large—e.g. power amplifiers.

It is desirable in all cases to reduce the internal resistance of the power supply, so that even at very low frequencies there may be no tendency towards the production of relaxation oscillations ("motor-boating"). Power supplies having good regulation have low effective internal impedance; thermionic valve type voltage regulators are highly desirable for special applications and have the feature of retaining low internal impedance characteristics down to the lowest frequencies, if correctly designed.

Motor-boating in transformer-coupled amplifiers may frequently be cured by reversing the transformer connections on either primary or secondary. This has the effect of providing degeneration instead of regeneration, and may have an adverse effect on the frequency response (Ref. E3).

Fig. 12.54. Special circuit giving plate decoupling without decoupling condensers (Ref. E4).

(iv) Screen circuit decoupling

Resistance-coupled pentodes in multistage amplifiers should always have their screens separately decoupled from B+. By this means any impedance in the screen supply may be prevented from causing instability, and the hum is much reduced.

(v) Grid circuit decoupling

Fig. 12.55 is a method of applying grid-circuit decoupling with transformer input and cathode bias. The condenser C acts as a by-pass to resistors $R + R_k$ and if its reactance is small at the lowest frequencies to be amplified, a negligible portion of the signal voltage will occur across C at all signal frequencies. This method requires a smaller value of C than for cathode bias in the ratio $R_k : (R + R_k)$. This circuit is only effective with transformer coupling.

A similar arrangement for fixed bias is shown in Fig. 12.56, which may be used with any form of coupling.

Fig. 12.55. Grid circuit decoupling with transformer input and cathode bias.

Fig. 12.56. Grid circuit decoupling with fixed bias.

(vi) Hum in voltage amplifiers

(A) Hum from plate supply

The plate supply is generally filtered sufficiently for the final stage, but additional filtering is usually necessary for the earlier stages. This is usually provided by the plate decoupling circuits, which may be made more effective than demanded by stability in order to reduce the hum.

In a normal r.c.c. amplifier, such as Fig. 12.1, the hum voltage passed on to the following stage is given by

$$E_h' = E_h r_p / (R + r_p) \quad (9)$$

where E_h = hum voltage across the plate power supply

E_h' = hum voltage across R_{o2}

r_p = effective plate resistance of V_1 , taking into account any feedback and $R = R_L R_{o2} / (R_L + R_{o2})$.

If r_p is very much less than R , the hum voltage passed on to the following stage is much less than E_h . On the other hand, if r_p is greater than R then E_h' may approach E_h .

With a transformer-coupled amplifier (Fig. 12.23) the corresponding expression becomes, in vector form,

$$E_h' = E_h Z / (Z + r_p) \quad (10)$$

where E_h' = hum voltage across transformer primary

and Z = input impedance of transformer at hum frequency.

Normally $Z \gg r_p$, and E_h' approaches E_h .

In the case of parallel-feed (Fig. 12.24) the expression becomes, in vector form,

$$E_h' = E_h Z' / (Z' + R_L) \quad (11)$$

where $Z' = r_p Z / (r_p + Z) \approx r_p$.

The hum passed on to the following stage is normally only a small fraction of E_h .

The hum voltages of successive stages are usually out of phase, thus resulting in some cancellation, but this is very slight if the same degree of filtering is provided for all stages. In such a case the hum of the first stage is the only one to be considered.

For amplifiers using **negative feedback**, see Chapter 7 Sect. 2(ix).

(B) **Hum from the screens** may also be reduced by screen decoupling. The hum from the screen is out of phase with the hum from the plate, but the screen hum predominates. For amplifiers using negative feedback, see Chapter 7 Sect. 2(ix).

(C) **Hum from the grid bias supply** may be reduced in some cases by grid decoupling. This hum voltage may be either in phase, or out of phase, with the plate circuit hum, depending on the source.

(D) **Hum neutralization**

In a r.c.c. pentode the hum voltages from the plate and screen are out of phase, so that it is possible to neutralize the hum by a circuit such as Fig. 12.57. Here the screen is fed from a series resistance R_{g2} , and the hum voltage is applied to the screen by the capacitance divider C_1C_2 . If V_1 is type 6J7 with $R_L = 0.25$ and $R_{g2} = 1.5$ megohms, minimum hum is obtained when $C_1 = 0.05$ and $C_2 = 0.5 \mu\text{F}$, the hum then being about 14% of that without neutralization. C_1 and C_2 may have $\pm 10\%$ tolerances in quantity production. For perfect neutralization it is necessary to balance both resistive and capacitive elements.

An alternative form (Ref. E2) is shown in Fig. 12.58 in which, for perfect neutralization at all frequencies,

$$\frac{C_k}{C_1} = \frac{R_{L1}}{R_g} \left(1 + \frac{R_g}{r_{p1}} \right) \text{ and also } \frac{C_3}{C_1} = \frac{R_k}{R_g} \left(1 + \frac{R_{L1}}{r_{p1}} \right) \quad (12)$$

where r_{p1} = plate resistance of V_1 (preceding stage) and the other values are marked on the diagram. This circuit gives neutralization both for hum and for low frequency regeneration.

There are other methods which may also be used for hum neutralization or reduction (see Chapter 31 Sect. 5).

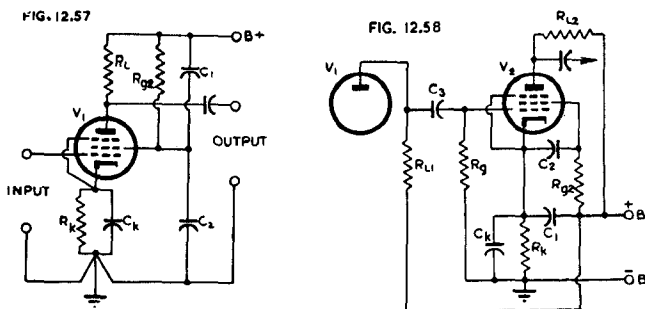

Fig. 12.57. Hum neutralization in a r.c.c. pentode.

Fig. 12.58. Alternative circuit giving perfect neutralization for hum and for low frequency regeneration at all frequencies (Ref. E2).

(E) **Hum caused by inductive coupling**

The most common cause is an a-f transformer or choke, which may be placed in an electromagnetic field. This effect may be minimized by altering the position of the transformer or choke, but cannot usually be eliminated entirely. The best procedure is to avoid using the transformer, to remove the cause of the electromagnetic field, or to employ a properly shielded transformer.

Some valves exhibit hum when they are placed in a strong field—the cure is obvious.

See also Chapter 18 Sect. 2(iii) on pre-amplifiers, and Chapter 31 Sect. 4 on hum.

(F) **Hum caused by electrostatic coupling**

This may be almost entirely eliminated by suitable placing of the mains and rectifier leads, and by electrostatic shielding of all low-level wiring (especially the first grid lead) and by shielding the valves and other susceptible components. See also Chapter 18 Sect. 2(iii) on pre-amplifiers.

(G) Hum due to heater-cathode leakage or emission

When a valve is operated at a fairly high input level, it is often sufficient to earth one side of the heater supply and to use a large by-pass condenser (40 μF or more) with cathode bias, or an earthed cathode with fixed bias.

At a somewhat lower input level, hum due to heater-cathode leakage or emission may be reduced as required, by one or more of the following devices—

1. Centre-tapped heater supply, with tap earthed.
2. Centre-tapped heater supply, with tap connected to a fixed positive or negative voltage (say 15 or 20 volts bias).
3. Potentiometer across heater supply, with moving arm connected to earth and adjusted for minimum hum.
4. Potentiometer across heater supply, with moving arm connected to a positive or negative voltage (not more than 50 volts maximum) selected experimentally to give minimum hum, in conjunction with adjustment of the potentiometer.

For further information see Chapter 18 Sect. 2 (pre-amplifiers) and Chapter 31 Sect. 4 (hum).

SECTION 11: TRANSIENTS AND PULSES IN AUDIO FREQUENCY AMPLIFIERS

(i) *Transient distortion* (ii) *Rectangular pulses.*

(i) Transient distortion

A transient is a complex wave which does not repeat periodically; it may be analysed into a fundamental and harmonic frequencies (see Chapter 6 Sect. 8). If an a-f amplifier contains a tuned circuit, e.g. in a compensated wide band amplifier, or in a tone control stage, distortion of transients can occur if the damping of the tuned circuit is too slight. The effect is actually shock excitation of the tuned circuit; this may be reduced to acceptable proportion if Q does not exceed 0.7 (Ref. A12 p. 428).

(ii) Rectangular pulses

The design of special pulse amplifiers is beyond the scope of this handbook, but amplifiers are frequently tested with a rectangular input voltage ("square wave") and their performance under these conditions is of interest.

Fig. 12.59. A single resistance-capacitance coupling and its response to a rectangular waveform.

In the case of a single r.c. coupling (Fig. 12.59), the voltage across R is given by

$$e = E e^{-t/RC} \quad (1)$$

where E = amplitude of pulse voltage input

$$R = R_g + r_p R_L / (r_p + R_L) \approx R_g$$

and t = time measured from commencement of pulse, in seconds.

If t is small compared with RC , we may write the equation as the approximation (Ref. F1)

$$e \approx (1 - t/RC)E \quad (2)$$

$$\text{or } E/(E - e) \approx RC/t = (\text{say}) X \quad (3)$$

the error being negligible if t is not greater than 0.1 RC .

The value of the time constant RC to give any desired value of X at the end of a pulse is given by

$$RC \approx TX \quad (4)$$

where T = time length of pulse,

and $X = E/(E - e)$,

provided that X is not less than 10.

For example, if X is required to be 20 (i.e. the amplitude of the square top falls by 5% at the end of the pulse) and if $T = 0.01$ second, then $RC \approx 0.2$ second. If $R = 0.5$ megohm, then $C = 0.4 \mu\text{F}$.

If the pulses are repeated periodically with the length of pulse equal to the time between pulses, and if the applied voltage is zero during the period between pulses (as Fig. 12.59),

$$\text{then } RC \approx X/2f_1 \quad (5)$$

where f_1 = frequency in cycles per second.

With sine-wave input, the frequency (f_0) at which the response of a single-stage r.c.c. amplifier falls by 3 db is given by

$$f_0 = 1/(2\pi RC) \quad (6)$$

But with "square-wave" input, $RC \approx X/2f_1$

$$\text{where } f_1 = \text{frequency of square wave in cycles per second.} \quad (7)$$

$$\text{Therefore } f_0 = f_1/\pi X \quad (8)$$

By using a square wave input, and noting on a C.R.O. the frequency f_1 at which there is (say) 10% drop at the end of the pulse (i.e. $X = 10$), it is possible to calculate the frequency for 3 db attenuation with sine-wave input :

$$f_0 \approx f_1/10\pi \quad [\text{for } X = 10] \quad (9)$$

Vice versa, by measuring the frequency f_0 at which the sine-wave response is 3 db below that at the mid-frequency, it is possible to calculate the frequency f_1 at which the square wave shows a specified drop at the end of the pulse :

$$f_1 = X\pi f_0 \quad (10)$$

where $X = E/(E - e)$.

Equations (9) and (10) may also be used in connection with multi-stage amplifiers.

SECTION 12 : MULTISTAGE VOLTAGE AMPLIFIERS

(i) *Single-channel amplifiers* (ii) *Multi-channel amplifiers.*

(i) Single channel amplifiers

Almost any desired number of single r.c.c. stages may be connected in cascade, if adequate provision is made for decoupling. A practical limit is reached when the noise and hum from the first stage become excessive (see Chapter 18 Sect. 2—pre-amplifiers).

The total voltage gain of the amplifier (A) is given by

$$A = A_1 \times A_2 \times A_3 \times \dots$$

where A_1 = voltage gain of first stage, etc.

For decibel calculations see Chapter 19 Sect. 1.

The attenuation in decibels below the mid-frequency gain (A_0) is given, for any frequency f , by the sum of the attenuations in decibels of the individual stages at the same frequency.

It is normal practice to design such an amplifier with a flat, or nearly flat, response over the desired frequency range, and to introduce one or more stages for either fixed tone compensation or manual tone control, or both (see Chapter 15). These stages usually give very limited gain at the mid-frequency.

(ii) Multi-channel amplifiers

Amplifiers having 2 or 3 channels are sometimes used. For example, a 3 channel amplifier may be preceded by a frequency dividing network such that each channel only amplifies a limited range of frequencies—low, middle and high. Each channel may have its own attenuator, with an additional attenuator for the whole amplifier (see Chapter 18). The three outputs may feed three separate power amplifiers, or they may be recombined to form a tone compensating amplifier (see Chapter 15).

SECTION 1 : INTRODUCTION

(i) Types of a-f power amplifiers (ii) Classes of operation (iii) Some characteristics of power amplifiers (iv) Effect of power supply on power amplifiers.

(i) Types of a-f power amplifiers

An interesting analysis of possible types of a-f power amplifiers is given in Ref. G1. However, for practical applications we may sub-divide the arrangements as under :

On basis of form of loading—

- (a) Plate loaded (the normal arrangement).
- (b) Cathode loaded (i.e. cathode follower).
- (c) Combined plate and cathode loaded (e.g. the McIntosh amplifier—see Fig. 13.50D and the Acoustical QUAD amplifier, Refs. H4, H6).

On basis of coupling to load—

- (a) Transformer coupled.
- (b) Choke-capacitance coupled (shunt feed).

On basis of load connection—

- (a) Single-ended output (i.e. one valve).
- (b) Push-pull output.
- (c) Parallel output.
- (d) Push-pull parallel output.
- (e) Single-ended push-pull (Refs. E32, H1, H2).

On basis of excitation—

- (a) Single input to grid.
- (b) Push-pull input to grids.
- (c) Single input to one grid, with other valve excited from common plate or cathode circuit—see Sect. 6(viii).
- (d) Grounded-grid single input.*
- (e) Grounded-grid push-pull input*.

*Not normally used with a-f amplifiers.

On basis of input coupling—

- (a) Resistance-capacitance.
- (b) Choke-capacitance.
- (c) Transformer.
- (d) Direct coupling.

On basis of type of valve—

- (a) Triode.
- (b) Pentode.
- (c) Beam power amplifier.

On basis of use of feedback (see Chapter 7)—

- (a) Without feedback.
- (b) Negative voltage feedback.
- (c) Negative current feedback.
- (d) Cathode follower.
- (e) Combined positive and negative feedback.

On basis of Class of Operation—see (ii) below.**On basis of input power required—**

- (a) No grid input power.
- (b) With grid input power.

(ii) Classes of operation

Class A operation* is the normal condition of operation for a single valve, and indicates that the plate current is not cut off for any portion of the cycle.

Limiting Class A push-pull operation* is operation such that one valve just reaches plate current cut-off when the other reaches zero bias.

Class AB operation* indicates overbiased conditions, and is used only in push-pull to balance out the even harmonics.

Class B operation* indicates that the valves (which are necessarily in push-pull) are biased almost to the point of plate current cut-off.

The numeral "1" following A or AB indicates that no grid current flows during any part of the cycle, while "2" indicates that grid current flows for at least part of the cycle. With Class B operation the "2" is usually omitted since operation with grid current is the normal condition.

(iii) Some characteristics of power amplifiers

Amplifiers incorporating **negative feedback** are covered in Chapter 7. The design of **output transformers** is covered in Chapter 5 Sect. 3.

For a limited supply voltage Class A₁ gives the lowest **power output** with given valves, while Class AB₁ and Class AB₂ give successively higher outputs. Pentodes and beam power amplifiers give greater power output than triodes under the same conditions. Negative feedback does not affect the maximum power output.

The **power plate efficiency** is the ratio of the audio frequency power output to the d.c. plate and screen power input. It is least for Class A₁, and increases progressively with Class AB₁, AB₂ and B. It is less for Class A₁ triodes than for Class A₁ pentodes or beam power amplifiers.

The **sensitivity**† is normally taken as the ratio of milliwatts output to the square of the r.m.s. grid voltage. Pentodes and beam power amplifiers have considerably greater sensitivity than triodes. Class AB₁ or any push-pull operation decreases the sensitivity. Amplifiers with grid current require power in the grid circuit; sensitivity cannot be quoted for such types except for the whole section including the driver valve.

*See also definitions in Sect. 5(i)B.

†The writer favours the use of the alternative form

$$\text{Sensitivity} = \frac{\sqrt{\text{power output in milliwatts}}}{\text{grid voltage r.m.s.}}$$

which gives values from slightly over 1 (e.g. type 45) to nearly 50. This form has the advantage that, for the same power output, the value is proportional to the voltage gain. This value is the square root of the "sensitivity" as normally measured.

Another alternative form is the ratio of milli-watts output to the square of the peak grid voltage.

The **effective plate resistance** (or output resistance) of a power amplifier is an important characteristic when the load is a loudspeaker. The optimum value of plate resistance depends upon the loudspeaker, but in the majority of cases the optimum is about one fifth of the load resistance for the best frequency response—lower values give heavier loudspeaker damping but a loss of bass response. Feedback amplifiers with very high feedback factors normally have a very low value of output resistance as the result of negative voltage feedback; in some cases the output resistance is purposely raised to a more suitable value by some device such as bridge feedback—see Chapter 7 Sect. 1(iv). The general question of the optimum plate resistance is covered in Chapter 21 Sect. 1(ii), while loudspeaker damping is covered in Chapter 21 Sect. 3.

Critical load resistance—Pentodes are much more critical than triodes as regards the effects of variation from the optimum value of load resistance—this holds with or without feedback in both cases. See Sect. 2(iv), Sect. 3(viii), Sect. 5(ii), Sect. 6(ii), and summary Chapter 21 Sect. 1(iii).

Distortion—Single Class A_1 triodes are usually operated with 5% second harmonic distortion at maximum output, while the third and higher order harmonics are small under the same conditions. All published data for such valves are based on 5% second harmonic unless otherwise specified. With push-pull Class A_1 triodes the even harmonics are cancelled and only small third and higher order odd harmonics remain. Push-pull class A_1 triode operation is regarded as providing the best fidelity obtainable without the use of feedback.

As the bias is increased towards Class AB_1 operation the odd harmonic distortion increases only slightly until cut-off is just reached during the cycle (i.e. up to Limiting Class A operation), beyond which point a kink appears in the linearity (transfer) characteristic, and the distortion is more displeasing to the listener than is indicated by the harmonic distortion.

Power pentodes operated under Class A_1 conditions on a resistive load may have very slight second harmonic distortion but from 7% to 13% total distortion. This is largely third harmonic with appreciable higher order harmonics. When operated into a loudspeaker load the harmonic distortion is much more severe at low and high frequencies due to the variation of loudspeaker impedance with frequency. Negative feedback may be used to reduce distortion at all frequencies.

With a load of varying impedance, such as a loudspeaker, there is a selective effect on the harmonic distortion. For example, if the impedance of the load is greater to a harmonic than to the fundamental, the harmonic percentage will be greater than with constant load resistance equal to that presented to the fundamental. See Sect. 11(iii) and Fig. 13.54, also Sect. 2(iv) for triodes, Sect. 3(viii) for pentodes.

Owing to the fact that the dominant harmonic with power pentodes is the third, there is very little reduction of distortion due merely to push-pull operation. If, however, the load resistance per valve is decreased, the effect is to increase the second harmonic per valve (which is cancelled out in push-pull) and to decrease the third harmonic, and thus to improve the fidelity.

Some of the distortion occurring with Class AB_2 or Class B operation is due to the effect of grid current on the input circuit. The design of such amplifiers is treated more fully later in Sections 7 and 8.

Normally the harmonic distortion is stated for full power output, but the **rate of increase** is also of importance. Second harmonic distortion (Class A_1 triodes or beam power tetrodes) increases more or less linearly from zero to full power. Third harmonic distortion in pentodes increases less rapidly at first, and then more rapidly as full output is approached. Higher order odd harmonics show this effect even more markedly.

Beam power amplifiers in Class A_1 have considerable second harmonic, but less third and higher order harmonics. When operated in push-pull the second harmonic is cancelled, and the total harmonic distortion on a constant resistive load is small. On a loudspeaker load, however, the same objections apply as for pentodes, and negative feedback is necessary in all cases where good fidelity is required.

For further information on fidelity and distortion see Chapter 14.

In calculating the **frequency response** of an output stage, it should be noted that the inductance of the output transformer varies with the applied signal voltage.

When the d.c. plate current remains nearly constant at all output levels the **regulation of the power supply** is not important as regards the output power, provided that it is adequately by-passed—see (iv) below. With Class AB_1 operation there is a greater variation in current drain from zero to maximum signal, and improved regulation is required in the power supply in order to avoid loss of power and increased distortion. Class AB_2 , and particularly Class B amplifiers, require extremely good power supply regulation owing to the large variations in current drain.

The use of **self bias** (cathode bias) reduces the variation of plate current due to change of signal level, and frequently enables less expensive rectifier and filter systems to be used, although in some cases the output may be slightly reduced and the distortion slightly increased as a result. Self bias cannot be used with Class AB_2 or Class B operation.

Parasitic oscillation in the power stage is sometimes encountered, either of a continuous nature or only under certain signal conditions. High-mutual-conductance valves are particularly liable to this trouble, which may be prevented by one or more of the expedients listed below. Class AB_2 or Class B amplifiers sometimes suffer from a negative slope on portion of the grid characteristic; this may sometimes be recognised by a “rattle” in the loudspeaker. Improvement in most cases may be secured by the use of one or more of the following expedients:

A small condenser from each plate to earth.

A condenser from each grid to earth (with transformer input only).

Series stopping resistors in grid, screen and plate circuits, arranged as close as possible to the valve.

Improved layout with short leads.

Input and output transformers with less leakage inductance.

In addition to these expedients, it is usually helpful to apply negative feedback from the plate of the output valve to its grid circuit or to the cathode of the preceding stage.

A Class AB_2 or Class B amplifier requires a **driver stage** and (usually) coupling transformer in addition to the final stage. These, together with the additional cost due to the good regulation power supply, should all be considered in calculating the total cost. It is desirable to consider the whole combination of driver valve, driver transformer and push-pull power stage as forming the power amplifier, and the input voltage to the driver will generally be comparable with that required by a single power pentode.

When fixed bias is required for a class AB_1 , AB_2 or B amplifier, this may be obtained from a battery or from a separate rectifier and filter. In order to reduce the cost, back-bias with the addition of a heavy bleeder resistance is often used. Some variation in bias is inevitable with this arrangement, and a loss of power output and an increase of distortion will result. The additional cost of the power supply and filter needed to handle the total current of valves and bleeder must also be considered.

Pentodes and beam power amplifiers may be used as triodes by connecting plate and screen. If the suppressor is brought out to a separate pin it may be connected to the plate. Care should be taken to avoid operating such a valve at a plate voltage higher than the maximum rated screen voltage unless special “triode” maximum ratings are available.

The load impedance with triode power amplifiers may be open-circuited (if necessary) without any serious effects; it should never be short-circuited. The load impedance with pentodes may be short-circuited only if the valve is being operated considerably below its maximum plate dissipation; it should never be open-circuited unless an appreciable degree of negative voltage feedback is being used.

(iv) Effect of power supply on power amplifiers

The usual by-pass capacitor connected across the power supply is large enough to act as a reservoir and maintain practically constant voltage, except at low frequencies.

The analysis of a power supply shunted by a condenser and supplying sine-wave signal current does not appear to have been published.

An analysis has been made (Ref. B6) for the simpler case where the signal current is of rectangular form. The minimum frequency of rectangular waveform for a specified variation of supply voltage over the half-cycle is given by

$$f_r = \frac{K(R_L/R_s) + 1}{4.606KR_L C \log_{10} A} \quad (1)$$

where $K = I_{b0}/(I_{b0} + I_p)$

R_s = resistance of voltage source

$R_L = E_{b0}/I_{b0}$

C = shunt capacitance

$$A = \frac{(1 - K)}{(1 - K) - [K(R_L/R_s) + 1]x/100}$$

E_{b0} = direct voltage across C

I_{b0} = direct plate current of valve

I_p = peak signal current through valve plate circuit

and x = fall of supply voltage between beginning and end of positive half-cycle, expressed as a percentage of E_{b0} .

The only approximation in eqn. (1) is that the voltage across the condenser at the commencement of the positive half-cycle is taken as being E_{b0} .

Eqn. (1) has been applied to the following example—

$E_{b0} = 250$ V, $I_{b0} = 40$ mA, $I_p = 30$ mA, $C = 16\mu\text{F}$, $x = 2$,

to give these results :

When $R_L/R_s =$	5	10	20	30	35
then $f_r =$	170	157	127	96	49 c/s

This example is a severe one since a rectangular waveform is more severe than a sine waveform with the same peak current, while the value of x only allows 2% drop in voltage over the half-cycle. If 5% voltage drop is permissible, f_r becomes 39 c/s for $R_L/R_s = 10$. The importance of good power-supply regulation for satisfactory performance at low frequencies is demonstrated.

This effect does not occur to any appreciable extent with push-pull Class A amplifiers, and is not so pronounced with Class AB amplifiers as it is with single-ended Class A or with Class B.

Amplifiers should always be tested for frequency response and distortion at maximum power output, as well as for frequency response at a lower level.

SECTION 2 : CLASS A SINGLE TRIODES

(i) *Simplified graphical conditions, power output and distortion* (ii) *General graphical case, power output and distortion* (iii) *Optimum operating conditions* (iv) *Load-speaker load* (v) *Plate circuit efficiency and power dissipation* (vi) *Power sensitivity* (vii) *Choke-coupled amplifier* (viii) *Effect of a.c. filament supply* (ix) *Overloading* (x) *Regulation and by-passing of power supply.*

(i) Simplified graphical conditions, power output and distortion

The basic circuit of a single Class A₁ triode is Fig. 13.1. The load resistance (R_L) is normally connected to the secondary of a transformer (T) whose primary is connected in the plate circuit of the valve. The load resistance (R_1) presented to the valve is given (see Chapter 5 Sect. 1) by

$$R_1 = (N_1/N_2)^2 R_L \quad (1)$$

where N_1/N_2 = transformer turns ratio, primary to secondary. In the ideal case, the primary and secondary windings of T may be assumed to have zero resistance, and the d.c. plate current I_b to remain constant under all operating conditions.

The valve characteristics are shown by Fig. 2.22 in which the loadline AQB has a slope $-1/R_L$ and passes through the operating point Q. In this example, $E_b = 250$ volts and $E_c = -10$ volts, and Q is vertically above $E_b = 250$ volts, because the full E_b voltage is applied between plate and cathode.

The maximum grid swing which can be used is 20 volts, that is from A ($E_c = 0$) to B ($E_c = -20$ volts) since the $E_c = 0$ curve is the border of the grid current region. Actually a slight grid current usually flows at zero bias, but this is generally neglected.

Fig. 13.1. Basic circuit of a Class A₁ triode with transformer-coupled load.

Fig. 13.2. Loadline applied to triode plate characteristics to determine power output and distortion.

The **power output** may be calculated from a knowledge of the maximum and minimum voltages and currents along the loadline, assuming a sinewave input voltage (Fig. 13.2):

$$\text{Power Output} \approx \frac{1}{2}(E_{max} - E_{min})(I_{max} - I_{min}) \quad (2)$$

$$\approx \frac{1}{2}R_L(I_{max} - I_{min})^2 \quad (3)$$

$$\approx \frac{1}{2}(E_{max} - E_{min})^2/R_L \quad (4a)$$

$$\approx \frac{1}{2}E_b I_Q (1 - E_{min}/E_b)(1 - I_{min}/I_b) \quad (4b)$$

Equations 2, 3 and 4 give the exact fundamental frequency power output when the odd harmonic distortion is negligible. The power output of 5% second harmonic frequency is only 1/400 of the fundamental power output, which is negligible.

The load resistance corresponding to the loadline is

$$R_L = (E_{max} - E_{min})/(I_{max} - I_{min}) \quad (5a)$$

$$= (E_b/I_b)(1 - E_{min}/E_b) \quad (5b)$$

The percentage second harmonic distortion

$$= \frac{\frac{1}{2}(I_{max} + I_{min}) - I_Q}{I_{max} - I_{min}} \times 100 \quad (6)$$

$$= \frac{AQ - QB}{2(AQ + QB)} \times 100 \quad (7a)$$

$$= \frac{AQ/QB - 1}{2(AQ/QB + 1)} \times 100 \quad (7b)$$

The equation (7b) has been plotted graphically in Fig. 13.3.

The **voltage gain** of a power amplifier is given by

$$M = (E_{max} - E_{min})/(2E_{c1}) \quad (8)$$

$$= 2.82\sqrt{P_o/R_L}$$

where P_o = power output in watts.

The peak values of the fundamental and second harmonic components of the signal plate current are:

$$\text{Fundamental } I_{h1} = \frac{1}{2}(I_{max} - I_{min}) \quad (9)$$

$$\text{Second harmonic } I_{h2} = \frac{1}{4}(I_{max} + I_{min} - 2I_Q) \quad (10)$$

If $AQ/QB = 11/9 = 1.22$, then the second harmonic distortion will be 5%. This

Fig. 13.3. Curve of second harmonic distortion plotted against the ratio AQ/QB for the two portions of the loadline (Fig. 13.2).

is the principle of "5% distortion rule" reproduced in Fig. 13.4. The rule has each division to the left of 0 a length of $11/9$ or 1.22 of the length of a corresponding division to the right of 0. It may be made with each left-hand division 11 millimetres and each right-hand division 9 millimetres. Each of these divisions may be divided into 10 equal subdivisions. It may be used by placing the "0" of the distortion rule at any likely operating point and tilting the rule gradually until the reading on the rule corresponding to the zero bias curve is the same as the reading corresponding to the curve of twice the grid bias at the operating point. AQ/QB will then be $11/9$ and the second harmonic distortion corresponding to AQB as a loadline will be 5%.

There are also methods for the graphical determination of any degree of second harmonic distortion. One of these was originated by Espley and Farren (Ref. B1) and is illustrated in Fig. 13.5; it must be drawn on transparent material. It is applied to the curves in a manner similar to the 5% distortion rule, except that a loadline is first drawn in, and then the Harmonic Scale is moved so that DBC is parallel with the loadline. For example, with the loadline EFG the distortion is 20% while with E'FG the distortion is 10%. The scale may be constructed on the basis of:

2nd Harmonic Distortion %	0	5	10	15	20
DB/BC	1.0	1.22	1.5	1.86	2.33

If the valve is to be operated with a known plate voltage, the usual procedure is to take as the operating point (Q) the intersection of the vertical line through E_b with one of the E_c curves such that Q is either on, or below, the "maximum plate dissipation curve" (Fig. 13.2). If the latter is not included in the published curves, it may readily be plotted over a small range. This dissipation curve only affects the operating point Q, and there is no harm if the loadline cuts the curve. In general, if the plate voltage is fixed, a triode gives greatest output when it is operated at the maximum permissible plate current, with the limit of $I_b = \frac{1}{4}E_b/r_p$ (see eqn. 22).

If there is no predetermined plate voltage, a triode gives increasing power output as the plate voltage is increased, even though the plate current is limited in each case by the dissipation.

(ii) General graphical case, power output and distortion

In practice there are several additional factors which should be taken into account.

(A) Resistance of transformer primary

Provision may be made for this resistance by giving the line QE_b a slope of $-1/R'$ where R' is the resistance of the transformer primary or choke (Fig. 13.6). By this means the plate voltage of point Q is less than E_b by the value $R'I_Q$. This does not affect the slope of the loadline, which is determined solely by the effective impedance of the load reflected across the primary of the transformer. It is assumed that the final filter condenser has sufficient capacitance to supply the varying current over each cycle without appreciable change in voltage.

(B) Effect of primary inductance

The reactance of the transformer primary gives an elliptical loadline [see Chapter 2 Sect. 4(vi)]. This may be reduced to any desired extent by increasing the inductance. Obviously this effect is only serious at the lowest signal frequencies; suitable values of inductance are given in Chapter 5 Sect. 3(iii)c.

Fig. 13.4. 5% distortion rule for use in calculating the power output of triodes.

It will be observed that D'' does not correspond to the intersection of the loadline and the static bias curve. Point P'' is not the quiescent point (which is Q) but may be described as "the point of instantaneous zero signal voltage on the dynamic loadline." Point P'' must therefore be used in the calculations for harmonic distortion at maximum signal. The loadline $A'D''P''B''$ provides the data necessary for the calculation of power output, second harmonic distortion, and average direct current. All these will, in the general case, differ from those indicated by the loadline AQB .

Summary :

1. Power output is calculated from the loadline $A'B''$ in the usual manner.
2. Second harmonic distortion (per cent) at maximum signal $= (2D''P''/A'B'') \times 100$.
3. Average d.c. current at maximum signal $= I_{b''} = I_Q + \Delta I_{b''} =$ current for point D'' .

The graphical method above is accurate, within the limits of graphical construction, but rather slow. Approximate results may be calculated from the original loadline by the equations :

$$I_{b''} \approx I_Q + \frac{1}{4}(I_{max} + I_{min} - 2I_Q)(1 + R_L/r_p) \quad (13)$$

$$\Delta I_{b''} \approx \frac{1}{4}(I_{max} + I_{min} - 2I_Q)(1 + R_L/r_p) \quad (14)$$

Alternatively the rise in current may be calculated from the second harmonic distortion (H_2) and power output :

$$\Delta I_{b''} \approx \sqrt{2H_2} \sqrt{P_o/R_L}(1 + R_L/r_p) \quad (15)$$

In another form, the rise in current may be calculated from the harmonic distortion, I_Q and I_{min} :

$$\Delta I_{b''} \approx (I_Q - I_{min})(1 + R_L/r_p)[H_2/(1 - 2H_2)] \quad (16)$$

or less accurately by

$$\Delta I_{b''} \approx (0.78 I_Q)(1 + R_L/r_p)[H_2/(1 - 2H_2)] \quad (17)$$

(on the assumption that $I_{min} = 0.22 I_Q$).

Eqn. (17) is interesting, since it does not involve any data beyond those normally published. If $H_2 = 0.05$ it may be reduced to

$$\Delta I_{b''} \approx 0.043 I_Q(1 + R_L/r_p) \quad (18)$$

Eqns. (13) to (18) give results slightly lower than the graphical method.

For rectification effects with cathode bias see below.

(E) Cathode bias

Cathode bias loadlines may be drawn on the mutual characteristics [Chapter 2 Sect. 4(v)] but the position is complicated by the rise in plate current caused by rectification. The simplest approach is to assume a voltage between plate and cathode (E_b), determine the plate current under maximum signal conditions as for fixed bias

Fig. 13.8. Determining change of plate current with fixed and cathode bias, having operating conditions identical at maximum signal.

($I_{b''}$) and then to calculate the cathode bias resistor (R_k) from the equation $R_k = E_c/I_{b''}$. It is then necessary to check for plate dissipation at no signal; this may be done by the method of Fig. 2.27, drawing a cathode loadline having the correct slope, and noting the plate current (I_{b1}) at which the cathode loadline intersects the mutual characteristic for the desired value of E_b . The dissipation with no signal input is then $E_b I_{b1}$. There is a slight error through assuming that E_b remains constant from zero to maximum signal, but this is usually negligible. Alternatively, the maximum value of I_{b1} may be calculated from the maximum dissipation, and marked on the corresponding E_b curve; through this point a cathode loadline may be drawn whose slope will indicate the minimum permissible value of cathode bias resistor.

If it is desired to make allowance for the transformer primary resistance, the slope of $D'E_{bb}$ in Fig. 13.8 should be $-1/(R' + R_k)$ where $R' =$ primary resistance.

In general, any single Class A triode may be operated either with fixed or cathode bias as desired. The maximum value of grid circuit resistance frequently depends on the source of bias. When it is permissible to use a value of cathode bias resistor which provides the same grid bias as required for fixed bias, the load resistance, distortion, and power output will be identical. When it is necessary, on account of plate dissipation, to use a higher value of R_k , then the conditions in the two cases will be different.

Cathode by-passing—It is important for the by-pass condenser to be sufficiently large to maintain the bias voltage constant over each cycle—any fluctuation leads to increased distortion and loss of power output. When operating at low levels it is usually sufficient to ensure that the reactance of the by-pass condenser, at the lowest frequency to be amplified, does not exceed one tenth of the resistance of the cathode bias resistor.

At high operating levels it is necessary to ensure that the direct voltage from B + to cathode remains substantially constant over each half-cycle. This may be treated in the same manner as the by-passing of the power supply—see Sect. 1(iv) and Eqn. (1).

The network comprising the resistive elements R_s and R_k and the capacitive elements C and C_k may be replaced by its equivalent network comprising C_1 in parallel with R_1 , connected from B + to cathode. In the special case when $C/C_k = R_k/R_s$ we have $R_1 = R_s + R_k$ and $C_1 = CC_k/(C + C_k)$, but the general case is more involved. Eqn. (1) of Sect. 1 may then be applied directly.

Fig. 13.9B. Plate characteristics type 6J5 with g_m and g_p curves and loadlines (Ref. B5).

(F) Alternative method using g_m and g_p curves

$$A = -g_m R_L / (1 + g_p R_L) \quad (19B)$$

where A = amplification with small input signal

g_m = mutual conductance

and g_p = plate conductance = $1/r_p$.

For predominant second harmonic distortion :

$$A' = \frac{1}{2}(A_1 + A_2) \quad (19C)$$

Second harmonic distortion per cent = $25(A_1 - A_2)/(A_1 + A_2)$

where A' = amplification with maximum input signal

A_1 = amplification at maximum positive excursion

and A_2 = amplification at maximum negative excursion.

The values of A_1 and A_2 may be calculated, using eqn. (19B), from the values of g_m and g_p corresponding to the relevant points on the loadline which may be derived from Fig. 13.9B for type 6J5. Alternatively, the values of g_m and g_p may be derived by measurement or graphically at the points of maximum positive and negative excursion on the loadline. By this means it is possible to calculate amplification and distortion with high signal inputs from measurements made at low inputs.

This method may be used for cathode followers by using eqn. (19D) in place of (19B) :

$$A = g_m R_k / [1 + (g_m + g_p) R_k] \quad (19D)$$

It may also be used for degenerative amplifiers by using eqn. (19E) :

$$A = -g_m R_L / [1 + (g_m + g_p) R_k + g_p R_L] \quad (19E)$$

References B5, B7, B8, H17.

(iii) Optimum operating conditions

The preceding graphical treatment enables the optimum load resistance to be determined to give maximum power output for limited distortion, provided that valve curves are available. It is frequently desirable to be able to make an approximate calculation without going to so much trouble. The optimum load resistance is a function of the operating conditions (see Refs. A). The following treatment is based on Ref. A14, and relates to "ideal" (linear) valve characteristics.

Case 1 : Grid current and distortion zero, fixed signal input voltage, no limitations on plate current or voltage

See loadline AQB in Fig. 13.10 in which the characteristics are parallel and equidistant straight lines. The loadline may be placed anywhere between the $E_c = 0$ curve and the E_b axis. Maximum power output will be obtained when $R_L = r_p$, that is when the slope of AQB is equal in magnitude to the slope of the characteristic curves. The power output with any load resistance is given by

$$P_0 = \frac{(\mu E_g)^2 R_L}{(r_p + R_L)^2} \quad (20)$$

where E_g = r.m.s. grid input voltage.

Since there is no advantage in having the loadline in the position shown, it may be transferred to the position A'Q'B' where it has the lowest possible grid bias and plate voltages. Under these conditions the "plate circuit efficiency"* is 16.6% when $R_L = r_p$.

Case 2 : Grid current and distortion zero, fixed plate voltage, no limitations on plate current or signal input voltage

Let E_{b1} be the fixed plate voltage. The loadline may be CPD in Fig. 13.10 where C is the intersection with the $E_c = 0$ curve which is the boundary of the grid current region. PD must equal CP for zero distortion. Maximum power output is obtained when the loadline is adjusted so that its lower extremity touches the E_b axis, as with EFG, and when $R_L = 2r_p$. Under these conditions the plate circuit efficiency* is 25%.

The maximum power output with any load resistance is given by

$$P_0 = \frac{\frac{1}{2} E_{b1}^2 R_L}{(2r_p + R_L)^2} \quad (21)$$

See also equations (31) to (34) inclusive.

*See Section 2(v).

Applying this procedure to each of the previous cases, we have :

(1) No change— $R_L = r_p$.

(2) No change— $R_L = 2r_p$.

(3) $P_0 = \frac{1}{2}[E_{b1} - (2I_{b1} - I_{bmin})r_p - E_{bmin}][I_{b1} - I_{bmin}]$ (27)

The optimum value of load resistance is given by

$$R_L = (E_{b1}/I_{b1}) - 2r_p + (E_{b1}/I_{b1} - r_p - E_{bmin}/I_{bmin})I_{bmin}/(I_{b1} - I_{bmin}) \quad (28)$$

The plate circuit efficiency is given by

$$\eta = \frac{1}{2}(1 - 2r_p I_{b1}/E_{b1} + r_p I_{bmin}/E_{b1} - E_{bmin}/E_{b1})(1 - I_{bmin}/I_{b1}) \quad (29)$$

(4) The optimum value of load resistance for maximum power output is given by

$$R_L = (4I_{b1}/I_{bmin} - 1)r_p + E_{bmin}/I_{bmin} \quad (30)$$

FIG. 13.12

FIG. 13.13

Fig. 13.12. Plate characteristics of imaginary triode with "ideal" characteristics above I_{bmin} and curved characteristics below this line.

Fig. 13.13. Ideal triode characteristics with $R_L = 2r_p$.

Summary of operating conditions

(A) Ideal characteristics

If there is no limitation on plate current, the optimum load $R_L = 2r_p$ and the load-line is as Fig. 13.13.

Grid bias : $E_{c1} = 0.75E_{b1}/\mu$ (31)

Plate current : $I_{b1} = E_{b1}/4r_p$ (32)

Max. power output : $P_0 = E_{b1}^2/16r_p$ (33)

Plate circuit efficiency : $\eta = 25\%$ (34)

(B) Practical characteristics

The optimum plate current for ideal characteristics is given by

$$I_{b0} = \frac{1}{4}E_{b1}/r_p$$

and in practice is slightly higher.

Grid bias for optimum plate current :

$$E_{c1} = 0.75(E_b - E_i)/\mu \quad (35)$$

where E_i = plate voltage at intersection of E_b axis and tangent to $E_c = 0$ curve at current I_{max}

and E_{c1} = grid bias for d.c. filament operation (add $E_f/2$ for a.c. operation).

Usual values of E_i are between 30 and 45 volts. Examples are :

Type 2A3 $E_i = 35$ volts approx.

Type 45 $E_i = 40$ volts approx.

Note : At voltages above about 180 volts, the grid bias will have to be increased to reduce the plate dissipation.

When a triode is being operated at the optimum plate current, the load resistance should be approximately $2r_p$. Fig. 13.14 shows the variation in power output, and second harmonic distortion, of a typical small power triode indicating that maximum power output occurs at slightly less than $2r_p$. The percentage **third harmonic distortion** is usually between one third and one tenth of the second harmonic distortion up to 5% of the latter ; the ratio decreases as the load resistance is increased.

When a triode is being operated at a plate current which is less than the optimum, then R_p will be greater than $2r_p$ for maximum power output. Refer to Case (3), eqns. 23, 24 and 25.

(iv) Loudspeaker load

A loudspeaker (see Chapters 20 and 21) presents a load impedance which is neither purely resistive nor constant. At most frequencies it causes an elliptical loadline [see Chapter 2 Sect. 4(vi)] with the shape of the ellipse varying widely over the audio frequency range. All that can be said here is that the elliptical loadline results in higher distortion and lower power output than a purely resistive load.

The variation in impedance is almost entirely an increase above the nominal (400 c/s) impedance. As a result, with constant signal voltage applied to the grid, the distortion and the power output decrease as the load resistance is increased (see Fig. 13.14).

A triode applies nearly constant voltage across the load impedance. This is a standard condition of test for a loudspeaker, and some models of loudspeakers are designed to operate under these conditions (see Chapters 20 and 21). A triode is almost the ideal output stage for a loudspeaker load when looked at from the load point of view, with or without feedback.

See also Sect. 3(viii) for pentodes, Sect. 11(iii) and Fig. 13.54, and Chapter 21 Sect. 1.

Fig. 13.14. Power output and distortion of type 45 triode plotted against load resistance. The curves were derived graphically, with allowance for shifting loadline. The operating conditions are: $E_b = 250$ volts, $E_c = -50$ volts, peak grid signal voltage 50 volts, $I_b = 34$ mA (zero signal), $r_p = 1610$ ohms.

(v) Plate circuit efficiency and power dissipation

The plate circuit efficiency is defined as the ratio of the maximum signal frequency power output to the d.c. power input under these conditions. (Owing to rectification, the d.c. power input under maximum signal conditions is usually greater than with zero signal input).

The plate circuit efficiency cannot exceed 50% in any Class A amplifier, and usually does not exceed 25% with Class A triodes. The plate circuit efficiency in an ideal Class A triode is given by

$$\eta = R_L / (2R_L + 4r_p) \quad (36)$$

The power relationships in a Class A triode are shown in Fig. 13.15 on the assumption that no second harmonic or rectification effects are present, and that fixed bias is employed. Allowance is made for the power loss in the d.c. resistance of the transformer primary. The plate-to-cathode voltage is E_b , but the total supply voltage is E_{bb} .

The plate dissipation in a Class A triode is greatest with zero input signal. If there are no rectification effects, the power input remains constant and the power output is simply power transferred from heating the plate to useful output. With normal rise of plate current for 5% second harmonic distortion, the plate dissipation is more nearly constant, but it is still sufficient to base the design on the zero-signal condition.

The quiescent operating point may be limited by one or more of the following:

1. Maximum plate dissipation.
2. Maximum plate voltage.
3. Maximum plate current.

Fig. 13.16 is an example including all three. The dissipation curve may be plotted from the relationship $I_b = P_0/E_b$. The horizontal line AB is the maximum plate current, while the vertical line CD is the maximum plate voltage. The quiescent operating point must not be outside the area ABCD.

Fig. 13.15. Power output and dissipation relationships in a Class A triode.
Fig. 13.16. Plate characteristics of small battery operated power triode with limits of maximum plate dissipation, maximum plate voltage and maximum plate current.

(vi) Power sensitivity

A triode suffers from low power sensitivity when compared with pentodes and beam power amplifiers, but the difference becomes smaller when a higher degree of negative feedback is applied to the latter. In any case, it is usually a simple matter to provide sufficient gain in the voltage amplifier.

Maximum power sensitivity is obtained when $R_L = r_p$, although this limits the maximum power output for a fixed value of distortion.

See Sect. 1(iii) for the form in which the sensitivity is expressed.

(vii) Choke-coupled amplifier

The choke-coupled amplifier of Fig. 13.17 may be used as an alternative to the transformer-coupled arrangement of Fig. 13.1, and the foregoing discussion may be applied exactly on the understanding that

1. the choke inductance and resistance correspond to the transformer primary inductance and resistance,
2. the condenser C offers negligible impedance to signal frequencies compared with R_1 .

(viii) Effect of a.c. filament supply

The curves of power triodes are usually drawn for the condition with d.c. filament supply and with the negative filament terminal regarded as the cathode. When a.c. is applied to the filament, roughly the same performance is achieved by increasing the grid bias by $E_f/2$. The increase is taken as 1.5 volts for a 2.5 volt filament.

FIG. 13.17

Fig. 13.17. Choke-coupled amplifier.

FIG. 13.18

Fig. 13.18. Basic circuit of power pentode.

(ix) Overloading

A triode has no "cushioning" effect such as occurs with a pentode when the peak signal voltage approaches the bias voltage. There is therefore no warning of the impending distortion which occurs when grid current flows. The distortion may be minimized by the use of a low-plate-resistance triode in the preceding stage, a low grid circuit resistance or a grid stopper resistor (10 000 ohms is normally satisfactory, but values from 1000 to 50 000 ohms have been used).

(x) Regulation and by-passing of power supply

The regulation and by-passing of the power supply affect the minimum frequency which can be handled satisfactorily at full power output—see Sect. 1(iv).

SECTION 3 : CLASS A MULTI-GRID VALVES

(i) Introduction (ii) Ideal pentodes (iii) Practical pentodes—operating conditions (iv) Graphical analysis—power output and distortion (v) Rectification effects (vi) Cathode bias (vii) Resistance and inductance of transformer primary (viii) Loud-speaker load (ix) Effects of plate and screen regulation (x) Beam power valves (xi) Space charge tetrodes (xii) Partial triode operation of pentodes.

(i) Introduction

Multi-grid valves include pentodes, beam power amplifiers and similar types, and space-charge valves. All of these have a family resemblance, in that they have higher plate circuit efficiencies and greater power sensitivities than triodes, but on the other hand they have higher distortion, particularly odd harmonic distortion. Their advantages over triodes generally outweigh their disadvantages, particularly as the distortion may be minimized by negative feedback, and they are almost exclusively used in ordinary commercial radio receivers. Reference should be made to Chapter 7 for amplifiers incorporating negative feedback.

The basic circuit of a power pentode with transformer-coupled load is Fig. 13.18. A choke-capacitance coupled load may also be used, as for a triode (Fig. 13.17). The

only essential difference from a triode is that provision must also be made for a constant voltage to be applied to the screen. In some cases the screen is operated at the same voltage as the plate, so as to avoid a separate screen voltage supply.

In a practical circuit the screen, the plate return and the grid return should each be by-passed to the cathode,

(ii) Ideal pentodes

An ideal pentode is one having infinite plate resistance, a 90° angular knee and equally spaced characteristic curves (Fig. 13.19). The zero bias characteristic is OAC, the $-E_{c1}$ characteristic is ODE, while the $-2E_{c1}$ characteristic is OB. The operating point is Q, the optimum loadline is AQB where $AQ = QB$ and the distortion is zero.

The following may readily be derived—

$$\text{Optimum } R_L = E_b/I_b \quad (1)$$

Then for optimum load resistance :

$$P_o = \frac{1}{2} E_b I_b \quad (2)$$

$$\text{D.C. power input} = E_b I_b \quad (3)$$

$$\text{Plate circuit efficiency} = \frac{1}{2} E_b I_b / E_b I_b = 50\% \quad (4)$$

$$E_{c1} = E_{c2} / 2\mu_t \quad (5)$$

where E_{c2} = screen voltage

and μ_t = triode amplification factor = μ_{a102} .

For any value of load resistance :

$$P_o = \frac{1}{2} I_b^2 R_L \text{ when } R_L \text{ is less than } E_b/I_b \quad (6)$$

$$P_o = \frac{1}{2} E_b^2 / R_L \text{ when } R_L \text{ is greater than } E_b/I_b \quad (7)$$

(It is assumed here that the signal voltage is reduced for other than optimum R_L in order to avoid distortion.)

Fig. 13.19. Plate characteristics of ideal pentode.

Fig. 13.20. Plate characteristics of typical pentode compared with ideal characteristics.

(iii) Practical pentodes—operating conditions

A practical pentode has characteristics of the form of Fig. 13.20 on which has been superimposed the “ideal characteristics” for the same plate voltage and current.

(A) The **load resistance** corresponding to the loadline AQB is slightly lower than the ideal value E_b/I_b . A good general rule for all pentodes is

$$R_L \approx 0.9 E_b/I_b \quad (8)$$

which is usually correct within $\pm 10\%$ for maximum power output. Eqn. (8) is safe to use under all circumstances, although an adjustment may be made experimentally or graphically to secure the best compromise between distortion and power output.

(B) The **power output** is always less than $\frac{1}{2} E_b I_b$, and may be calculated graphically [see (iv) below].

(C) Owing to rectification effects, the direct **plate current** may rise or fall from zero signal to maximum signal [see (v) below].

(D) The **plate circuit efficiency** is usually between 28% and 43% for total harmonic distortion less than 10%. Of course, the screen current is wasted, so that the total plate + screen circuit-efficiency is lower. The plate dissipation is equal to the d.c. watts input less the signal power output. The screen dissipation is equal to the d.c. screen input.

(E) **Screen current** : In a pentode, if the control grid bias is kept constant and only the plate voltage varied, the total cathode current (plate + screen) will remain nearly constant, decreasing slightly as the plate voltage is reduced down to the knee of the curve. Below this plate voltage the screen current increases more rapidly until zero plate voltage is reached, at which point the screen current is a maximum (Fig. 13.21). It is evident therefore that if a dynamic loadline cuts the zero bias curve below the knee, the screen current will rise rapidly and the screen dissipation may be exceeded. The average maximum-signal screen current may be calculated from the approximation

$$I_{c2 \text{ av}} \approx \frac{1}{2} I_A + \frac{1}{2} I_Q \quad (9)$$

where I_A = screen current at minimum plate voltage swing and zero bias (point A), and I_Q = screen current at no signal and normal bias.

The screen dissipation is therefore P_{s2} where

$$P_{s2} = E_{c2}(\frac{1}{2} I_A + \frac{1}{2} I_Q) \quad (10)$$

The variation of screen current with change of control grid voltage is such that the ratio between plate and screen currents remains approximately constant provided that the plate voltage is considerably higher than the knee of the curve. This ratio may be determined from the published characteristics.

A pentode, or beam power tetrode may be used as an amplifier with the plate voltage in the region of the knee of the curve of the $E_c = 0$ characteristic, that is somewhere about one fifth of the screen voltage, provided that care is taken to keep both plate and screen dissipations within their ratings. This gives operation very similar to that of a triode with a non-critical and low value of load resistance, which may be useful in some special applications (Ref. C6). This method of operation is not here described in detail.

Fig. 13.21. Plate, screen and cathode current characteristics of pentode.

Fig. 13.22. Calculation of pentode power output and distortion using the five selected ordinate method.

(F) The screen should be supplied from a voltage source of good regulation ; a voltage divider, whose "bleed" current is very much higher than the maximum screen current under dynamic conditions, is the most common source when the screen voltage is lower than the plate voltage.

(G) The **voltage gain** is determined as for a triode [Section 2(i) eqn. 8].

(H) If **oscillation or parasites** are experienced, a grid stopper resistance of about 500 ohms may be used. A small mica condenser from the plate terminal to earth is often beneficial. The bias resistor and its electrolytic by-pass condenser may be by-passed by a 0.001 μ F mica condenser. The shells of metal valves should be earthed directly. The length of leads should be as short as possible, particularly between the valve terminals and their by-pass condensers.

With type 807, a stopper resistor of 100 ohms (non-inductive) may be connected directly to the screen terminal of the valve, and a by-pass condenser (0.01 μ F mica) taken from the end of the resistance remote from the screen, directly to earth.

(I) **Overload characteristics**—Owing to the crowding together of the characteristics at and below the knee of the curves, a pentode tends to give a smoother overload characteristic than a triode. There is no point at which the distortion begins sharply, but rather a gradual flattening effect on the top, or top and bottom, of the signal current wave. Pentodes or beam power amplifiers with negative feedback lose most of this “cushioning effect,” and more closely resemble triodes as regards overload. The distortion due to grid current may be minimized by a low impedance (triode) preceding stage and a fairly low value of grid resistor; this will then leave the distortion due to the characteristics as the predominant feature, and provide a reasonably smooth overload.

(iv) Graphical analysis—power output and distortion

The choice of loadline for a pentode is usually made by firstly selecting the screen voltage and then selecting a convenient plate voltage. The third step is to note the grid voltage which allows a small plate current to flow, and to divide this voltage by 2 to obtain the grid voltage for the working point—thus determining the quiescent operating point Q . A scale is then swung around Q (a small pin is helpful as a pivot) until the two parts of the loadline are equal. If the scale is calibrated in millimetres, the 10 cm. calibration may be held at Q and the two parts compared directly by eye. When the two parts are equal, the second harmonic distortion will be zero, and the loadline is a first approximation for maximum power output.

In the case of some pentodes, and particularly beam power amplifiers of the 6L6 class, the loadline for zero second harmonic is obviously far from the knee of the curve. In such a case the loadline should be taken to the knee of the curve, if sharply defined.

To determine the exact loadline for maximum power output, it is necessary to take several angles, and to calculate the power output for each. The final choice of loadline is usually a compromise between power output and distortion; in such a case the load resistance is always less than the one giving maximum power output.

Load resistances higher than that giving maximum power output are to be avoided because they give greater harmonic distortion, less power output and higher screen current. It is better to err on the low side, particularly with nominal loudspeaker loads.

Owing to the presence of appreciable percentages of third and higher order odd harmonics, the formulae for triodes are not suitable for pentodes. There are several methods for pentodes, the choice depending on whether third harmonic only is required, or third and higher harmonics. Reference should be made to Chapter 6 Sect. 8(iii) “Graphical Harmonic Analysis.”

The treatment here is based on a working loadline. If the amount of second harmonic is very small, the rise of plate current due to rectification may be neglected. If there is an appreciable amount of second harmonic, it is necessary to use the method of Sect. 3(v) for drawing the corrected loadline; the formulae below should then be applied to the corrected loadline.

(A) Five selected ordinate method (For second and third harmonics only)

This method makes use of the plate currents corresponding to grid voltages -0.293 and $-1.707 E_{c1}$ in addition to the three currents used with Class A_1 triodes. If these are all available, the loadline of Fig. 13.22 is all that is required—if not, it will be necessary to plot the dynamic characteristic as in Fig. 13.24.

$$P_0 = [I_{max} - I_{min} + 1.41 (I_X - I_Y)]^2 R_L / 32 \quad (11)$$

$$R_L = (E_{max} - E_{min}) / (I_{max} - I_{min}) \quad (12)$$

$$\% \text{ 2nd harmonic} = \frac{I_{max} + I_{min} - 2I_{b1}}{I_{max} - I_{min} + 1.41 (I_X - I_Y)} \times 100 \quad (13)$$

$$\% \text{ 3rd harmonic} = \frac{I_{max} - I_{min} - 1.41 (I_X - I_Y)}{I_{max} - I_{min} + 1.41 (I_X - I_Y)} \times 100 \quad (14)$$

where I_X = plate current at $-0.293 E_{c1}$

I_Y = plate current at $-1.707 E_{c1}$.

Eqns. (11) to (14) are exact provided that there is no harmonic higher than the third. The power output is that for fundamental frequency only, but the power output for 10% harmonic distortion is only 1% of the fundamental power output.

The presence of third harmonic distortion has a flattening effect on both the positive and negative peaks, thus increasing the power output for a limited value of $I_{max} - I_{min}$. For example, 10% third harmonic reduces the value of I_{max} by 10% while it increases the total power output by 1%. If there were no distortion, and the value of I_{max} were maintained at 90%, the power output would be only 81%. Thus the ratio of power output with and without 10% third harmonic distortion is $101/81 = 1.25$, on condition that $I_{max} - I_{min}$ is kept constant. In simple language, for the same plate current swing, 10% third harmonic distortion increases the total power output by 25%. This will be modified by the presence of fifth and higher harmonics [see iv(D) below; Sect. 7(iii)].

(B) Five equal-voltage ordinate method (Espley)

For second, third and fourth harmonics only.

The previous method requires characteristics for -0.293 and $-1.707 E_{c1}$, which are often not directly available. The following method is usually more convenient and is exact provided that all harmonics above H_4 are zero (see Fig. 13.23 for symbols).

$$P_0 = (I_0 - I_{2.0} + I_{0.5} - I_{1.5})^2 R_L / 18 \quad (15)$$

$$\% \text{ 2nd harmonic} = \frac{3(I_0 - 2I_{1.0} + I_{2.0})}{4(I_0 + I_{0.5} - I_{1.5} - I_{2.0})} \times 100 \quad (16)$$

$$\% \text{ 3rd harmonic} = \frac{(I_0 - 2I_{0.5} + 2I_{1.5} - I_{2.0})}{2(I_0 + I_{0.5} - I_{1.5} - I_{2.0})} \times 100 \quad (17)$$

$$\% \text{ 4th harmonic} = \frac{(I_0 - 4I_{0.5} + 6I_{1.0} - 4I_{1.5} + I_{2.0})}{4(I_0 + I_{0.5} - I_{1.5} - I_{2.0})} \times 100 \quad (18)$$

$$\text{D.C. plate current} = \frac{1}{6}(I_0 + 2I_{0.5} + 2I_{1.5} + I_{2.0}) \quad (19)$$

A third harmonic scale may be prepared for reading the third harmonic percentage (Ref. A14 pp. 71-72).

(C) Seven equal-voltage ordinate method (Espley)

This is exact for harmonics up to the sixth, provided that higher harmonics are zero. It is sometimes more convenient than the five ordinate method, when there are no -0.5 and $-1.5 E_{c1}$ curves, even when the higher harmonics are of no interest.

The symbols have the same significance as in Fig. 13.23 with the subscript indicating the grid voltage.

$$P_0 = (167I_0 + 252I_{0.33} - 45I_{0.67} + 45I_{1.33} - 252I_{1.67} - 167I_{2.0})^2 R_L / 819\,200 \quad (20)$$

$$H_{2\%} = 25(559I_0 + 486I_{0.33} - 1215I_{0.67} + 340I_{1.0} - 1215I_{1.33} + 486I_{1.67} + 559I_{2.0}) / I \quad (21)$$

$$H_{3\%} = 250(45I_0 - 36I_{0.33} - 63I_{0.67} + 63I_{1.33} + 36I_{1.67} - 45I_{2.0}) / I \quad (22)$$

$$H_{4\%} = 450(17I_0 - 42I_{0.33} + 15I_{0.67} + 20I_{1.0} + 15I_{1.33} - 42I_{1.67} + 17I_{2.0}) / I \quad (23)$$

$$H_{5\%} = 4050(I_0 - 4I_{0.33} + 5I_{0.67} - 5I_{1.33} + 4I_{1.67} - I_{2.0}) / I \quad (24)$$

$$H_{6\%} = 2025(I_0 - 6I_{0.33} + 15I_{0.67} - 20I_{1.0} + 15I_{1.33} - 6I_{1.67} + I_{2.0}) / I \quad (25)$$

where $I = 167I_0 + 252I_{0.33} - 45I_{0.67} + 45I_{1.33} - 252I_{1.67} - 167I_{2.0}$.

(D) Eleven selected ordinate method

To use this method, it is first necessary to plot the loadline on the plate characteristics, and then to transfer it to a dynamic mutual characteristic (Fig. 13.24) from which the required values of plate current may be derived.

$$P_0 = \frac{1}{2}(0.5I_0 - 0.5I_{2.0} + I_{h\,m3} - I_{h\,m5})^2 R_L \quad (26)$$

$$I_{h1} = 0.5I_0 - 0.5I_{2.0} + I_{h\,m3} - I_{h\,m5} = \text{fundamental} \quad (27)$$

$$I_{h2} = \frac{1}{4}(I_0 + I_{2.0} - 2I_{1.0}) \quad (28)$$

$$I_{h3} = 0.167(2I_{0.5} + I_{2.0} - I_0 - 2I_{1.5}) \quad (29)$$

$$I_{h4} = \frac{1}{8}(I_0 + 2I_{1.0} + I_{2.0} - 2I_{0.3} - 2I_{1.7}) \quad (30)$$

$$I_{h5} = 0.1(2I_{0.7} + I_0 + 2I_{1.8} - 2I_{0.2} - 2I_{1.3} - I_2) \quad (31)$$

$$\text{Percentage second harmonic} = (I_{h2} / I_{h1}) \times 100$$

Fig. 13.23. Calculation of pentode power output and distortion using the five equal-voltage ordinate method.

Fig. 13.24. Calculation of pentode power output and distortion using the eleven selected ordinate method.

Percentage third harmonic = $(I_{hm3}/I_{hm1}) \times 100$ etc.

Note that all currents, including I_{hm1} , I_{hm2} etc., are peak values. The exact values of grid voltage are 0, 0.191, 0.293, 0.5, 0.691, 1.0, 1.309, 1.5, 1.707, 1.809 and 2.0. The approximate values are, however, sufficiently accurate for most purposes.

Eqn. (26) shows that third harmonic distortion adds to the power output, while fifth harmonic subtracts from the power output as calculated for distortionless conditions. See also (iv)A above; Sect. 7(iii).

For theoretical basis see Chapter 6 Sect. 8(iii).

(v) Rectification effects

The general effects are the same as for a triode except that it is sometimes possible with a pentode to have zero second harmonic and no loadline shift. In all other cases it is necessary to determine the corrected loadline before applying harmonic analysis or calculating power output. The method of deriving the corrected loadline is the same for pentodes as for triodes [Sect. 2(ii)D]. For example see Fig. 13.28.

With a triode, the loadline always shifts upwards into such a position that the distortion is less than it would otherwise be. With a pentode, the loadline shifts upwards when the load resistance is lower than a certain value, and shifts downwards when the load resistance is higher than this value. When a pentode loadline shifts downwards it causes increased distortion or decreased power output.

(vi) Cathode bias

The operation of cathode bias is the same as with triodes [Section 2(ii)E] except that the total current flowing through the cathode bias resistor is the sum of the plate and screen currents [Chapter 2 Section 4(v)]. If the screen is supplied from a voltage divider which is returned to the cathode, the bleed current must be added to the cathode current in calculating R_k . This tends to stabilize the bias voltage. Even in cases where there is no rise of plate current at maximum signal, there will always be a rise in screen current [Section 3(iii)E].

When a tentative value of R_k has been determined for maximum signal conditions, it is necessary to check both plate and screen dissipations at zero signal. If the plate and screen voltages are equal, the simplest method is the use of the "triode" mutual characteristics, if available [Chapter 2 Sect. 4(v)].

If there is a "bleed" current through R_k , the procedure is shown in Fig. 13.25 where the triode mutual characteristic is shown in the upper part, with OA representing the bleed current in the lower part. The cathode loadline is drawn from A (instead of from 0) with a slope of $-1/R_k$ where R_k is the value determined for maximum signal conditions.

The no-signal grid bias is $-E_{c1}$ and the cathode current $(I_b + I_{c2})$ is I_{k1} . The dissipation on plate and screen is given by

$$P_o = I_{k1}E_b/m/(m+1); P_{o2} = I_{k1}E_{c2}/(m+1) \quad (32)$$

where m = ratio of plate to screen currents = I_b/I_{c2} .

The rectification effects with cathode bias may, like triodes (Fig. 13.8) be determined from the plate characteristics but an approximation is involved since $D''E_{bb}$ must have a slope of $-m/R_k(m+1)$ where $m = I_b/I_{c2}$. The value of I_{c2} may be taken as that for maximum signal, and a slight error will then be introduced when deriving the zero signal condition. The cathode bias loadline should, ideally, be drawn as two loadlines—one for zero signal, and the other for maximum signal. For most purposes, however, the maximum signal cathode loadline may be used for both conditions. The zero bias lines are, in each case, above the lines for maximum signal, and the difference in slope is of the order of 5% to 10%.

In general, any Class A₁ pentode may be operated either with fixed or cathode bias, as desired, except for the limitations on the maximum grid circuit resistance [see Sect. 10(i)]. It occasionally happens that a condition is permissible only with fixed bias, owing to the rise in plate dissipation at zero signal.

For back bias, further details regarding fixed bias, and grid circuit resistance see Sect. 10.

For cathode by-passing see Sect. 2(ii).

Fig. 13.25. Cathode loadline of pentode with additional bleed current passing through the cathode resistor, plotted on mutual characteristics.

Fig. 13.26. Power output and harmonic distortion of typical pentode plotted against load resistance. Valve type 6AK6, $E_b = E_{c2} = 180$ V, $E_{c1} = -9$, peak signal = 9 volts.

(vii) Resistance and inductance of transformer primary

The **resistance** of the transformer primary may be allowed for in the same way as with triodes [Sect. 2(ii)A]. If R' is the resistance of the primary, and R_k is the cathode bias resistance, then the slope of the line QE_b in Fig. 13.6 should be $-1/(R' + R_k)$.

The **transformer primary inductance** may be based on Chapter 5 Sect. 3(iii)c.

For the same load impedance and the same high frequency attenuation, pentodes may have higher transformer **leakage inductance** than triodes if frequency response is the only criterion. However, owing to the distortion with reactive loads at high output levels, it is very desirable to maintain the leakage inductance as low as practicable, particularly in push-pull amplifiers.

(viii) Loudspeaker load

A pentode is, unfortunately, critical in its load resistance for both maximum power output and distortion. At low operating levels the output power rises steadily as the load resistance is increased up to the value $R_L = r_p$ provided that the grid input voltage is maintained constant (the low operating level is to avoid overloading under any conditions). A loudspeaker has pronounced impedance peaks at the bass resonant frequency and at high audio frequencies. When a loudspeaker is operated at a low level, the acoustical output is accentuated at the bass resonant frequency and at high audio frequencies. The latter may be reduced to any desired degree by a

shunt filter—a resistance R in series with a capacitance C . If R is variable, the combination is the simplest form of tone control. If R is fixed, typical values are :

$$R = 1.3R_L; \quad C = 0.025\mu\text{F for } R_L = 5000 \text{ ohms.}$$

This does not affect the rise of impedance at the bass resonant frequency, which is a function of the loudspeaker design and the type of baffle—see Chapter 20 Sect. 2(iv) and Sect. 3.

At maximum signal voltage the conditions are somewhat different (Fig. 13.26). The power output in this case reaches a maximum at $R_L = 9000$ ohms. The second harmonic reaches a minimum (practically zero) at about $R_L = 14\,000$ ohms, and then rises steadily; actually it undergoes a change of phase near $R_L = 14\,000$ ohms. The third harmonic rises all the way from zero to the limit of the graph. Minimum “total distortion” occurs at $R_L = 10\,000$ ohms, which is the published typical load, being a close approach to maximum power output. In this particular case the load resistance for zero second harmonic is not that for maximum power output.

In the case of a loudspeaker load, the load resistance may rise from the nominal value to (say) 6 or 8 times this value; all the variation is in the upwards direction. If full signal voltage is maintained for all frequencies, the distortion will be very severe and the maximum power output will be reduced at low and high frequencies. The only methods of minimizing the trouble are the use of a loudspeaker and baffle with less prominent impedance peaks, and the use of negative voltage feedback (see Chapter 7) or reduced signal voltage on the grid. A pentode, operating well below its nominal power output, is capable of giving reasonable fidelity even on an ordinary loudspeaker load. In a normal radio receiver, a power pentode with a nominal maximum power output of 4 or 5 watts can give reasonable fidelity up to somewhat over 1 watt, but it has the advantage of being capable of delivering its full power output when the distortion can be tolerated.

The effect of these high impedance loads, which are here assumed to be purely resistive for the purpose of illustration, is shown by the beam power amplifier plate characteristics in Fig. 13.27. The effect may be minimized by reducing R_L slightly below the optimum value.

Fig. 13.27. Plate characteristics of 6L6 or 807 beam tetrode with loadlines of optimum resistance also twice, four times and eight times optimum. The loadlines have been corrected for the rectification effect.

The impedance of a loudspeaker is, however, far from being resistive (see Chapters 20 and 21), having a reactive component varying with frequency, which must be combined with the shunt reactance of the transformer primary at low frequencies and that of the shunt capacitance from plate to earth at high frequencies. The combined reactive components increase the distortion and reduce the power output [see also Chapter 5 Sect. 3(iii)c and Chapter 2 Sect. 4(vi); Ref. C4].

The published values of power output apply to highly efficient output transformers. The available power output from the secondary of a normal power transformer is equal to η times the published value, where η is the efficiency [see Chapter 5 Sect. 2(ii) and Sect. 3(vi)]. Typical efficiencies are from 70% to 95% (depending on the price class) for well-designed transformers.

(ix) Effects of plate and screen regulation

The internal resistances of plate and screen supply sources cause a reduction in power output. If the regulation of the power supply is such that the rise of plate and screen currents causes a decrease of 1% in all the electrode voltages, the decrease in power output (by the use of conversion factors) will be approximately 2.5%. This will be modified by the shape of the characteristics and rectification effects, and the only accurate method is the graphical one outlined below. See also remarks on push-pull—Sect. 6(iii).

In addition, the regulation and by-passing of the power supply also affect the minimum frequency which can be handled satisfactorily at full power output—see Sect. 1(iv).

Graphical method (Ref. B4).

Let R_1 = internal resistance of plate supply source,

R_2 = internal resistance of screen supply source,

ΔI_b = increase in plate current from zero to maximum signal, with constant electrode voltages,

ΔI_{c2} = increase in screen current, with constant electrode voltages,

ΔE_b = change in plate voltage,

ΔE_{c1} = change in screen voltage,

E_b' = plate voltage at maximum signal,

and E_{c2}' = screen voltage at maximum signal.

$$\text{Then } E_b' = E_b - \Delta E_b \quad (33) \quad E_{c2}' = E_{c2} - \Delta E_{c2} \quad (34)$$

$$\text{where } \Delta E_b = R_1 \Delta I_b \quad (35) \quad \Delta E_{c2} = R_2 \Delta I_{c2} \quad (36)$$

Fig. 13.28. Plate characteristics of 6L6 or 807 illustrating method of correcting the loadline for rectification. The corrected loadline is $A'B'$.

On the plate characteristics (Fig. 13.28) AB is the uncorrected loadline with C as its average current point, $A'B'$ is a parallel loadline with C' as its average current point, $A'B''$ is the corrected loadline. The average current may be determined from the point on $A'B''$ which has a plate voltage 300 volts; from this the rise of current ΔI_b may be calculated. The value of ΔI_{c2} may be determined from eqn. (9), ΔE_{c2} may be calculated by eqn. (36) and E_{c2}' by eqn. (34). In the example of Fig. 13.28 let it be assumed that the plate, screen and grid voltages are all reduced proportionally, F_e^* being 0.9:

$$E_b = E_{c2} = 300 \text{ volts}$$

$$E_b' = E_{c2}' = 270 \text{ volts}$$

$$E_{c1} = -15 \text{ volts}$$

$$E_{c1}' = -13.5 \text{ volts}$$

The procedure is:

1. Plot a new curve for $E_{c1} = 0$, $E_{c2}' = 270$ volts, by the use of conversion factors*. This is drawn on Fig. 13.29. For $F_e = 0.9$, $F_i = 0.86$.
2. Plot a curve for $E_{c1}' = -13.5$, $E_{c2}' = 270$ volts similarly. This will be the -15 volt curve (for $E_{c2} = 300$ volts) with the current ordinates multiplied by the factor 0.86.

*For conversion factors see Chapter 2 Sect. 6 and Fig. 2.32A.

Fig. 13.29. Plate characteristics of 6L6 or 807 giving graphical method for deriving the effect of internal resistance in the voltage supply source.

3. Plot a curve for $E_{c1}' = -27$, $E_{c2}' = 270$ volts. This will be the -30 volt curve (for $E_{c2}' = 300$ volts) with the current ordinates multiplied by 0.86.
4. Mark the point Q at $E_b = 270$, $E_{c2} = 270$, $E_{c1} = -13.5$ volts.
5. Through Q draw the uncorrected loadline RQS.
6. Draw the corrected loadline R'D'S' by the same method as previously (Fig. 13.28).
7. Determine the rise of plate current from Q to D' (intersection of R'S' with $E_b = 270$ volts). This should be approximately the same as derived in the first case (ΔI_b). If there is an appreciable error, some adjustment should be made.

(x) Beam power valves

Beam power amplifier valves, otherwise known as output tetrodes, are in two principal classes. The first class includes most of the smaller valves, which have characteristics so similar to pentodes that they may be treated as pentodes in all respects. The second class includes types such as 6L6, 807 and KT66, which differ from pentodes principally in having sharper "knees" to their plate characteristics, more second harmonic but less third harmonic distortion. The optimum load resistance is more critical than with ordinary power pentodes.

The screen currents of many types of beam power valves, due to variations in grid alignment, may have considerably greater tolerances than in pentodes—up to $\pm 100\%$ in some instances—and screen dropping resistances should not be used unless recommended by the valve manufacturer. The screen supply should normally be obtained from a voltage divider.

The distortion and power output of type 6L6 beam power valve are plotted against load resistance in Fig. 13.30. The second harmonic is 9.6% at the rated load resistance, the third harmonic only 2.4% and all higher harmonics negligible. At lower load resistances the second harmonic rises, although not seriously, the third harmonic decreases steadily, and all higher harmonics are negligible—the overall effect being quite satisfactory. At higher load resistances the performance is not good, and the overall effect is roughly the same as with a pentode. See Chapter 7 for the effect of negative feedback.

Reference C3.

(xi) Space charge tetrodes

A space charge tetrode is actually a triode operating on a virtual cathode provided by the thermionic cathode and the inner (space charge) grid. It is capable of low distortion, even lower than a triode, but the power output for a given d.c. power input is less than that of a triode, owing to the power taken by the space-charge grid.

See Refs. C1, C2.

(xii) Partial triode operation of pentodes ("ultra-linear" operation)

When the screen and plate of a pentode are being operated at the same voltage, pentode operation is obtained when the screen is connected to the B+ end of the output transformer primary, while triode operation is obtained when the screen is connected to the plate end of the primary. Any desired intermediate condition can be obtained by connecting the screen to a suitable tap on the primary. In such intermediate condition the valve operates as a pentode having negative feedback applied to the screen, with a section of the load impedance common to both electrodes, and minimum high level distortion with push-pull operation is usually obtained when the tapping point is about 43% of the total primary turns (Refs. C7, H5, H6).

FIG. 13.30

Fig. 13.30. Power output and distortion of type 6L6 beam power amplifier plotted against load resistance, for $E_b = E_{c2} = 250$ volts, $E_{c1} = -14$ volts, peak signal 14 volts.

SECTION 4 : PARALLEL CLASS A AMPLIFIERS

Any two Class A amplifier valves may be connected in parallel, with suitable provision for their correct operation, to provide double the power output. It is assumed that these have identical characteristics (the normal manufacturing tolerances have only a very slight effect). The load resistance will be half that for one valve. The distortion will be the same as for one valve. The input voltage will be the same as for one valve. The total plate current will be twice that for one valve. The effective plate resistance will be half that for one valve.

Parasitics are likely to occur, particularly with high-slope valves. Precautions to be taken include the following :

1. The two valves should be placed closely together, with very short leads between grids and plates (and screens in the case of pentodes).
2. A grid stopper should be connected directly to one or both grids. It is usually cheaper—and just as effective—to have one grid stopper of, say, 200 ohms than two stoppers each of 100 ohms.
3. Screen stoppers (50 or 100 ohms for each screen) are very helpful, particularly with types 6L6 or 807 [see Sect. 3(iii)H].

N.B. Plate stoppers are less helpful, are wasteful of power, and are generally unnecessary.

The advantages of parallel operation lie principally in the elimination of the phase-splitter or input transformer required with push-pull operation. The disadvantages are :

1. The necessity for handling the heavy direct plate current. This necessitates either a special output transformer or a choke (say 20 henrys) with parallel feed to the output transformer.
2. The higher distortion—this is not serious if negative feedback is used, and in any case is no worse than that of a single valve.
3. The attenuation of lower frequencies at maximum power output due to the limited size of the by-pass capacitor. This effect is also a function of the plate supply regulation—see Sect. 1(iv).

Parallel operation may be used with a cathode-follower stage, permitting the use of two smaller valves with lower plate voltage in place of one valve with higher plate voltage, and thereby reducing the difficulties of grid excitation.

SECTION 5 : PUSH-PULL TRIODES CLASS A, AB₁

(i) Introduction (ii) Theory of push-pull amplification (iii) Power output and distortion (iv) Average plate current (v) Matching and the effects of mismatching (vi) Cathode bias (vii) Parasitics.

(i) Introduction

(A) Fundamental principles of push-pull operation

The fundamental circuit of a push-pull power amplifier is Fig. 13.31. A balanced (push-pull) input voltage must be applied to the three input terminals, and a balanced

Fig. 13.31. Fundamental circuit of push-pull power amplifier.

(push-pull primary) output transformer must be connected to the two plates with its centre-tap connected to $E_{bb} +$. For the best results the input voltage must be exactly balanced, the valves must have identical characteristics and the output transformer must be exactly balanced between the two sections of the primary, with perfect coupling between them. Under these conditions, any even harmonics introduced by the valves will be cancelled, but the odd harmonics will not be affected; the flux in the core due to the d.c. plate currents would be zero.

The load resistance R_L is connected across the secondary, and the reflected resistance* across the whole primary is

$$R_L = 4R_2(N_1^2/N_2^2)$$

*See Chapter 5 Sect. 1(ii).

and the reflected resistance across half the primary is

$$R_L'' = \frac{1}{2}R_L = 2R_2(N_1^2/N_2^2)$$

where N_1 = turns in half primary winding

and N_2 = turns in secondary winding.

If valve V_2 in Fig. 13.31 were removed from its socket, the load resistance effective* on V_1 would then be

$$R_L' = \frac{1}{2}R_L = R_2(N_1^2/N_2^2)$$

which is half the load resistance on V_1 under push-pull conditions. This is the condition which occurs when one of the valves reaches plate current cut-off.

If the output transformer were replaced by two separate transformers, one from each plate to E_{bb} +, the even harmonics would be cancelled but some advantages of push-pull operation would be lost. The whole principle of push-pull operation is based on the assumption that the two plates are always exactly 180° out of phase with one another. This is achieved by an "ideal" output transformer (see Chapter 5 Sect. 1) even if one of the valves is not operating.

If two valves are to be operated in push-pull, the plate and grid voltages may be the same as for single valve operation, the plate-to-plate load resistance may be twice and the plate currents twice the respective values for a single valve; under these conditions the power output will be exactly twice that for a single valve. On the other hand, higher power output is obtainable, with some increase in third harmonic distortion, merely by decreasing the plate-to-plate load resistance without any change in grid bias (Ref. E7). Still higher power output is obtainable by increasing the grid bias and the signal input voltage, also by increasing the plate voltage to its maximum value.

(B) Classes of operation

A **Class A amplifier** is an amplifier in which the grid bias and alternating grid voltages are such that the plate current of the output valve or valves flows at all times. The suffix 1 indicates that grid current does not flow during any part of the input cycle.

A **Class AB₁ amplifier** is an amplifier in which the grid bias and alternating grid voltages are such that the plate current in any specific valve flows for appreciably more than half, but less than the entire, input cycle. The suffix 1 has the same meaning as with Class A.

A very useful operating condition is the borderline case between Class A and Class AB₁, that is when the plate current just reaches the point of cut-off—this is called **Limiting Class A₁ operation**.

Class A₁ triodes may be operated from poor regulation power supplies without serious loss of power output owing to the comparatively small rise of current at maximum signal. Class AB₁ triodes require good regulation of the power supply. Class AB₂ also requires very tight coupling between the two halves of the transformer primary.

Automatic bias control has been developed (Refs. A24, A25) whereby the operation is pure Class A₁ with small input voltages, with the bias automatically increasing with the input voltage to provide firstly Class AB₁ and finally Class AB₂ operation. See also Sect. 11(ii).

(C) Important features

Class A₁ triodes may be operated in push-pull from power supplies having poor regulation without any serious loss of power output, owing to the comparatively small rise of current at maximum signal. In addition, with normal by-passing, the regulation of the power supply does not affect the minimum frequency that can be handled satisfactorily at full power output.

Good regulation of the power supply is necessary with Class AB operation, on both these counts.

With Class AB operation, the current in one half of the output transformer is zero for part of the cycle—this causes a very rapid rate of change of current at the cut-off point, tending to cause parasitics due to the leakage inductance of the transformer. This effect may be minimized by the use of a transformer with low leakage induct-

*See Chapter 5 Sect. 1(ii).

ance—see Chapter 5 Sect. 3(iii)c—or by reducing the rate of change of current. The latter is accomplished in limiting Class A operation owing to the avoidance of the sharp bend or “discontinuity” in the characteristic at the cut-off point. Valves of the 6L6 or 807 class, when connected as triodes, have a slower rate of cut-off than normal triodes, and are therefore particularly adapted to Class AB₁ operation, which merges closely into limiting Class A.

The use of a resistive network to pass a steady current through the primary of the transformer does nothing to reduce the rate of change of current, although it may help in damping out any parasitics which may occur.

(ii) Theory of push-pull amplification

It is assumed that the input voltage is sinusoidal, that the operation is Class A₁, that the output transformer is ideal having no resistance or leakage reactance, and that the input and output voltages are balanced. The valves are assumed to be perfectly matched. For circuit and conditions see Fig. 13.31.

(A) The plate-current grid-voltage characteristic of any valve may be expanded into an infinite series—

$$i_{b1} = a_0 + a_1 e_g + a_2 e_g^2 + a_3 e_g^3 + a_4 e_g^4 + a_5 e_g^5 + \dots \quad (1)$$

where i_{b1} = instantaneous plate current,

e_g = instantaneous grid signal input voltage,

a_0 = plate current at zero signal,

and a_1, a_2, a_3 , etc. are coefficients.

The instantaneous fundamental power output is given by

$$P_0 = (a_1 e_g)^2 R_L \quad (2)$$

where R_L = load resistance on one valve.

In a push-pull amplifier the second valve V_2 has a grid voltage opposite in polarity to V_1 :

$$i_{b2} = a_0 - a_1 e_g + a_2 e_g^2 - a_3 e_g^3 + a_4 e_g^4 - a_5 e_g^5 + \dots \quad (3)$$

where i_{b2} = instantaneous plate current of V_2 ,

a_0 = plate current of V_2 at zero signal,

and a_1, a_2, a_3 etc. have the same meanings as in eqn. (1).

Eqn. (3) has been derived from eqn. (1) merely by making e_g negative, so that e_g^2 becomes positive and e_g^3 becomes negative.

As the plate currents are in phase opposition to the output load, the net flux-producing current is

$$\begin{aligned} i_d &= i_{b1} - i_{b2} \\ &= 2a_1 e_g + 2a_3 e_g^3 + 2a_5 e_g^5 + \dots \end{aligned} \quad (4)$$

where i_d = net flux-producing current in N_1 turns, i.e. one half the primary winding,

and all currents are instantaneous values.

The d.c. components and all the even harmonic terms are seen to have been cancelled, only the fundamental and odd harmonic terms remaining.

The total plate current from E_{bb} is given by

$$\begin{aligned} i_t &= i_{b1} + i_{b2} \\ &= 2a_0 + 2a_2 e_g^2 + 2a_4 e_g^4 + \dots \end{aligned} \quad (5)$$

from which it will be seen that the d.c. components plus the even harmonic terms are present. Thus the total supply current will only remain constant when there is no even harmonic distortion.

(B) The effect of hum in the plate and grid supply voltages

If the plate supply voltage E_{bb} in a distortionless Class A amplifier is changed slightly, both plate currents will change together, and the net flux-producing current (i_d) will be unchanged. Hum from the supply voltage would not therefore appear in the output. The effect of hum from the grid bias supply will be similar.

In a practical amplifier, owing to the curvature of the valve characteristics, the effect may be analysed as follows, commencing with hum in the grid bias supply voltage. Assume that there is a hum voltage $E_h \cos pt$ in series with E_g , and that the input signal is $E_g \cos qt$.

The input voltage to V_1 is $E_h \cos pt + E_g \cos qt$.

The input voltage to V_2 is $E_h \cos pt - E_g \cos qt$.

Substituting these values in equation (1) we have

$$\begin{aligned} i_{b1} &= a_0 + a_1(E_h \cos pt + E_g \cos qt) + a_2(E_h \cos pt + E_g \cos qt)^2 + \dots \\ &= a_0 + a_1 E_h \cos pt + a_1 E_g \cos qt + a_2 E_h^2 \cos^2 pt + a_2 E_g^2 \cos^2 qt + \\ &\quad 2a_2 E_h E_g \cos pt \cos qt + \dots \end{aligned}$$

Similarly

$$\begin{aligned} i_{b2} &= a_0 + a_1(E_h \cos pt - E_g \cos qt) + a_2(E_h \cos pt - E_g \cos qt)^2 + \dots \\ &= a_0 + a_1 E_h \cos pt - a_1 E_g \cos qt + a_2 E_h^2 \cos^2 pt + a_2 E_g^2 \cos^2 qt - \\ &\quad 2a_2 E_h E_g \cos pt \cos qt + \dots \end{aligned}$$

$$\begin{aligned} \text{Therefore } i_d &= i_{b1} - i_{b2} = 2a_1 E_g \cos qt + 4a_2 E_h E_g \cos pt \cos qt \\ &= 2a_1 E_g \cos qt [1 + 2(a_2/a_1) E_h \cos pt] \quad (6) \end{aligned}$$

Eqn. (6) has the form of a carrier $(2a_1 E_g \cos qt)$ modulated to the depth $2(a_2/a_1)E_h$ by a hum frequency $\cos pt$.

The effect of hum in the plate supply voltage is similar to its effect on the grid bias supply, that is to say the hum frequency modulates the signal frequency. It should be noted that these modulation components appear in single-ended amplifiers to the same extent, but in combination with the fundamental and harmonics of the ripple, which latter are absent with push-pull operation.

Summary—Push-pull operation tends always to reduce the effects of hum in either the grid bias or plate supply voltage.

(C) Effects of common impedance

The fact that no fundamental component is found in the total plate current i_d (eqn. 5) prevents any fundamental signal voltage from being fed back to earlier stages as the result of a common impedance in the plate voltage source. As the even harmonics are fed back, each will again result in higher order harmonics, so that there can be no instability caused by feedback around a push-pull stage.

General deductions

1. Because the d.c. components of the plate currents cancel each other, no steady flux is maintained in the core of the output transformer.
2. Because the even harmonics are zero, the limit placed on single-ended amplifiers no longer applies. It is usual to design push-pull amplifiers for maximum power output without primarily considering the odd harmonics; when distortion is objectionable, this may be reduced—at the expense of power output—by increasing the load resistance.

The effects of the regulation and by-passing of the power supply are covered in Sect. 5(i).

(D) Application to characteristic curves—Composite characteristics

From eqn. (4) the net flux-producing current in one half of the primary winding is

$$i_d = i_{b1} - i_{b2} \quad (7)$$

Thus a "composite" characteristic may be drawn for the fixed grid voltage $-E_c$ by subtracting the currents in the two valves. At the quiescent plate voltage E_{bb} , both valves draw the same plate current and therefore $i_d = 0$. The composite characteristic must therefore pass through the point $E_b = E_{bb}$, $i_d = 0$. At other plate voltages the value of i_d is given by $i_{b1} - i_{b2}$ when the plate voltage of one is increased

Fig. 13.32. The derivation of the composite characteristic for matched push-pull valves.

by the same voltage that the other is decreased. This may be applied graphically as shown in Fig. 13.32; the upper half includes the E_c characteristic for V_1 (ACDE) while the lower half includes the E_c characteristic for V_2 but inverted and placed left to right (FGHJ). Point C on the V_1 characteristic is the quiescent operating point, and point B corresponds to the plate voltage E_{bb} . The V_2 characteristic is placed so that H, the quiescent operating point, comes below C; then since $BC = BH = I_{b0}$ the point B is on the composite characteristic. At any other plate voltage N, the point L on the composite characteristic is found by subtracting PN from KN, giving LN as an ordinate. Valve V_2 cuts off at point J, so that the amount to be subtracted from the V_1 ordinate is zero, giving D (and its opposite number G) as points on the composite characteristic. The composite characteristic is therefore FGRBLDE which may be compared with the straight line FBE. Sudden bends occur at D and G, but the portion between D and G is fairly straight; the latter includes the whole Class A operating region. It is obvious that the non-linearity of the composite characteristic becomes worse as the quiescent operating point is moved towards the foot of the characteristic—that is as I_{b0} becomes less. Thus we have the Class A condition (including limiting Class A) with nearly straight composite characteristics, the Class AB₁ condition which includes the kinks at the points of plate-current cut-off, and finally the Class B condition with quite considerable non-linearity.

The composite characteristic of Fig. 13.32 is that for zero signal input voltage ($e_g = 0$). Other composite characteristics may be drawn by a somewhat similar method, except that the $(E_c + e_g)$ characteristic of V_1 must be combined with the $(E_c - e_g)$ characteristic of V_2 to give the $+e_g$ composite characteristic. For example, if $E_c = -60$ volts, we may take e_g in increments of 10 volts, giving:

e_g	0	+10	+20	+30	+40	+50	+60	volts
$E_c + e_g$	-60	-50	-40	-30	-20	-10	0	volts
$E_c - e_g$	-60	-70	-80	-90	-100	-110	-120	volts

A family of composite characteristics is shown in Fig. 13.33 in which $E_{bb} = 300$ volts and $E_c = -60$ volts, with values of e_g in accordance with the table above. The

Fig. 13.33. Family of composite characteristics for two type 2A3 triodes.

composite operating point is $e_g = 0$ and $E_b = E_{bb} = 300$ volts. The composite loadline is a straight line through this point, with a slope corresponding to $R_L' = \frac{1}{2}R_L$, where $R_L =$ load resistance plate to plate. We may therefore imagine a composite valve, taking the place of both V_1 and V_2 , working into half the primary winding with the other half open-circuited. This composite valve will have a plate resistance (r_a) as indicated by the slope of the composite characteristic, which value is approximately half that of one valve at the quiescent operating point (r_{p0}). For this reason the slope of the composite characteristic changes slightly with the grid bias.

Maximum power output is obtained from the composite valve when its load resistance is equal to its plate resistance

i.e. when $R_L' = R_L/4 = r_{p0}/2$ or $R_L = 2r_{p0}$ (8)

On the composite characteristics therefore, maximum power output is obtained when the slope of the loadline is the negative of the slope of the composite characteristics.

Owing to the good linearity of the composite characteristics for Class A_1 operation, and the freedom from limitations in the vertical direction, **elliptical loadlines** may be accommodated with less distortion than with any other method. **Negative voltage feedback** makes such an amplifier practically distortionless for any type of load, resistive or reactive, of any value of impedance; the only limitation is regarding grid current.

FIG. 13.34

Fig. 13.34. Method of deriving the loadline on an individual valve (AQV) from the composite characteristic AOB .

The loadline on one valve (e.g. V_1) is determined as Fig. 13.34 in which the composite characteristics, the composite loadline AB , and the individual V_1 characteristics are the same as in Fig. 13.33. At every intersection of a composite characteristic with the composite loadline (e.g. point C) draw a vertical line (e.g. CS) to cut the corresponding V_1 characteristic. Then join these points $APQSTV$ etc. with a smooth curve, which is the loadline on a single valve, Q being the quiescent operating point. It is obvious that this loadline is curved, although it is less curved with Class A than with Class AB_1 operation.

Equivalent circuit for push-pull amplifier

There are various forms which an equivalent circuit might take, but the one adopted here (due to Krauss) has some special advantages for the purpose (Fig. 13.35). The two valves are assumed to have equal constant amplification factor (μ), and plate resistances (r_{p1} and r_{p2}) which are functions of the plate current.

From equation (4) we have

$$i_d = i_{b1} - i_{b2}.$$

We may write

$$i_{b1} = I_{b0} + \Delta i_{b1} \text{ and } i_{b2} = I_{b0} - \Delta i_{b2} \quad (9)$$

where I_{b0} = quiescent plate current of either valve

Δi_{b1} = change of plate current in valve V_1

and Δi_{b2} = change of plate current in valve V_2 .

Combining (4) and (9),

$$i_d = \Delta i_{b1} + \Delta i_{b2} \quad (10)$$

in which the varying components of i_{b1} and i_{b2} add so far as i_d is concerned. Let the varying components be i_{p1} and i_{p2} thus leading to the equivalent circuit of Fig 13.35 in which two generators each developing a voltage μe_g through their internal resistances r_{p1} and r_{p2} , are effectively in parallel to supply the load current i_d through the load resistance R_L' . All quantities except R_L' and μ are instantaneous values.

Fig. 13.35. Equivalent circuit which may be used for deriving certain impedance and current relationships.

The impedance seen by V_1 is the impedance of the circuit to the right of the line ab , which is called r_{ab} .

It may be shown (Ref. E7) that

$$r_{ab} = R_L'(1 + r_{p1}/r_{p2}) \quad (11)$$

The dynamic plate resistance of the composite valve may be expressed

$$r_d = \Delta e_{b1}/i_d \quad (12)$$

From (10) $i_d = \Delta i_{b1} + \Delta i_{b2}$.

$$\text{Now } \Delta i_{b1} = \Delta e_{b1}/r_{p1} \quad (13)$$

$$\text{and } \Delta i_{b2} = \Delta e_{b2}/r_{p2} \quad (14)$$

$$\text{From (12), (13), (14), } r_d = r_{p1}r_{p2}/(r_{p1} + r_{p2}) \quad (15)$$

This indicates that the plate resistance of the composite valve at any instant is equal to the parallel combination of the individual plate resistances of V_1 and V_2 . For Class A operation r_d is very nearly constant, so that

$$r_d \approx r_{p0}/2 \quad (16)$$

where r_{p0} = plate resistance of V_1 or V_2 at the quiescent operating point.

Now if $R_L' = r_d$ (the condition for maximum power output)

$$R_L' = r_d \approx r_{p0}/2 \quad (17)$$

The load impedance seen by a single valve (V_1 or V_2) in Class A operation is given by [From (11), (15), (17)], $r_{ab} \approx r_{p1}$ (18)

so that each valve at any instant is working into a load resistance approximately equal to its own plate resistance.

(iii) Power output and distortion

It has been shown in the preceding subsection that maximum power output is obtained from two matched valves in push-pull when the load resistance from plate to plate (R_L) is equal to 4 times the plate resistance of the imaginary composite valve (r_d) or approximately twice the plate resistance of one of the valves at the quiescent operating point (r_{p0}). This value of R_L may be regarded as the minimum value, since any decrease would cause loss of power output, increased distortion, and high peak currents. In some circumstances it is found desirable to increase R_L —even though this reduces the power output—thereby reducing the odd harmonic distortion, the peak currents and plate dissipation.

The value of load resistance to provide maximum power output may be determined approximately from the plate characteristics of one valve (Fig. 13.36). Since the $E_c = 0$ characteristic approximately follows the 3/2 power law, it may be shown (Ref. E5) that maximum power output occurs when the loadline intersects the $E_c = 0$ curve at $0.6E_{bb}$. The plate current at this point is I_{bm} and the other values are:

$$R_L = 1.6E_{bb}/I_{bm} \text{ plate to plate} \quad (19)$$

$$P_o = 0.2E_{bb} \cdot I_{bm} \text{ for 2 valves} \quad (20)$$

If it is desired to determine the optimum value of R_L in a particular case, several half-loadlines may be drawn as in Fig. 13.36 but radiating from B . The power output for each may be calculated from the expression

$$P_o = \frac{1}{8} I_{bm}^2 R_L \quad (21)$$

$$\text{or } P_o = \frac{1}{2} I_{bm} (E_{bb} - E_{min}). \quad (22)$$

Eqns. (21) and (22) may be used with reasonable accuracy for Class AB_1 , since the third harmonic distortion is usually less than 3%. A useful rule is to multiply the power output, as indicated by these equations, by the factor $10\,000/(100 - H_3\%)^2$ to obtain a close approximation to the actual power output. Values of this factor for various third harmonic percentages are given below:

H_3	1%	2%	3%	5%	7%	10%
Factor	1.02	1.04	1.06	1.11	1.15	1.23

It is here assumed that fifth and higher order odd harmonics are negligible.

The loadline slope is unaffected by the grid bias, but the two extremities are slightly affected—as the grid bias is decreased, the point A (which is really the intersection of the loadline with the composite characteristic) moves slightly towards B . Thus with Class A_1 the output will be slightly less than indicated by eqns. (20), (21) and (22).

Fig. 13.36. Method of deriving the approximate power output and load resistance of a Class AB_1 amplifier from the characteristics of a single valve. The method may also be used with poorer accuracy for Class A_1 .

Fig. 13.37. Calculating third harmonic distortion with balanced push-pull. Curve A is the dynamic characteristic.

The dissipation at maximum signal may be calculated from the product of the plate supply voltage E_{bb} and the average plate current [see (iv) below], minus the power output. The normal procedure is firstly to select a grid voltage such that the plate dissipation is slightly below the maximum rating at zero signal, then to adjust the loadline so that it approaches as closely as possible the value for maximum power output, without exceeding the plate dissipation limit at maximum signal.

Simple method for calculating third harmonic distortion

This method is only accurate in the absence of all distortion other than third harmonic; it is a close approximation under normal conditions provided that all even harmonics are zero.

The procedure is to draw the loadline on the plate characteristics, then to transfer this to the mutual characteristics in the form of a dynamic characteristic (Fig. 13.37).

Curve A is the dynamic characteristic while B is a straight line joining the two ends of A and passing through O. ΔI_b is the difference in plate current between curve A and line B at one half of the peak grid voltage. The percentage of third harmonic is given by

$$\left(\frac{2}{3} \Delta I_b \times 100 \right) / \left(I_{bm} - \frac{2}{3} \Delta I_b \right) \quad (23)$$

or $\left(\frac{2}{3} \Delta I_b \times 100 \right) / I_{bm}$ approximately. (24)

Calculating up to fifth harmonic distortion

The usual method is to transfer from the loadline to a dynamic characteristic, then to proceed using the "eleven selected ordinate method" (Sect. 3(iv)D). This gives the power output and harmonics up to the fifth. If the balance is good, only the third and fifth harmonics are likely to be required; the fifth is very much less than the third harmonic for Class A operation.

(iv) Average plate current

The average plate current with maximum signal input is always greater than under quiescent conditions—slightly greater for "single valve" conditions, more so for limiting Class A₁, and considerably greater for Class AB₁.

The average plate current may be calculated approximately by the expression

$$I_b \approx I_{b0} + \frac{1}{4}(I_{max} + I_{min} - 2I_{b0}) \quad (25)$$

provided that the plate current does not actually cut off (Ref. E1).

More generally, and more accurately, the average plate current may be determined by adding the plate currents of the two valves instead of subtracting them as for the composite characteristics. The total plate current may then be plotted as in Fig. 13.38 as a function of the signal grid voltage. In order to find the average current it is generally most convenient to take equal angle increments over the cycle, for example, every 10° as shown in Fig. 13.39. The plate current should then be noted at each point corresponding to 10° increase in angle over the whole 360°. The average plate current is then the average of these individual values.

In order to reduce the amount of work involved in this calculation, use may be made of the fact that each quadrant (90°) is similar. It is very easy to make an error in this calculation and the following method of obtaining the average from the plate current curve over one quadrant is therefore given.

Fig. 13.38. Plate current (both valves) plotted as a function of the signal grid voltage.

Fig. 13.39. Plate current (both valves) with 10° angular increments.

This method is illustrated in Fig. 13.40 which shows the total plate current for both valves over one-quarter of a cycle. Grid voltages are shown as fractions of the peak grid voltage. The plate currents corresponding to grid voltages of 0, 0.17, 0.34, 0.5, 0.64, 0.77, 0.87, 0.94, 0.98 and 1.0 times the peak voltage are shown as $I_0, I_{0.17}$ etc. The average plate current (I_{av}) is then given by

$$I_{av} = \frac{1}{2}(I_0 + I_{0.17} + I_{0.34} + I_{0.5} + I_{0.64} + I_{0.77} + I_{0.87} + I_{0.94} + I_{0.98} + \frac{1}{2}I_{1.0}). \quad (26)$$

Fig. 13.40. Plate current (both valves) plotted over one quadrant for the calculation of average plate current.

(v) Matching and the effects of mismatching

Matching is the process of selecting valves for satisfactory push-pull operation. Most valve manufacturers are prepared to supply, at some additional cost, valves which have been stabilized and matched for the application required.

It is important to specify the conditions of operation when ordering matched valves, as unless the valves are stabilized and matched under conditions similar to those in which the valves are to be used, they will drift apart during life or may even be mismatched initially if the matching conditions are unsuitable.

All valves intended for matching should be operated for at least 50 hours under similar conditions to those under which the valves are intended to be operated in the amplifier.

The matching technique varies with the class of operation for which the valves are intended.

Matching valves for class A_1 service is not as critical as for valves intended for class AB_1 , class AB_2 or class B. For class A_1 service it is usually sufficient to match for zero signal plate current only.

Triodes for class AB_1 , AB_2 or class B service should be checked at a number of points on the plate current grid bias curve. The points usually taken are (a) zero signal condition (b) a bias corresponding to the maximum permissible plate dissipation. The plate currents so measured should agree at all points within 2%. Triodes intended for class AB_2 or class B service should also be matched for amplification factor.

When matching tetrodes and pentodes it is usually sufficient to match for zero signal plate current and power output.

Even with perfect initial matching, valves are likely to drift apart during life and in critical applications it is desirable to provide some means of balancing the plate currents of the valves in the equipment. This may take the form of separate bias resistors in the case of self-bias or adjustable bias supplies in the case of fixed-bias applications. Pentodes and tetrodes may also be balanced by adjusting the screen voltages.

It is important that matched valves should never be run, even momentarily, at dissipations or ratings in excess of those recommended by the valve manufacturers as such treatment will render the valves unstable and destroy the matching.

Effects of mismatching with Class A_1 triodes

In Class A_1 push-pull triodes, a considerable degree of mismatching between the valves is permissible without serious effects, provided that the valves are being oper-

ated under single valve conditions as regards grid bias. There will be only a slight effect on the maximum power output or the odd harmonic distortion, but there will be some second harmonic distortion and some out-of-balance flux-producing current in the transformer. The second harmonic distortion will normally be small, particularly if the plate-to-plate load resistance is not much less than $4r_{p0}$, and for most purposes it may be neglected with valves of ordinary tolerances. The maximum out-of-balance plate current should be provided for in the design of the output transformer and this additional cost should be compared with the alternative additional cost of using valves which have been stabilized and matched for quiescent plate current only. There is normally no real need for matching for any other characteristic.

In order to demonstrate the effects of abnormal mismatching, composite characteristics have been drawn in Fig. 13.41 for two valves of entirely different types. It has been shown by Sturley (Ref. E27) that the method of deriving composite characteristics also holds with mismatching.

Type	2A3	45
Amplification factor	4.2	3.5
Mutual conductance	5250	2175 μmhos
Plate resistance	800	1610 ohms

There is a difference of 12% in amplification factor, while there is a ratio exceeding 2 : 1 for the other characteristics. The selected operating conditions are : $E_b = 250$ volts, $E_c = -50$ volts, $R_L = 5800$ ohms (plate-to-plate). It will be seen that the composite characteristics (dashed lines) are not quite parallel, although they are very nearly straight. On account of the unmatched condition, rectification occurs, leading to a shift of the loadline, and the corrected loadline may be derived by the method of Sect. 2(ii)D and Fig. 13.7. The second harmonic distortion on the corrected loadline is only 5%.

Fig. 13.41. Composite characteristics for two different valves (2A3 and 45) in Class A_1 push-pull. $E_b = 250$ volts, $E_c = -50$ volts, $R_L = 5800$ ohms plate-to-plate.

The fact that two valves so different in characteristics can be used in Class A_1 push-pull to give what is generally classed as good quality (5% second harmonic) indicates the wide latitude permissible, provided that the bias is retained at the value for a single valve and also that the load resistance is not much less than the sum of the single valve loads (or 4 times the average plate resistance).

For Class A_1 triodes it has been suggested (Ref. E8) that the following are reasonably satisfactory limits in conjunction with ordinary commercial tolerances for valves :

Signal input voltages on the grids of V_1 and V_2 :	Max. unbalance
Phase unbalance at high and low frequencies :	5%

Quadrature component = 3%

These are easily achieved by attention to the phase splitter or other source (see Chapter 12 Sect. 6). When testing for balance with a C.R.O. on the grids of V_1 and V_2 , it is important to reverse the connections of the B.F.O. when changing from one grid to the other.

(vi) Cathode bias

In an accurately balanced push-pull Class A_1 amplifier there is no point in by-passing the common cathode bias resistor, since there is no fundamental signal current flowing through it. In Class A_1 amplifiers which are not accurately balanced, there will be some degeneration, and it is usual to by-pass the cathode bias resistor, although this is not essential.

In Class AB_1 amplifiers it is essential to by-pass the cathode bias resistor.

Provision may be made, with cathode bias, for balancing the plate currents provided that they do not differ too seriously. One excellent arrangement is incorporated in Fig. 7.44 which may be used, with the necessary adjustments in the values of the resistances, for triodes, pentodes or beam power amplifiers.

The value of cathode bias resistance may be determined, in the same way as for a single valve, on the basis of the maximum signal total plate current and desired bias voltage. This will give the same performance as fixed bias, but it is necessary to check for plate dissipation at zero signal [for method see Sect. 2(ii)E]. If the dissipation at zero signal is too great, it will be necessary to increase the bias resistance. This will introduce a tendency to change from Class A_1 to AB_1 , which may be undesirable ; it may be minimized by the use of a bleed resistor to pass current from E_b to the cathode, and thence through the bias resistor, thus giving an approach towards fixed bias. Alternatively, the load resistance may be increased, thereby reducing the maximum signal plate current and grid bias ; this will also reduce the power output.

Cathode bias causes a smaller change in average plate current from no signal to maximum signal than fixed bias. This permits a poorer regulation power supply than may be used with fixed bias. However, the regulation and by-passing of the power supply also affect the minimum frequency which can be handled satisfactorily at full power output—see Sect. 1(iv).

Changes in effective gain occur in Class AB_1 amplifiers employing cathode bias, during heavy low frequency transients, which add to the distortion measured under steady conditions.

(vii) Parasitics

Parasitic oscillations in the plate circuit may occur with Class AB_1 operation when the plate current is cut off for an appreciable part of the cycle, as a result of the transformer leakage inductance and the rapid rate of change of current at the cut-off point—see Sect. 5(i)C. They may usually be cured by the use of a RC network shunted across each half of the primary of the output transformer—see Sect. 7(i)—and, if necessary, by the use of a transformer with lower leakage inductance—see Chapter 5 Sect. 3(iii)c.

Parasitics in the grid circuit are not usually troublesome except when the valves are driven to the point of grid current flow. Grid stoppers up to 50 000 ohms are often used with both Class A and AB_1 operation to give a smoother overload without parasitics.

SECTION 6: PUSH-PULL PENTODES AND BEAM POWER AMPLIFIERS, CLASS A, AB₁

(i) Introduction (ii) Power output and distortion (iii) The effect of power supply regulation (iv) Mismatching (v) Average plate and screen currents (vi) Cathode bias (vii) Parasitics (viii) Phase inversion in the power stage (ix) Extended Class A (x) Partial triode ("ultra-linear") operation.

(i) Introduction

Push-pull pentodes follow the same general principles as triodes (see Sect. 5) although there are some special features which will here be examined. Provision must be made for the supply of voltage to the screens, and for it to be maintained constant with respect to the cathode. For economy, the screens are often operated at the same voltage as the plates. If the screens are to be operated at a lower voltage, the alternatives are the use of a separate power supply, or a low resistance voltage divider. The McIntosh Amplifier may also be used for Class A or AB₁ operation—see Sect. 8. Quiescent push-pull pentodes are covered in Sect. 7(vii).

(ii) Power output and distortion

Composite characteristics may be drawn as for triodes, on the assumption that the screen voltage is maintained constant, but they will not be straight (Fig. 13.42). The loadline will pass through the point ($E_b = E_{b2}$, $I_b = 0$) and the two knees of the characteristics ($e_g = \pm E_{c1}$).

In practice it is not necessary to draw the composite characteristics, if we are only interested in power output. In limiting Class A₁ or in AB₁ one valve reaches cut-off, so that the $E_{c1} = 0$ characteristic is the same as the e_g characteristic. Even with ordinary Class A₁ the error due to the approximation is small. The loadline may therefore be drawn (AB in Fig. 13.43) and the plate-to-plate load resistance will be 4 times that indicated by the slope of AB. With valves of the 6L6 class, the third

Fig. 13.42. Composite characteristics for push-pull Class A₁ beam power amplifiers type 6L6, $E_{b1} = 250$ volts, $E_{c2} = 250$ volts, $E_{c1} = -15$ volts.

harmonic is so small that its effect on the power output may be neglected, so that

$$P_o = \frac{1}{2} I_{bm}(E_{bb} - E_{min}) \quad (1)$$

which is the same as for triodes. With pentodes the power output will be somewhat higher than indicated by eqn. (1) owing to the third harmonic distortion. In general, the third harmonic distortion is slightly less than half that with a single valve, owing to the effect of the lower load resistance. If it is desired to calculate the harmonic distortion, it will be necessary to plot at least portion of the composite characteristics.

The effect of a higher load resistance is to increase rapidly the odd harmonic distortion, while the effect of a lower load resistance is to decrease the power output. It is therefore advisable, with a loudspeaker load, to adopt a nominal impedance rather less than the value for maximum power output.

The power output of Class A push-pull pentodes is only slightly greater than twice that for a single valve.

Fig. 13.43. Calculation of power output using $E_{c1} = 0$ characteristic of one valve only.

(iii) The effect of power supply regulation

As with the case of a single valve the screen is more sensitive to voltage changes than the plate. If neither screen nor plate is being operated at its maximum rating, the simplest procedure is to adjust the voltages as desired for maximum signal and allow them to rise with no signal. Alternatively, if it is desired to obtain maximum power output, both screen and plate may be adjusted to their maximum ratings with no signal, and allowed to fall with increasing signal. If it is desired to calculate the maximum power output, the procedure for a single valve [Sect. 3(ix)] may be followed, except that in this case there is no loadline shift caused by rectification.

The regulation of a common plate and screen power supply will not have a serious effect on the minimum frequency which can be handled satisfactorily at full power output with Class A push-pull operation, provided that a reasonably large by-pass capacitor is used. If separate plate and screen supplies are used the screen supply regulation is very much more important than the plate supply regulation, with Class A operation.

With Class AB₁ operation, the regulation of both plate and screen supplies should be good.

(iv) Matching and the effects of mismatching

Matching is covered generally in Sect. 5(v). It is important to match the valves under the operating conditions in the amplifier.

The effects of mismatching with pentodes are more serious than with triodes. If no care is taken in matching, or in the design of the output transformer, it is possible for the distortion to be higher than with two valves in parallel. The advantages of push-pull operation will only be obtained in proportion to the care taken to achieve correct balance, particularly with regard to the quiescent plate currents and the signal input voltages. As with triodes, Class AB₁ is more sensitive to mismatching than Class A₁.

(v) Average plate and screen currents

The average plate current for Class A₁ may be calculated approximately as for triodes [Sect. 5(iv), Eqn. 25]. In all other cases, the composite characteristics are required, following the same method as for triodes.

The average screen current may be calculated by the same method as for single pentodes [Sect. 3(iii)E].

(vi) Cathode bias

See Sect. 5(vi) as for push-pull triodes, except that the screen dissipation must also be checked.

(vii) Parasitics

See Sect. 5(vii) as for push-pull triodes, also Sect. 3(iii)H.

(viii) Phase inversion in the power stage

In the interests of economy, push-pull is sometimes used in the output stage without a prior phase inverter. All such methods—except the Cathamplifier—have inherently high distortion, and some have serious unbalance between the two input voltages.

(A) Phase inverter principle (Fig. 13.44)

The grid of V_2 is excited from the voltage divider R_3R_4 across the output of V_1 . $R_3 + R_4$ must be very much greater than the load resistance (say 50 000 ohms). R_5 and R_6 are grid stoppers. All other components are normal. R_k may be by-passed if desired.

FIG. 13.44

FIG. 13.45

Fig. 13.44. Push-pull circuit using phase inversion in the power stage.

Fig. 13.45. Push-pull circuit using screen resistance coupling from V_1 to the grid of V_2 .

The signal voltage on the grid of V_2 must first pass through V_1 where it is distorted, then through V_2 where it will be distorted again. Thus the second harmonic will be the same as for a single valve, and the third harmonic will be approximately twice the value with balanced push-pull. The balance, if adjusted for maximum signal, will not be correct for low volume, owing to the third harmonic "flattening."

(B) Screen resistance coupling (Fig. 13.45)

This is a modification of (A) being an attempt to obtain from the screen a more linear relationship than from the plate. No comparative measurements have been published. R_7 may be about 1500 ohms for type 6V6-GT or 2500 for type 6F6-G, with $E_b = E_{c2} = 250$ volts—the exact value should be found experimentally; C_2 may be 0.002 μ F. For better balance an equal screen resistor might be added for V_2 . Ref. E10.

(C) Common cathode impedance (Fig. 13.46)

R_1 and R_2 in series provide a common cathode coupling impedance [see Chapter 12 Sect. 6(vi)]. R_2 may have a value of, say, 1000 ohms to give an approach towards balance, but necessarily must carry the plate currents of both valves—say, 70 or 80 mA—and will have a voltage of, say, 70 to 80 with a dissipation around 6 watts. Care should be taken to avoid exceeding the maximum heater-cathode voltage rating.

See Reference E23.

FIG. 13.46

Fig. 13.46. Push-pull circuit with common cathode impedance coupling.

(D) The Parry "Cathamplifier"

The basic circuit is Fig. 13.46A, the two cathodes being coupled by a centre-tapped a-f transformer, whose secondary winding excites the grid of V_2 . A theoretical analysis is given in Ref. E29, while some practical designs are in Ref. E30.

For balance, $\frac{N_3}{N_1 + N_2} = \frac{1 + g_m R/2}{g_m R}$ and $N_1 = N_2$
 where g_m = mutual conductance of V_2 .

Distortion is reduced by the factor $T(2T - 1)$
 where $T = N_3/(N_1 + N_2)$.

Note that T should normally be slightly greater than 1.

Gain is reduced by the factor $T(T - 0.5)$.

The common cathode resistor R_0 helps to reduce unbalance.

In practice, R is made variable (say 100 ohms total) so as to permit the amplifier to be balanced experimentally. One method is to connect a valve voltmeter across R_0 , and to adjust R for minimum reading.

Instability may occur if R is too small.

A modified circuit is Fig. 13.46B in which the centre-tapped primary of T_1 is not necessary.

Fig. 13.46C permits both a.c. and d.c. balancing.

Fig. 13.46D keeps the circulating screen current out of the cathode circuit and so maintains the ratio between plate and screen currents at the negative voltage peak swing. Resistors R_1 are to prevent coupling from cathode to cathode through the screen by-pass condensers; their values should be low—say 100 to 250 ohms each.

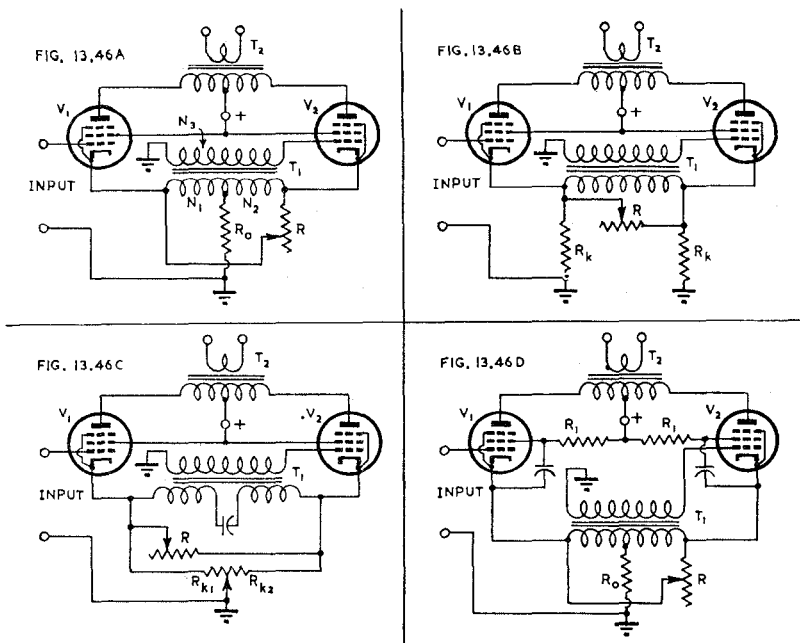

Fig. 13.46A. Basic circuit of Parry Cathamplifier, (B) Modified circuit, (C) With both a.c. and d.c. balancing, (D) Keeps circulating screen current out of cathode circuit (Ref. E30).

(ix) Extended Class A

Extended Class A is the name given to a push-pull amplifier using a triode and a pentode in parallel on each side. The amplifier operates entirely on the push-pull triodes at low levels, with the pentodes (or beam power amplifiers) cut off; at high levels the output is mainly from the pentodes. Consequently there is some curvature in the linearity ("transfer") characteristic at the transition point. The total dissipation is, however, only about one third of that of a Class A amplifier with the same maximum power output (Ref. E31).

This principle might also possibly be applied to any Class AB or Class B amplifier merely to avoid current cut-off in the transformer and its resultant parasitics (Ref. E13) unless one with very low leakage inductance is used.

(x) Partial triode ("ultra-linear") operation

See page 570.

SECTION 7 : CLASS B AMPLIFIERS AND DRIVERS

(i) *Introduction* (ii) *Power output and distortion—ideal conditions—Class B₂* (iii) *Power output and distortion—practical conditions—Class B₂* (iv) *Grid driving conditions* (v) *Design procedure for Class B₂ amplifiers* (vi) *Earthed-grid cathode coupled amplifiers* (vii) *Class B₁ amplifiers—quiescent push-pull.*

(i) Introduction

A Class B amplifier is an amplifier in which the grid bias is approximately equal to the cut-off value, so that the plate current is approximately zero when no signal voltage is applied, and so that the plate current in a specific valve flows for approximately one half of each cycle when an alternating signal voltage is applied.

Class B amplifiers are in two main groups—firstly Class B₁ (otherwise known as quiescent push-pull, see below) in which no grid current is permitted to flow, secondly Class B₂ (generally abbreviated to Class B) in which grid current flows for at least part of the cycle.

Class B₂ amplifiers have inherently high odd harmonic distortion, even when the utmost care is taken in design and adjustment. This distortion frequently has a maximum value at quite a low power output, making this type of amplifier unsuitable for many applications. They are also comparatively expensive in that a driver valve and transformer together with two output valves form an integral part of the stage, and together give only the same order of sensitivity as a pentode.

The one outstanding advantage of a Class B₂ amplifier is in the very high plate-circuit efficiency, although the current drawn by the driver stage should be included. The principal applications are in battery-operated amplifiers, public address systems and the like.

The grid bias must be fixed (either battery or separate power supply) and special high- μ triodes have been produced to permit operation at zero bias to avoid the necessity for a bias supply. In the smaller sizes, twin triodes are commonly used. For the best results, accurate matching of the two valves is essential. If they are being operated at a negative bias it is possible to match their quiescent plate currents by adjusting the bias voltages separately. If the dynamic characteristics are not matched, a difference of 10% in the two plate currents, measured by d.c. milliammeters under operating conditions, will produce roughly 5% second harmonic distortion (Ref. E18). The matching of valves is covered in Sect. 5(v).

Well regulated plate, screen (if any) and bias supplies (if any) are essential.

The rate of change of current in each half of the output transformer at the plate current cut-off point is considerable, often resulting in parasitics

Parasitics in the grid circuit may be eliminated by the use of a driver transformer having low leakage inductance [Chapter 5 Sect. 3(iii)a] and, if necessary, by connecting a small fixed condenser from each grid to cathode—a typical value is 0.0005 μF —see (iv) below.

Parasitics in the plate circuit may be eliminated by the use of an output transformer with low leakage inductance—see Chapter 5 Sect. 3(iii)c—together with a series resistance-capacitance network connected across each half of the primary or alternatively from plate to plate.

Typical values for connection across each half of primary :

Load resistance (p-p)	6000	10 000	12 000	ohms
R	3300	5600	6800	ohms
C	0.05	0.05	0.05	μ F

Typical values for connection from plate to plate :

Load resistance (p-p)	6000	10 000	12 000	ohms
R	6800	12 000	15 000	ohms
C	0.03	0.02	0.02	μ F

Note—The McIntosh Amplifier may also be used for Class B operation—see Sect. 8(iii).

(ii) Power output and distortion—ideal conditions—Class B₂

(Circuit Fig. 13.31 ; characteristics Fig. 13.36.)

If the input voltage is sinusoidal, the output transformer ideal, the plate characteristics equidistant straight lines, and the valves biased exactly to cut-off, the operating conditions will be—

$$\text{Power output (total) : } P_0 = \frac{1}{2} I_{bm}(E_{bb} - E_{min}) \quad (1)$$

$$\text{or } P_0 = \frac{1}{2} I_{bm}^2 R_L = 2(E_{bb} - E_{min})^2 / R_L \quad (2)$$

where I_{bm} = maximum (peak) plate current of either valve

E_{min} = minimum plate voltage of either valve

and R_L = load resistance plate-to-plate.

$$\text{Load resistance (plate-to-plate) : } R_L = 4(E_{bb} - E_{min}) / I_{bm} \quad (3)$$

$$\text{Load resistance per valve : } R_L' = R_L / 4 = (E_{bb} - E_{min}) / I_{bm} \quad (4)$$

Maximum power output is obtained when $R_L = 4r_p$
i.e. when $E_{min} = 0.5E_{bb}$

where r_p = plate resistance of one valve.

$$\text{Average plate current (each valve) : } I_b = I_{bm} / \pi \approx 0.318 I_{bm} \quad (5)$$

$$\text{Power input from plate-supply : } P_b = 2E_{bb} I_b \approx 0.637 E_{bb} I_{bm} \quad (6)$$

$$\text{Plate circuit efficiency : } \eta = (1 - E_{min} / E_{bb}) \times 0.785 \quad (7)$$

$$\begin{aligned} \text{Plate dissipation : } P_p &= \text{d.c. power input} - \text{power output} \\ &= I_{bm}(0.137 E_{bb} + 0.5 E_{min}) \end{aligned} \quad (8)$$

Power output in terms of plate dissipation and plate circuit efficiency :

$$P_0 = P_p \eta / (1 - \eta) \quad (9)$$

The current in the secondary of the transformer will be sinusoidal, there being no distortion. The plate current in each valve will have the form of a rectified sine wave.

The slope of the composite characteristic is half that for Class A operation, so that the slope of the composite plate resistance will be twice that for Class A.

(iii) Power output and distortion—practical conditions—Class B₂

The practical treatment is based on the use of the composite characteristics [Sect. 5(ii)D]. If the valves are biased completely to cut-off, each half of the composite characteristic is identical with the individual valve characteristic, and a considerable degree of non-linearity occurs in the middle region (Fig. 13.47A). As a result, the greatest distortion of the loadline occurs with fairly small signals. For any particular characteristic there is one value of grid bias beyond which the distortion increases rapidly with increase of bias—there is a small quiescent plate current at this point (Fig. 13.47B). Even in this case the whole of the composite characteristic, except the small middle portion, is identical with the single valve characteristic.

It is therefore practicable to calculate the **power output** from the characteristics of a single valve (e.g. Fig. 13.48). The power output as calculated by eqns. (1) and (2) is modified by the presence of harmonics and should be multiplied by the factor

$$F = (1 + H_3 + H_5 + H_7 + H_9 + H_{11})^2 \quad (10)$$

where H_3 = third harmonic distortion (i.e. I_3/I_1),

and H_5 = fifth harmonic distortion (i.e. I_5/I_1), etc.

The various harmonics are unpredictable, but at maximum power output H_3 usually predominates, and a purely arbitrary approximation is to take

$$F = (1 + 0.6H_3)^2.$$

Usual values of H_3 at maximum power output vary from 0.05 to 0.10, so that F varies from 1.06 to 1.12, a reasonable design value being 1.08. Thus, from eqn. (2),

$$P_0 \approx 0.135 I_{bm}^2 R_L \quad (11)$$

Alternatively, the total power output may be calculated from a knowledge of the average and quiescent currents of one valve, with an error not exceeding 9% (see eqns. 12 and 13 below)—

$$P_0 \approx 2.47(I_b - 0.25I_{b0})^2 R_L \quad (12)$$

The more accurate method is to use the composite characteristics (which are the same as the single valve characteristics of Fig. 13.48 over the range concerned) and to apply the "eleven selected ordinate method" [Sect. 3(iv)D] for the determination of power output and distortion. Although harmonics higher than the fifth are appreciable, it is difficult to calculate them graphically with any degree of accuracy.

Fig. 13.47. Composite characteristics of Class B amplifiers (A) biased to cut-off (B) biased to the point of minimum distortion.

Fig. 13.48. Plate and grid characteristics of a typical small battery-operated Class B triode (1J6-G).

The **load resistance** may be calculated by eqn. (3) or (4).

Maximum power output is usually achieved when the slope of the loadline is numerically equal to the slope of the individual valve characteristic corresponding to the peak grid voltage, at its point of intersection with the loadline. A different loadline is usually necessary for each value of peak grid voltage. Each loadline should be checked for peak current, average current, plate dissipation and grid driving power.

When any loadline has been established as permissible, a higher load resistance may be used with perfect safety without any further checking. This will require less grid driving power, and will draw less plate current, but will give a lower power output; the distortion will be roughly unchanged, and the plate circuit efficiency will be higher.

The **average plate current** may be calculated by the accurate method of Sect. 5(iv) and eqn. (26). Alternatively, with an accuracy within 3% for third harmonic not exceeding 10% (Ref. E11)—

$$\text{(for each valve)} I_b \approx 0.318 I_{bm} + 0.25 I_{b0} \quad (13)$$

Eqn. (13) may also be put into the form—

$$I_{bm} \approx 3.14 I_b - 0.785 I_{b0} \quad (14)$$

The average power input from the plate supply is given by

$$P_b = 2E_{bb} I_b \approx E_{bb} (0.637 I_{bm} + 0.5 I_{b0}). \quad (15)$$

$$\text{Plate circuit efficiency: } \eta = P_0 / 2E_{bb} I_b \quad (16)$$

[Usual values of plate circuit efficiency are from 50% to 60%.]

$$\text{Plate dissipation: } P_p \approx E_{bb} (0.637 I_{bm} + 0.5 I_{b0}) - P_0 \quad (17)$$

With a plate circuit efficiency of 60%, the power output is 1.5 times the total plate dissipation, whereas with Class A operation and a plate circuit efficiency of 25%, the power output is 0.25 times the plate dissipation. Thus, if in both cases the plate

dissipation is the only limiting factor, six times more output may be obtained from the same valves in Class B than in Class A.

(iv) Grid driving conditions

Grid current characteristics are provided for use with valves suitable for Class B amplification (e.g. Fig. 13.48). It is usual practice to select a likely peak positive grid characteristic and loadline, then to calculate the grid driving power and power output. This may be repeated for several other loadlines, and the final choice will be made after considering all the relevant features.

In the case of a particular loadline such as AB in Fig. 13.48, the peak grid current may be determined by noting the intersection of the vertical through A and the grid current curve (shown with a broken line) corresponding to the E_c characteristic which passes through A. This is shown in Fig. 13.49 where $-E_c$ indicates the fixed grid bias and the positive grid current commences to flow at approximately $E_c = 0$. The peak grid current is I_{gm} and the peak signal grid voltage is E_{gm} , corresponding to a positive grid bias voltage E_{cm} . The peak grid input power is then given by

$$P_{gm} = E_{gm} I_{gm} \quad (18)$$

and the minimum grid input resistance is given by

$$r_{gmin} = E_{gm} / I_{gm} \quad (19)$$

[Note: The minimum variational grid resistance is derived from the slope of the I_g curve—it is always less than r_{gmin} .]

The driver valve has to supply this peak power, plus transformer losses, into a half-secondary load varying from infinity at low input levels to r_{gmin} at the maximum input. The basic driver circuit is shown in Fig. 13.50A, where V_1 is the driver valve and T_1 the step-down transformer with a primary to half-secondary turns ratio N_1/N_2 . In practice, the transformer has losses, and it may be represented by the equivalent circuit Fig. 5.9 (omitting C_W).

The efficiency is usually calculated (or measured) at 400 c/s where r_1 , r_2 and R_0 are the principal causes of loss. An efficiency of from 70 to 80% at peak power is typical of good practice. The voltage applied to the grid of V_2 , provided that the iron losses are small, is approximately [Chapter 5 Sect. 2(ii)].

$$E_{g2} \approx E_p \eta (N_2/N_1) \quad (20)$$

where η = percentage efficiency $\div 100$,

and E_p = voltage applied across primary.

The load presented to V_1 is roughly as calculated for an ideal transformer [Chapter 5 Sect. 2(ii)] driving the same grid.

At high audio frequencies, the effects of L_1 and L_2 (Fig. 5.9) become appreciable, causing an additional loss of voltage during the time of grid current flow, and a tendency towards instability. The instability is brought about by a negative input resistance which some valves possess over a portion of the grid characteristic [Chapter 2 Sect. 2(iii)]. It is therefore important to reduce the leakage inductance of the transformer to the lowest possible value. Fortunately the bad effects of any remaining leakage inductance may be minimized by connecting a small condenser across each half of the secondary so as to resonate at a frequency about 1.5 times the highest frequency to be amplified (Ref. E18). The condenser and leakage inductance form a half-section of a simple two-element constant k type low-pass filter [Chapter 4 Sect. 8(vii)].

Fig. 13.49. Typical grid mutual characteristic illustrating Class B operating conditions.

At low audio frequencies the primary inductance L_0 causes loss of gain as with any a-f transformer. It should be designed for an unloaded secondary (Chapter 5 Sect. 3) because it is unloaded for part of the cycle. Secondary loading resistances should be avoided with Class A triode drivers (Refs. E17, E18).

In order to avoid excessive distortion due to the non-linear grid current characteristic, the effective impedance looking backwards from the grid-cathode terminals towards the driver, must be small compared with the effective input impedance of the valve. The "looking backwards" impedance has as its components (Fig. 5.9):

$$\text{"Driver resistance"} \quad R' = r_2 + (N_2/N_1)^2(r_{p1} + r_1) \quad (21)$$

$$\text{"Driver inductance"} \quad L' = L_2 + (N_2/N_1)^2 L_1 \quad (22)$$

It is usual to restrict the driver resistance R' to a value less than $0.2 r_{g \min}$ for the most favourable conditions with high- μ valves and with limited grid drive, where $r_{g \min}$ does not differ seriously from the minimum variational grid resistance; in other cases it should be less than one fifth of the minimum variational grid resistance (Refs. E2, E12). For minimum distortion, R' should be made as low as practicable. Hence the transformer usually has a step-down ratio from primary to half-secondary.

The "driver inductance," if large and uncompensated, produces an effect like a faint high pitched hiss or scratch that rises and falls with the signal (Ref. E18).

The effect of the varying load resistance on the driver valve is shown by the curved loadline in Fig. 13.50B. The horizontal portion corresponds to the conditions without grid current flow, while the slope at any other point corresponds to the variational grid resistance at that point. The broken line joining the two extremities has a slope corresponding to a resistance of $r_{g \min}(N_1/N_2)^2$; this should not be less than $4r_{p1}$. The driver valve should preferably be operated near its maximum rated plate voltage and dissipation.

Fig. 13.50A. Fundamental driver and Class B (or AB) amplifier circuit.

Fig. 13.50B. Loadline on a typical triode driver.

As the output valves are driven harder, the driver valve is called upon to provide increased power into a decreased minimum grid resistance; this necessitates a greater step-down ratio in the transformer. The extreme limit is when the "diode line" is reached. As a guide which may be used for a first trial, the minimum plate voltage may be taken as twice the "diode line" voltage at the peak current level. The diode line is shown in many characteristic curves, and is the envelope of the characteristics—it is the line where the grid loses control, in other words the minimum plate voltage for any specified plate current no matter how positive the grid may be.

The cathode follower makes an excellent driver for all forms of amplifiers drawing grid current, having very low effective plate resistance and low distortion—see Chapter 7 Sect. 2(i).

A cathode follower has been applied as a transformerless driver, one 6SN7-GT twin triode being used as a push-pull driver to the grids of two 6L6 valves giving an output of 47 watts (Ref. E22). However, this is not usually the most efficient arrangement—see Chapter 7 Sect. 1(ii).

(v) Design procedure for Class B₂ amplifiers

The major difficulty is in keeping the electrode voltages stabilized.

The following procedure applies to the case where the voltages are stabilized and the plate voltage and desired power output are known.

1. Assume a value of plate-to-plate load resistance R_L . Draw a loadline with a slope corresponding to $R_L/4$ on the characteristics for one valve, through the point $E_b = E_{b0}$, $I_b = 0$.

2. Select a value of grid bias to give the minimum distortion of the composite characteristic (Fig. 13.47).

3. Determine the quiescent plate current I_{b0} of one valve.

4. Calculate the peak plate current from the approximation :

$$I_{bm} \approx \sqrt{7.4P_0/R_L} \quad (23)$$

5. Calculate the average power input from the plate supply, using eqn. (15).

6. Calculate the plate dissipation from equation (17).

7. Check the plate dissipation and the peak plate current to see that they do not exceed the maximum ratings.

8. Determine the maximum positive grid voltage E_{cm} from the loadline and I_{bm} .

9. Determine the peak grid current I_{gm} corresponding to extreme point of the loadline.

10. Calculate the peak signal grid voltage : $E_{gm} = E_{cm} + E_c$.

11. Calculate the peak grid input power : $P_{gm} = E_{gm}I_{gm}$.

12. Calculate the minimum input resistance : $r_{gmin} = E_{gm}/I_{gm}$.

13. Repeat steps 1 to 12 for several other values of R_L and select what appears to be the best compromise, with a view to the lowest driving power.

14. Assume a reasonable peak power transformer efficiency—say 70%. This value is used in the following step.

15. Select a driver valve with a maximum power output at least $0.9P_{gm}$ under typical operating conditions (this makes allowance for the higher load resistance).

16. Select a driver load resistance twice the typical value or at least four times the plate resistance.

17. Draw the assumed (straight) driver loadline on the driver plate characteristics and determine the maximum available peak signal voltage E_{pm} .

18. Determine the transformer ratio from primary to half-secondary :

$$N_1/N_2 = \eta E_{pm}/E_{gm}$$

19. Calculate the "driver resistance" from eqn. (21) using values for r_1 and r_2 indicated* from similar transformers. These resistances are usually less than 1900 and 350 ohms respectively for 10 watt amplifiers, or 2700 and 500 ohms respectively for low power battery amplifiers.

20. Check the "driver resistance" to see that it is less than $0.2r_{gmin}$ for high- μ valves or $0.1r_{gmin}$ for other cases (this assumes that r_{gmin} is approximately twice the minimum variational grid resistance).

*Alternatively the driver transformer may be tentatively assumed to have 10% primary and 10% secondary copper losses, and 10% iron losses. On this basis,

$$r_2 = r_{gmin}/7 \text{ and } r_1 \approx r_{gmin}(N_1^2/N_2^2)/9.$$

(vi) Earthed-grid cathode-coupled amplifiers

A cathode-coupled output stage, with earthed grids, has the advantages of a much more nearly constant input resistance than a Class B stage, but it requires more driver power for the same output. It is more suited to high-power amplifiers or modulators than to conventional a-f amplifiers (Ref. E15). The increase in plate resistance due to feedback is disadvantageous.

(vii) Class B₁ amplifiers—Quiescent push-pull

Class B₁ amplifiers do not draw any grid current whatever, but in other respects resemble Class B₂ amplifiers. Either triodes or pentodes may be used, the latter being more popular—they are used as "quiescent push-pull pentodes" in battery receivers. The two valves (or units) must be very accurately matched, and an adjustable screen

voltage is desirable. A high-ratio step-up input transformer is used to supply the high peak signal voltage, nearly equal to the cut-off bias. Both the input and output transformers should have low capacitance and leakage inductance. The output transformer should have its half-primary inductance, and its leakage inductance, accurately balanced. Condensers (0.002 to 0.005 μ F) are usually connected across each half primary (Ref. E4).

SECTION 8 : CLASS AB₂ AMPLIFIERS

(i) *Introduction* (ii) *Bias and screen stabilized Class AB₂ amplifier* (iii) *McIntosh amplifier.*

(i) Introduction

Class AB₂ amplifiers closely resemble Class B₂ amplifiers, but the valves are biased as for Class AB₁ operation. Consequently they are less critical with regard to matching, and the distortion which occurs in the plate circuit is much the same as for Class AB₁. The plate circuit efficiency is intermediate between Class AB₁ and B₂ operation—typical values for triodes are from 40 to 48%. The variation in plate current from zero to maximum signal is less than with Class B operation, being of the order of 1 : 2.

The matching of valves is covered in Sect. 5(v).

Pentodes and beam power amplifiers may be used quite successfully in Class AB₂ operation.

Fixed bias is essential.

Type 6L6 or 807 beam power amplifiers may be used in Class AB₂ with plate circuit efficiencies of about 65% (or 61% including screen losses). The peak grid input power does not exceed 0.27 watt for power outputs from 30 to 80 watts. The total harmonic distortion under ideal laboratory conditions is 2% at maximum signal and less than 2% at all lower output levels (this assumes a low-distortion driver stage).

Well regulated plate, screen and bias power supplies are essential.

Parasitics in plate and grid circuits—see Sect. 7(i).

References E20, E21.

(ii) Bias and screen stabilized Class AB₂ amplifier (Ref. E26)

Fig. 13.50C gives a circuit with 807 valves operated in Class AB₂ with stabilization of the bias and screen supply provided by the driver valve. Two high tension sources are used, obtained from separate windings on the power transformer, and neither needs good regulation, so that condenser input filters can be used.

Fig. 13.50C. Class AB₂ amplifier with stabilized bias and screen voltages (Ref. E26).

The circuit offers three types of compensation, the combined effect being to allow the output valves to draw a minimum of plate current in the no signal condition, although still being capable of delivering an output of 60 watts for small distortion. The three types of compensation are

(a) As the 807 plate voltage falls, due to increasing plate current with signal input, the screen voltage is increased and the bias reduced.

(b) When the 807's are driven into grid current their bias is increased due to the current in the 500 ohm resistor

R_1 . This is minimized by a d.c. negative feedback circuit giving several times reduction of the effect, and is offset by a corresponding increase in 807 screen voltage.

(c) Any tendency for the 807 screen voltage to fall and for the bias voltage to increase with rising 807 screen current due to signal input is minimized by the same negative feedback circuit.

Referring to Fig. 13.50C, the voltage divider from the positive side of the 600 volt supply to the negative side of the 300 volt supply has values to provide a suitable bias for the triode-operated 6V6 so that it draws about 45 mA with a standing plate voltage of 250 V. A decrease in the 807 plate voltage causes the 6V6 grid to become more negative, decreasing its plate current which also flows through R_1 and so decreases the 807 bias. The low voltage power supply is deliberately given poor regulation with resistive filtering so that the decrease in 6V6 plate current appreciably increases its plate voltage and thus the 807 screen voltage.

The 807 grid current at large output levels increases the negative potential at C and also at A and B and thus increases the 6V6 bias. This reduces the 6V6 plate current which makes point C less negative and minimizes the increase in 807 bias, and at the same time increases the 807 screen voltage thus off-setting the bias increase.

The 807 screen current rises with increasing signal input and this tends to decrease the screen voltage and increase the 807 bias. However the increased bias is also applied to the 6V6, reducing its plate current and thus tending to restore the 807 bias and screen voltages to their original values.

Between no output and full output the 6V6 plate current falls from 45 mA to 25 mA but the valve is still well able to provide the small power required to drive the 807's.

An additional feature of the circuit is that a very large input reduces the ability of the driver to overload the output valves, and after full output is reached very effective limiting is provided.

(iii) McIntosh Amplifier (Ref. E28)

With any push-pull amplifier in which each valve is cut-off during portion of the cycle, some form of quasi-transient distortion tends to occur at a point in each cycle at the higher audio frequencies (Ref. E13). This distortion is caused by the leakage reactance of the primary of the output transformer, which cannot be reduced sufficiently by conventional transformer design technique. A completely new approach to the problem is made by the McIntosh amplifier which incorporates special types of driver transformer and output transformer, together with many other novel features. The basic principles are indicated in Fig. 13.50D in which both driver transformer T_1 and output transformer T_2 have two windings wound together in a bifilar manner so that the coupling between them is almost unity. It is claimed that it is practicable to wind coils with a ratio of primary inductance to leakage inductance better than 200 000 to 1, whereas conventional transformers do not nearly reach the minimum requirement (for low distortion) of 80 000 to 1. This type of transformer is cheaper

to wind than a sectionalized winding as used in conventional high quality transformers.

Each output valve works into two primary sections, one in its plate circuit and the other in its cathode circuit, but these have practically unity coupling. The effective number of primary turns for each valve is equal to the total turns for each of the bifilar windings. The output transformer should therefore be designed to have a total impedance on each of its primaries equal to one quarter of the plate-to-plate load impedance.

Fig. 13.50D. Basic principles of McIntosh Amplifier (Ref. E28).

In the case of the amplifier of Fig. 13.50E the plate-to-plate load imped-

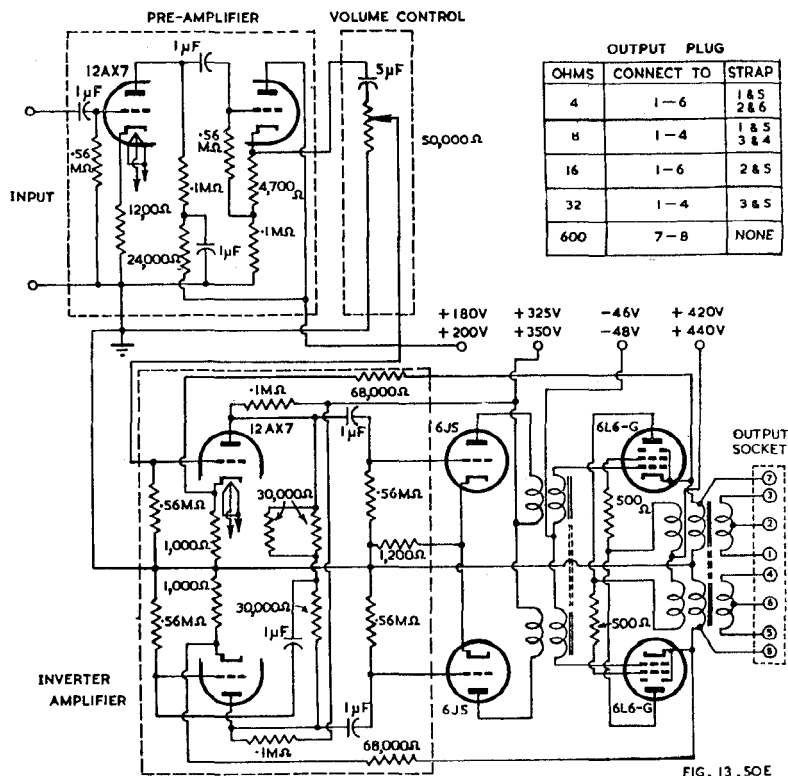

FIG. 13.50E

Fig. 13.50E. Circuit diagram of complete 50 watt McIntosh Amplifier (Ref. E28).

ance is 4000 ohms and the total impedance of each primary winding is 1000 ohms; the impedance from each cathode to earth is only 250 ohms. These low impedances reduce the effects of capacitive shunting and thereby improve the high frequency performance.

The voltage from each screen to cathode is maintained constant by the unity coupling between the two halves of the bifilar windings, no screen by-pass capacitor being required. This arrangement, however, has the limitation that it can only be used for equal plate and screen voltages.

The driver transformer T_1 makes use of the same bifilar winding method adopted in the output transformer. The primary impedance in this design is above 100 000 ohms from 20 to 30 000 c/s, while the response of the whole transformer is within 0.1 db from 18 to 30 000 c/s. These high performances are made necessary by the inclusion of this transformer in the second feedback path of the whole amplifier.

The method of loading the output stage, with half the load in the plate and half in the cathode circuit, provides negative feedback as a half-way step towards a cathode follower. Additional feedback is achieved by connecting suitable resistors between the cathodes of the output valves and the cathodes of the phase inverter stage. The complete amplifier (Fig. 13.50E) has a typical harmonic distortion of 0.2% from 50 to 10 000 c/s, rising to 0.5% at 20 c/s and 0.35% at 20 000 c/s, at an output level of 50 watts. The frequency response under the same conditions, measured on the secondary of the transformer, is level from 20 to 30 000 c/s, -0.4 db at 10 c/s and -0.3 db at 50 000 c/s. The phase shift is zero from 50 to 20 000 c/s, -10° at 20 c/s and +4° at 50 000 c/s.

The output resistance is one tenth of the load resistance, thus giving good damping and regulation.

These same principles may be applied to any type of push-pull output whether triode or pentode, with any class of operation, A, AB₁, AB₂ or B.

The high power output of the McIntosh amplifier as described above is due to the operation of the screens at voltages greater than 400 volts, which is very considerably in excess of the maximum rating of 270 volts (design centre) for type 6L6 or 300 volts (absolute) for type 807. It is unfortunate that the McIntosh amplifier is limited to operation with equal plate and screen voltages, but these should always be within the maximum ratings for the particular valve type.

See also Refs. E31, G1.

The principle of combined plate and cathode loading is applied in some high-fidelity Class A amplifiers, e.g. Acoustical QUAD, Refs. H4, H6.

SECTION 9 : CATHODE-FOLLOWER POWER AMPLIFIERS

The principles of cathode followers have been covered in Chapter 7 Sect. 2(i). A cathode follower may be used either as driver for a Class B or AB₂ stage, or as the output stage itself.

A cathode follower forms almost an ideal driver stage, having very low plate resistance and distortion, although it requires a high input voltage. It is commonly used, either singly or in push-pull, in high power a-f amplifiers where the distortion must be reduced as much as possible. If parallel-feed is used, the hum is reduced by the factor $1/(\mu + 1)$; see Chapter 7 Sect. 2(ix) Case 4. A cathode follower driver stabilizes the a-f signal voltage, but does not stabilize the grid bias.

Cathode follower output stages introduce serious problems, and are not suitable for general use, even though their low plate resistance and low distortion appear attractive. The difficulty is in the high input voltage which is beyond the capabilities of a resistance-coupled stage operating on the same plate supply voltage. Two methods are practicable, either a step-up transformer in the plate circuit of a general purpose triode, or a resistance-coupled amplifier with a plate supply voltage about 3 times the plate-cathode voltage of the cathode follower. In order to take advantage of the low distortion of the cathode follower, the preceding stage should also have low distortion. A general purpose triode is to be preferred to a pentode or high- μ triode with resistance coupling, and it may have an unbypassed cathode resistor.

One practical amplifier which has been described in the literature (Ref. F3) uses 700 volts supply voltage to the 6SN7 penultimate stage and eight 6V6-GT valves in push-pull parallel operation in the cathode follower output stage. Negative feedback is used from the secondary of the output transformer, and the damping on the loudspeaker is as high as practicable. However, the total harmonic distortion at 50 c/s is over 1% at 8 watts output, and 1.7% at 20 watts. The high output voltage which must be delivered by the resistance-coupled penultimate stage thus shows its effect on the distortion, even though the plate supply voltage has been increased to a dangerously high value.

SECTION 10 : SPECIAL FEATURES

(i) *Grid circuit resistance* (ii) *Grid bias sources* (iii) *Miller Effect* (iv) *26 volt operation* (v) *Hum*.

(i) Grid circuit resistance

A maximum value of grid circuit resistance is usually specified by the valve manufacturer, a higher value being usually permitted with cathode (self) bias than with fixed bias. The reason for the latter is that cathode bias provides increased bias as the plate current rises, and so gives a degree of protection against "creeping" plate current. This effect is due to the combined gas and grid emission currents which

flow through the grid-cathode circuit—see Chapter 2 Sect. 2(iii), also Chapter 3 Sect. 1(v)d, and Chapter 12 Sect. 2(iii)E, (iv)B, (iv)C, (iv)D ; Sect. 3(iv)C, (v).

Typical values (e.g. type 6V6-GT) are :

With cathode bias 0.5 megohm (maximum)

With fixed bias 0.1 megohm (maximum).

If the heater is operated, even for limited periods, more than 10% above its average rated voltage, the grid circuit resistance must be reduced considerably ; this holds in automobile receivers.

If partial self-bias operation ("back bias") is used, the maximum value of grid circuit resistance may be found from the relation :

$$R_{gm} = R_{gf} + P(R_{gs} - R_{gf}) \quad (1)$$

where R_{gf} = max. grid circuit resistance (fixed bias)

R_{gs} = max. grid circuit resistance (self bias)

and P = ratio of cathode current in output valve to the total current flowing through the bias resistor.

In cases where the maximum value of grid resistance for a particular application is not specified, the procedure of Chapter 3 Sect. 1(v)d should be followed, using eqn. (6) for pentodes or tetrodes, or eqn. (7) for triodes. The value of maximum reverse grid current (ΔI_{c1}) should be obtained from the specifications or from the valve manufacturer ; failing this, a value of $2\mu\text{A}$ may be tentatively assumed for valves of the 6F6, 6V6 class, and $4\mu\text{A}$ for valves having higher cathode currents.

If either the value of R_{g1} for cathode bias, or that for fixed bias is specified, the value for the other may be calculated from Chapter 3 Sect. 1 eqns. (8) to (13).

(ii) Grid bias sources

Fixed bias is normally obtained from a separate power source with rectifier, filter and load resistance. A typical circuit is Fig. 13.51 in which V_1 is the usual rectifier, V_2 is the bias rectifier and R_4 the bias load resistance. V_2 may be any half-wave indirectly-heated rectifier ; if the V_2 heater is operated from a common heater winding, V_2 should be a type capable of withstanding a high voltage between heater and cathode. Alternatively a shunt diode may be used (see Chapter 30 Sect. 6). If the output stage draws positive grid current, as in Class AB_2 or overloaded Class A operation, the grid current flowing through the bias load resistance increases the bias voltage. It is therefore advisable to design this to be as low as practicable. The effect of negative grid current on the bias is usually negligible.

FIG. 13.51

Fig. 13.51. Method of obtaining fixed bias using half of the transformer secondary (plate) winding. Typical values of resistors are : $R_1 = 2500$, $R_2 = 25\,000$, $R_3 = 15\,000$, $R_4 = 3000$ ohms ; $C_1 = 8\mu\text{F}$, $C_2 = 16\mu\text{F}$, $C_3 = C_4 = 50\mu\text{F}$. Alternatively R_2 may be replaced by a choke.

Voltage stabilized grid bias supplies are sometimes used (see Chapter 33).

It is sometimes convenient to have two plate voltage supplies, one to provide for the plates of the output stage only, the other for the earlier stages together with the screens of the output stage and grid bias. The second supply is loaded by a heavy current voltage divider (say 150 mA total drain) tapped near the negative end and the tapping connected to the cathodes of the output stage ; one section provides grid bias, and the other section provides the positive potentials.

Back bias is intermediate between cathode bias and fixed bias, so far as its constancy is concerned. With this arrangement, the whole return current of a receiver or amplifier is passed through a resistor between the cathodes (which are generally earthed) and $-E_b$ (Fig. 13.52). The value of R_1 is given by E_{c1}/I where E_{c1} is

(v) Hum from plate and screen supplies

The hum of amplifiers with and without feedback is covered in Chapter 7 Sect. 2(ix)C.

Power amplifiers not using feedback are here summarized briefly, using the conditions for types 2A3 and 6V6 as in Chapter 7.

Triode with (a) conventional output transformer—

Relative hum voltage = 0.85

(b) parallel feed (series inductor)—

Relative hum voltage = 0.024

Pentode with conventional output transformer

and (a) common plate and screen supplies—

Relative hum voltage = 2.05

(b) screen perfectly filtered—

Relative hum voltage = 0.09

Pentode with parallel feed (series inductor)

(a) common plate and screen supplies

Relative hum voltage = 1.78

(b) screen perfectly filtered

Relative hum voltage = 0.179

See also Chapter 31 Sect. 4(ii)—Effect of the output valve on hum originating in the plate supply voltage.

SECTION 11 : COMPLETE AMPLIFIERS

(i) *Introduction* (ii) *Design procedure and examples* (iii) *Loudspeaker load.*

(i) Introduction

While every amplifier must be built up of individual stages, the purpose of the design is to produce a complete amplifier having specified characteristics in regard to overall gain, maximum power output, frequency range, output resistance, distortion, hum, noise level and special features such as overload characteristics and tone control. A designer's job is to produce the required results at the minimum cost within any limitations imposed by space or by the availability of valve types.

(ii) Design procedure and examples

The correct procedure is to commence with the loudspeaker, and then to work backwards through the amplifier. For example, after investigation of the loudspeaker and speaker transformer efficiency (see Chapter 20 Sect. 6) it should be possible to estimate the maximum power output required from the output valve(s). Then the output valve(s) should be selected allowing for the possible use of feedback. Then the preceding stage should be designed to work into the known following grid resistor and effective input capacitance with a satisfactory frequency response and distortion level. Finally, the input stage should be designed to give the required hum and noise performance. If, after a first calculation, the overall gain is too high, it may be reduced by one of many expedients such as increasing (or adding) negative feedback on the output stage, removing a cathode by-pass, changing a voltage amplifier stage from pentode to triode operation, or changing one or more valves to a lower gain type. In large amplifiers a pre-set second volume control may be used, to be adjusted in the laboratory.

The following information is a general guide in the design of typical amplifiers

- A = public address (speech)
- B = typical radio receiver (a-f amplifier only)
- C = good quality radio receiver or amplifier
- D = high fidelity receiver or amplifier

Performance applies to amplifier only (resistance load).

Category	A	B	C	D
Frequency range	200-5 000	100-5 000	50-10 000	40-15 000 c/s
Attenuation at limits	3	3	2	1 db
Total harmonic distortion*	10	10	2	<1 %
Output resistance	—	—	$<R_L/2$	$<R_L/10\dagger$
Noise level†	—	-25	-25	-30 dbm
Hum level (120 c/s) **	—	-15 to -30	-35 to -40	-40 to -45 dbm
Intermodulation distortion*—				
r.m.s. sum (voltage ratio 4 : 1)	40	40	8	<4 %

*at maximum power output.

**For 3% loudspeaker efficiency. In all cases the hum should not be audible under listening conditions. See Chapter 31 Sect. 4(iii) for hum.

†For room volume 3000 cubic feet, 3% loudspeaker efficiency—see Chapter 14 Sect. 7(v). For measurement of noise see Chapter 19 Sect. 6.

‡Or as required to give the desired degree of damping at the bass resonant frequency.

See also Chapter 14 Sect. 12(i) for high fidelity.

With careful design and the use of negative feedback it is possible to make the total harmonic distortion of the amplifier less than 0.1% and the intermodulation distortion less than 0.5%. This has been achieved in the circuit of Fig. 7.44 and in the Williamson amplifier on which it is based (the new version of the Williamson amplifier is given in Figs. 17.35 B, C, D, E, F, G), also in the Leak amplifier. See Refs. F1, F4, F5, H4, H15, H16.

An example of category C is given in Figs. 7.42 and 7.43.

Undoubtedly one of the best and most versatile single-ended amplifiers incorporating negative feedback (and, if desired, also tone control) is the circuit Fig. 7.33. The feedback should be as high as permissible, being usually limited by the sensitivity required by a pickup. The only serious limitation is that V_1 cannot be a combined second detector and amplifier.

The **Lincoln Walsh amplifier** with automatic bias control (E24, E25) is quoted as having intermodulation distortion of 0.2% at 5 watts, 0.6% at 10 watts and 1.7% at 25 watts, the power in each case being the low frequency power only (50 c/s). The valves used in this amplifier are type 6B4-G (similar to 2A3).

The **McIntosh 50 watt Class AB₂ amplifier** (Fig. 13.50E) has harmonic distortion less than 0.5% from 20 to 30 000 c/s, with exceptionally flat frequency response and low phase shift—see Sect. 8(iii).

References to complete amplifiers: Refs. (F) and (H).

(iii) Loudspeaker load

Most amplifiers are designed to work into a constant resistive load, whereas a loudspeaker presents a far from constant impedance which is largely inductive or capacitive at almost all frequencies within its range. This feature is covered from the loudspeaker angle in Chapter 20 Sects. 1, 2 and 7. See also Sect. 2(iv) for triodes and Sect. 3(viii) for pentodes.

A simple 2 stage amplifier with a triode output stage is shown in Fig. 13.54, together with the fundamental, second, third and fourth harmonics (see Chapter 20 for comments). An obvious conclusion is that all amplifiers should be tested for output and distortion while delivering full power into a loudspeaker load. While highly desirable, this requires a large sound-proof room for all except low levels. An alternative which is highly recommended is to construct a dummy load which has the same impedance as the loudspeaker at 400 c/s, at 10 000 c/s, and at the bass resonant frequency, based on the circuit of Fig. 20.3. The value of $(R_0 + R_1)$ in Fig. 20.3 should be equal to the measured value of the working impedance of the loudspeaker at the bass resonant frequency as described in Chapter 20 Sect. 2(iv).

FIG. 13.5.

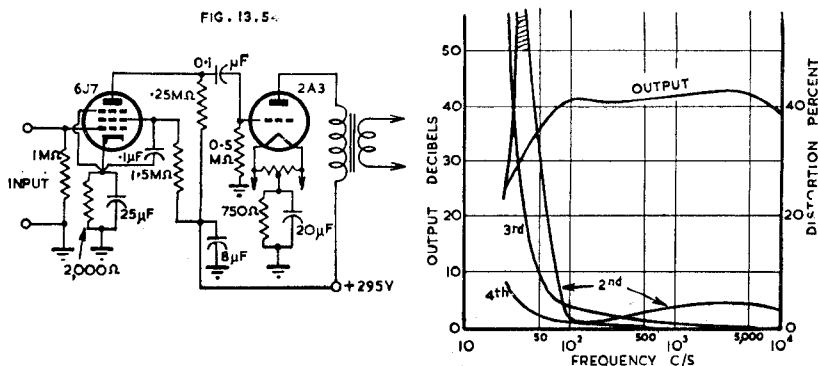

Fig. 13.54. Harmonic distortion of amplifier having type 6J7 pentode coupled to 2A3 triode loaded by a loudspeaker on a flat baffle. The distortion was measured by a wave analyser connected across the voice coil. The bass resonance frequency is 70 c/s.

SECTION 1 : INTRODUCTION

(i) *Fidelity* (ii) *Types of distortion* (iii) *Imagery for describing reproduced sound.*

(i) Fidelity

True fidelity is perfect reproduction of the original. In the case of an amplifier, true fidelity means that the output waveform is in all respects an amplified replica of the input waveform.

In acoustical reproduction, true fidelity is achieved if the listener has the same aural sensations that he would have if present among the audience in the studio or concert hall.

In practice, true fidelity can only be regarded as an ideal to be aimed at.

The concept of "hole in the wall" listening put forward by Voigt (c.g. Ref. A49) is a useful device. The listener, surrounded by his listening room, is imagined as being in the concert hall and able to hear directly, through his open window, the sound coming from the stage, together with echoes. Echoes from his own room will come from all directions, but echoes from the concert hall only come through the open window. This is probably the nearest approach to true fidelity which there is any hope of approaching with single channel transmission. See also Ref. A50.

The purpose of high fidelity reproduction of music is to satisfy a particular listener, who is primarily interested in the emotions arising from what he hears. The complete process involves sensations and emotions which cannot be treated objectively and must bring in personal preferences and differences of opinion.

It is manifestly impossible to reproduce at the two ears of the listener an exact equivalent of the sounds which he would hear in the concert hall. The greatest deficiencies are probably the single point sound reproducer (the loudspeaker) and the

volume level. The use of stereophonic reproduction is briefly mentioned in Chapter 20 Sect. 6(v)—it is impracticable with the existing radio and disc recording techniques. In the home it is rarely that orchestral reproduction is heard at the same maximum volume level as in the concert hall. This is the real dilemma from which there is no satisfactory escape. If we listen at a lower volume level we suffer attenuation of the low and high frequencies. If we apply tone correction in the form of bass and treble boost, it is difficult to gauge the correct amount, and most correcting circuits only give a rough approximation to the ideal. If we leave the adjustment of tone controls to the listener, he will adjust them to please himself and the result is usually far from a true reproduction of the original.

Refs. A10, A20.

(ii) Types of distortion

Distortion is lack of fidelity. In the case of an amplifier, distortion occurs when the output waveform differs in some respect from the input waveform. The purpose of the amplifier, and also of the whole equipment, is to reproduce the input waveform, not a band of frequencies. The latter may be necessary in order to achieve the former, but is only a means to an end.

Distortion may be grouped into six main classes.

1. Non-linear distortion (also known as amplitude distortion), and resulting in
 - 1a. Harmonic distortion and
 - 1b. Intermodulation distortion.
2. Frequency distortion (unequal amplification of all frequencies).
3. Phase distortion.
4. Transient distortion.
5. Scale distortion (or volume distortion).
6. Frequency modulation distortion.

There are other features in reproduction which are not normally classed as distortion, although they affect the listener as being untrue to the original. These include background noise and the use of a single point source of sound. Background noise includes needle scratch, hum and adjacent channel whistles. There are also some types of distortion peculiar to loudspeakers—see Chapter 20 Sect. 7.

(iii) Imagery for describing reproduced sound

The following is based largely on Ref. A48, and is merely a proposal which has not been generally accepted. It is included for general interest.

(a) Frequency Range Notation

Extreme Lows	Below 100 c/s
Lows	100— 300 c/s
Lower Middles	300— 800 c/s
Upper Middles	800—1500 c/s
Lower Highs	1500—4000 c/s
Highs	4000—8000 c/s
Extreme Highs	Above 8000 c/s

(b) Distortion

General : Dirty, non-linear distortion.

Overload : Hash-up, mush-up.

Thump (sudden rectification when signal hits bottom).

Sound often becomes strident if harmonic energy peaks in the lower highs.

Records : Fuzz or lace. Inability of stylus to track at high groove curvatures.

Crackle : Same as fuzz, but occurring principally on high-amplitude peaks.

Rattles or buzz, rub or wheeze.

Swish—scratch periodic with rotation of record.

Carbon Microphones : Frying, popping, sizzle.

Sub-harmonics : Breakup, birdies, tweets.

Intermodulation : Harsh, rough.

Cross-over distortion : Marbles, garble.

Transient distortion : Hang-over.

Attack—good or slurred.

Intermodulation with peak in the high-frequency region :

Violins sound wiry.

Male voices have kazoo.

Brass instruments show jamming in upper octaves.

(c) General Terms

Position presence : Localization, mass of sound ; advance, come forward, stand out ; distant, dead, recede, lost.

Intimacy presence : Intimate, rapport.

Detail presence : Transparent, translucent, clear, opaque, acoustic fog, veiled, muddy.

Source size : Live ; broad, volume, floods out, big tones, well-focused tones ; dead and flat, compressed, from a hole in the wall, out of a barrel.

Realism : Presence, natural, life-like, pleasing ; canned music.

Reproduction : Realistic, perfect, adequate.

	Lows	Lower Middles	Upper Midd les	Lower Highs	Highs	Extreme Highs
Excess	Grunt	Sock Muddy Solid Dead, dull or thick		Tinkly* Shrill Brassy	Harsh Hard	
	Boom	Flat- sounding Body Mellow	Masculine Baritone	Metallic Bright Brilliant Crisp	 Brittle	Brittle
Defici- ency		Lean Thin Tinny	Warm Soprano		Soft	Soft

*If confined to upper part of region.

SECTION 2 : NON-LINEAR DISTORTION AND HARMONICS

(i) *Non-linearity* (ii) *Harmonics* (iii) *Permissible harmonic distortion* (iv) *Total harmonic distortion* (v) *Weighted distortion factor* (vi) *The search for a true criterion of non-linearity.*

(i) Non-linearity

A distortionless amplifier has an input voltage versus output voltage characteristic that is a straight line passing through the origin (OA in Fig. 14.1), the slope of the line indicating the constant voltage gain. When non-linearity occurs, as may happen with curvature of the valve characteristics, the input-output characteristic becomes curved as in OB , thereby indicating that the gain of the amplifier is a variable quantity.

(ii) Harmonics

One effect of this non-linearity is the production of harmonic frequencies in the output when a pure sine-wave input voltage is applied, hence the name harmonic distortion. For example, if the input voltage is a pure sine wave of frequency 100 c/s, the output may consist of a fundamental frequency 100 c/s, a second harmonic of 200 c/s, a third harmonic of 300 c/s, and so on. Only the fundamental frequency is present in the input, and the harmonics are products of the non-linearity (for mathematical treatment see Chapter 6 Sect. 8).

Fig. 14.1. *Linearity characteristic (or transfer characteristic) — OA for distortionless amplifier ; OB for non-linear amplifier.*

Harmonics themselves are not necessarily displeasing, since all musical instruments and voices produce complex sounds having many harmonics (or overtones). But all sounds have certain relationships between the fundamental and harmonic frequencies, and it is such relationships that give the sound its particular quality*. If certain harmonics are unduly stressed or suppressed in the reproduction, the character of the sound (i.e. the tone) will be changed. For example, it is possible for a displeasing voice to be reproduced, after passing through a suitable filter, so as to be more pleasing.

The critical ability of the human ear to distinguish harmonic distortion depends upon the frequency range being reproduced and also upon the volume. Thus, with wide frequency range, the limit of harmonic distortion which can be tolerated is noticeably lower than in the case of limited frequency range, for the same volume level.

If the amplifier does not amplify the harmonics to the same extent as the fundamental, the effective harmonic distortion will be changed. Bass boosting reduces the harmonic distortion of bass frequencies, while treble boosting increases the harmonic distortion of fundamental frequencies whose harmonics are in the frequency range affected by the boosting.

The shape of the audibility curves for the ear, which has maximum sensitivity at about 3000 c/s (Fig. 19.7), indicates that there is some effective boosting of harmonics compared with the fundamental for harmonics up to about 3000 c/s, and an opposite effect for fundamental frequencies above 3000 c/s. This effect, however, is quite small at frequencies up to 1500 c/s, at the usual maximum listening levels (say 65 to 80 db on a sound level meter). At lower listening levels the effect will be appreciable, but the distortion is normally fairly low at these levels in any case. With fundamental frequencies above 3000 c/s there is an appreciable reduction of harmonic distortion at all levels (this effect has been referred to by Ladner, Ref. E14). For example, with a fundamental frequency of 3000 c/s, at a loudness level of 80 phons, the second harmonic will be attenuated by 9 db and the third harmonic by 15 db.

Harmonic voltages or currents may be expressed in the form of a percentage of the fundamental voltage or current. For example, if the fundamental voltage is 100 volts, and there is a second harmonic voltage of 5 volts, the second harmonic percentage is 5%.

Some harmonics are dissonant with the fundamental and (unless at a very low level) are distinctly unpleasing to the listener as regards their direct effect, quite apart from

*These remarks apply to sounds which have slow attack and recovery times. In the case of most orchestral instruments this effect is largely overshadowed by the more prominent effects of transients. Many sounds (e.g. vowels) have an inharmonic content in addition to the harmonic content (Ref. E14).

the secondary effect on intermodulation. The following table gives the relevant details when the fundamental frequency (C) is taken for convenience as 250 c/s.

Harmonic	Harmonic frequency	Musical scale*	Effect
2nd	500	C^i	
3rd	750	G	
4th	1000	C^{ii}	
5th	1250	E	
6th	1500	G	
7th	1750	---	dissonant
8th	2000	C^{iii}	
9th	2250	D	dissonant
10th	2500	E	
11th	2750	---	dissonant
12th	3000	G	
13th	3250	---	dissonant
14th	3500	---	dissonant
15th	3750	B	dissonant
16th	4000	C^{iv}	
17th	4250	---	dissonant
18th	4500	D	dissonant
19th	4750	---	dissonant
20th	5000	E	
21st	5250	---	dissonant
22nd	5500	---	dissonant
23rd	5750	---	dissonant
24th	6000	G	
25th	6250	$G \#$	dissonant

*Natural (just) scale. See Chapter 20 Sect. 8(iv).

(iii) Permissible harmonic distortion

The effect of non-linear distortion usually first becomes apparent to the listener through the production of inharmonic frequencies by intermodulation when two or more frequencies are present in the input (see Sect. 3). In practice, therefore, the percentages of the various harmonics which can be tolerated are fixed by their indirect effects rather than by their direct effect.

Under ideal theoretical conditions†, the magnitudes of the individual harmonics to produce equal intermodulation distortion are inversely proportional to the order of the harmonic. For example, 5% second harmonic produces the same intermodulation distortion as 3.3% third harmonic or 0.77% thirteenth harmonic—see below (v) Weighted distortion factor.

In order to make true comparisons between different sound systems, it is desirable to specify the frequency ranges, and the amplitudes of all the harmonics up to, say, the thirteenth. In the special case of single Class A triodes (below the overload point) the effect of the harmonics higher than the third may be neglected.

For a typical **single Class A triode** (type 2A3, Ref. E3) the harmonics, as derived from Olson, are :

Harmonic	2nd	3rd	4th	5th	
level	— 30	— 50	— 70	—	db
percentage	3.16	0.3	0.03	‡	%

With push-pull operation, the third harmonic becomes the dominant harmonic and, if the grid excitation is increased to give the same value of total harmonic distortion as with the single valve, the higher harmonics become more significant. With **Class AB₁ operation**, the higher harmonics are still further increased and, when weighted in proportion to the order of the harmonics, odd harmonics up to the thirteenth are prominent, and harmonics up to the twenty fifth may be appreciable.

†These conditions require the distortion to be similar to that produced by a Class A triode with not more than about 5% second harmonic distortion and without running into positive grid current.

‡Less than 0.01%.

With a **single pentode** the weighted values of the higher order harmonics are quite appreciable. The values of distortion—columns 1 and 2—are derived from Olson† for type 6F6 (Ref. E3).

Harmonic	level (db)	percentage	weighting factor‡	weighted distortion‡
2nd	-20	10	1	10%
3rd	-25	5.6	1.5	8.4%
4th	-35	1.8	2	3.6%
5th	-45	0.56	2.5	1.4%
6th	-62	0.08	3	0.24%
7th	-62	0.08	3.5	0.28%
8th	-63	0.07	4	0.28%
9th	-65	0.06	4.5	0.27%
10th	-73	0.022	5	0.11%
11th	-74	0.02	5.5	0.11%
12th	-73	0.022	6	0.13%
13th	-67.5	0.04	6.5	0.26%
14th	-74	0.02	7	0.14%

†These are based on the ideal theoretical condition for equal intermodulation distortion; they may differ considerably from the true effect on the listener.

With any system of amplification other than Class B, the percentage of total harmonic distortion, as defined in (iv) below, decreases as the power output level is reduced. Moreover, the percentages of the highest order harmonics decrease more rapidly than those of the lower order harmonics, as the power level is reduced.

The use of **negative feedback*** merely reduces all harmonics in the same proportion and does not affect their relative importance, except when the overload point is approached.

Comparative tests have been carried out by Olson (Ref. E3) which indicate

1. That slightly greater distortion is permissible with speech than with music.
2. That a higher value of total harmonic distortion is permissible with a single triode than with a single pentode, for the same effect on the listener.
3. That the permissible distortion decreases as the cut-off frequency is increased. However the rate of change varies considerably with the three categories of distortion, as given below.

4. **Perceptible distortion** (for definition see below).

Distortion becomes perceptible when the measured total harmonic distortion reaches the level of 0.7% for music, and 0.9% for speech, with a frequency range of 15 000 c/s and a pentode valve. Even with the very limited frequency range of 3750 c/s a total harmonic distortion of 1.1% on music, and 1.5% on speech, is perceptible with a pentode valve. The difference between pentode and triode is negligibly small.

5. **Tolerable distortion** (for definition see below).

The measured total harmonic distortion to give tolerable distortion on music, with either triode or pentode, increases about four times when the frequency range is reduced from 15 000 to 3750 c/s. The value of tolerable distortion with a pentode is 1.35% total harmonic distortion with a frequency range of 15 000 c/s, and 5.6% with a frequency range of 3750 c/s on music, and 1.9% and 8.8% respectively on speech. The amount of permissible total harmonic distortion with a triode is greater than that with a pentode for the same level of tolerable distortion, in the approximate ratio of 4 to 3.

The effect of frequency range on tolerable distortion is much greater than on perceptible distortion.

6. **Objectionable distortion** (for definition see below).

Objectionable distortion, on music, with either triode or pentode, increases about 5.5 times when the frequency range is reduced from 15 000 c/s to 3750 c/s; the

†By kind permission of the author and of the publishers and copyright holders, Messrs. D. Van Nostrand Company Inc.

*It is assumed that the feedback network is not frequency-selective.

effect of frequency range on objectionable distortion with music is thus greater than its effect on tolerable distortion and much greater than on perceptible distortion. The values of total harmonic distortion to provide objectionable distortion are 2% with a frequency range of 15 000 c/s and 10.8% with a frequency range of 3750 c/s for music, and 3% and 12.8% respectively for speech, with a pentode. The value of total harmonic distortion with a triode to give the same level of objectionable distortion as a pentode is approximately in the ratio 5/4.

Definitions—Perceptible distortion is defined as the amount of distortion in the distorting amplifier which is just discernible when compared with a reference system of very low distortion. Tolerable distortion is the amount of distortion which could be allowed in low-grade commercial sound reproduction. Objectionable distortion is the amount of distortion which would be definitely unsatisfactory for the reproduction of sound in phonograph and radio reproduction. The two latter are dependent upon personal opinion.

Test conditions—Information derived from these tests has been tabulated below, the conditions being

Triode : single 2A3, power output 3 watts.

Pentode : single 6F6, power output 3 watts.

The sound was reproduced in a room with acoustics similar to a typical living room with a noise level of about 25 db. The tests were performed with a limited number of critical observers.

Test Results (Ref. E3)

Cut-off frequency	3750	5000	7500	10 000	15 000 c/s
Objectionable distortion					
Music Triode	14.0	8.8	4.8	3.4	2.5%
Pentode	10.8	6.0	4.0	2.8	2.0%
Speech Triode	14.4	10.8	6.8	5.6	4.4%
Pentode	12.8	8.8	6.4	4.4	3.0%
Tolerable distortion					
Music Triode	6.8	5.6	4.4	3.4	1.8%
Pentode	5.6	4.0	3.2	2.3	1.35%
Speech Triode	8.8	7.2	4.8	3.6	2.8%
Pentode	8.8	5.2	4.0	3.0	1.9%
Perceptible distortion					
Music Triode	1.2	—	0.95	—	0.75%
Pentode	1.1	—	0.95	—	0.7%
Speech Triode	1.4	—	1.15	—	0.9%
Pentode	1.5	—	1.2	—	0.9%

(iv) Total harmonic distortion

The **distortion factor** of a voltage wave is the ratio of the total r.m.s. voltage of all harmonics to the total r.m.s. voltage.

The **percentage of total harmonic distortion** is the distortion factor multiplied by 100 :

$$D = \frac{\sqrt{E_2^2 + E_3^2 + E_4^2 + \dots}}{\sqrt{E_1^2 + E_2^2 + E_3^2 + E_4^2 + \dots}} \times 100 \quad (1)$$

where D = percentage of total harmonic distortion

E_1 = amplitude of fundamental voltage

and E_2 = amplitude of second harmonic voltage, etc.

If the distortion is small, the percentage of total harmonic distortion is given approximately by

$$D \approx \sqrt{(H_2\%)^2 + (H_3\%)^2 + \dots} \quad (2)$$

where $(H_2\%)$ = second harmonic percentage, etc.

with an error not exceeding 1% if D does not exceed 10%.

The measurement of total harmonic distortion is covered in Chapter 37 Sect. 3(ii).

(v) Weighted distortion factor

Some engineers use a weighted distortion factor in which the harmonics are weighted in proportion to their harmonic relationship :

$$W.D.F. = \frac{1}{2} \sqrt{\frac{(2E_2)^2 + (3E_3)^2 + \dots}{E_1^2 + E_2^2 + E_3^2 + \dots}} \quad (3)$$

For example, if $E_1 = 100$, $E_2 = 5$, $E_3 = 8$ volts,
 i.e. second harmonic = 5%
 and third harmonic = 8%
 then $W.D.F. = 0.129$ (or 12.9%)
 and Total distortion factor = 0.094 (or 9.4%).

When all the distortion is second harmonic, this weighted distortion factor is the same as the total distortion factor.

With this weighted distortion factor it is desirable to measure harmonics up to a high order (say the thirteenth) at frequencies where the high order harmonics come within the frequency band of the amplifier.

(vi) The search for a true criterion of non-linearity

Tests carried out by Olson—see (iii) above—indicate that, under the test conditions, the value of total harmonic distortion is a fairly accurate indication of “perceptible distortion”. Total harmonic distortion may thus be regarded as a true criterion of the subjective effects of distortion in an amplifier, provided that the value is of the order of 1% or less, and provided that overloading or “kinks” in the linearity characteristic do not occur. It has yet to be proved whether or not total harmonic distortion of the order of 1% is a true measure of the subjective effects of distortion under all conditions.

It is generally admitted that the value of total harmonic distortion does not provide a true criterion of non-linearity between different types of amplifiers under all possible conditions, even though the measurements may be made over the whole audible frequency range, and even though the frequency ranges may be identical.

It is the writer's opinion that the conventional weighted distortion factor—see (v) above—also fails to provide a true criterion of non-linearity.

It has been found that when measuring intermodulation distortion, the r.m.s. sum method is less effective than the arithmetical peak sum method in comparing different types of amplifiers—see Sect. 3. Since the principle of intermodulation testing inherently gives harmonic weighting, an obvious step would be to adopt the arithmetical sum of the weighted harmonics, using the conventional weighting factor.

One interesting investigation by Shorter (Ref. A45) has indicated that a very much more drastic weighting, using the square of the conventional weighting factor and including all harmonics with at least 0.03% amplitude, showed distortion values in the correct subjective sequence. The results obtained by Shorter are summarized in the table on page 611.

One inference which may reasonably be drawn is that any sharp kinks in the linearity curve, as usually occur in any Class AB₁ or AB₂ amplifier, have a far more serious subjective effect than is indicated by any of the standard methods of measuring distortion—whether total harmonic distortion, conventional weighted distortion factor or the standard form of intermodulation testing.

The excellent work by Olson—as described in (iii) above—has provided the correlation between frequency range and harmonic distortion for either music or speech, triode or pentode, for three levels of subjective distortion. What still remains to be done is for a comprehensive investigation to be made into the equivalent subjective effects (preferably following the definitions laid down by Olson) of all types of amplifiers—both good and bad design—measuring the individual harmonics up to, say, the twenty-fifth. The tests need only be taken with a single frequency range, since the effect of frequency has been adequately covered by Olson.

The test on each amplifier should be made at maximum rated power output into a resistive load, and also, if desired, at a specified level below maximum rated power

Results obtained by Shorter

System	Subjective Classification of Distortion	R.M.S. Sum of Harmonics	Weighted* Distortion	More drastic† Weighted Distortion	Linearity Curve‡
A	Bad	2.3%	5.1%	19.4%	Pronounced kink
D	Bad	3.7%	6.7%	16.5%	Pronounced kink
B	Perceptible	3.3%	5.1%	8.6%	Slight kink
E	Just perceptible	0.62%	1.3%	4.5%	
C	Just perceptible	2.6%	2.8%	3.3%	
F	Not perceptible	0.41%	0.8%	2.2%	

*As (v) above.

†With square of weighting factor of (v) above.

‡Indicated on a C.R.O. (input versus output voltage).

output. Tests should also be made on the same amplifiers for intermodulation distortion, using both r.m.s. and peak sum methods, with suitable test frequencies.

In all cases, any distortion measurements should be supplemented by

- (1) An oscillographic inspection of the waveform, and
- (2) An oscillographic inspection of the linearity (input versus output) characteristics for sharp "kinks."

From these results it should be possible to derive a system of harmonic weighting such that the weighted harmonic distortion is a true criterion of the subjective effects of the distortion.

SECTION 3 : INTERMODULATION DISTORTION

(i) *Introduction* (ii) *Modulation method of measurement—r.m.s. sum* (iii) *Difference frequency intermodulation method* (iv) *Individual side-band method* (v) *Modulation method of measurement—peak sum* (vi) *Le Bel's oscillographic method* (vii) *Comparison between different methods* (viii) *Synthetic bass.*

(i) Introduction

Intermodulation distortion is one of the effects of non-linearity when more than one input frequency is applied. It is evident to the listener in two forms, amplitude-modulation of one frequency by another, and the production of sum and difference frequencies. See also Chapter 2 Sect. 9(iv).

An example of amplitude-modulation is the effect of a non-linear amplifier on the reproduction of a choir with a heavy organ bass accompaniment. The choir is amplitude-modulated by the organ—a displeasing effect to the listener. This effect is negligibly small in amplifiers if the total harmonic distortion is less than say 2%, but it is apparent with some loudspeakers (see Chapter 20 Sect. 7).

The formation of sum and difference frequencies is the second and more serious form of intermodulation distortion. These frequencies are normally in-harmonic and are the principal cause of the distorted reproduction noticed by any listener—sometimes described as harsh, buzz, rough or unpleasant.

In actual operation there are very many input frequencies applied simultaneously, but it is possible to make comparative tests using only two frequencies. Tests for

intermodulation distortion may be made in accordance with any of the methods described below. For measurement see also Chapter 37 Sect. 3(ii)A.

The indicated value of intermodulation differs significantly with the method used, and the conditions of testing. It is important, in all cases, to specify both the method and the conditions of testing.

In all cases the two input voltages must be mixed, without intermodulation, before reaching the input terminals of the amplifier—bridge networks or hybrid coils are commonly used.

(ii) Modulation method of measurement—r.m.s. sum

In accordance with this method, one of the two input frequencies is preferably weaker than the other (a ratio of 4 : 1 in voltage or 12 db is used generally throughout this handbook unless otherwise indicated), and the stronger is usually lower in frequency than the other*. The sum and difference frequencies are usually expressed in the form of the percentage modulation of the weaker (high frequency) fundamental voltage. For one pair of sidebands the modulation percentage is given by

$$2 \times \text{sideband amplitude} \times 100 / \text{fundamental amplitude}.$$

When testing, in order to make a fair comparison with single-frequency conditions, the input should be adjusted so as to give the same peak output voltage as under single frequency conditions. **With the 4 : 1 ratio of the two input voltages, the equivalent single-frequency power output is 25/17 or 1.47 times the indicated power output under I.M. conditions** (Ref. B14). The indicated power output is that calculated from the r.m.s.-voltage across the load resistance.

Since there are many of these sum and difference frequencies, plus harmonics of both applied frequencies, it is necessary to take account of their magnitudes. This may be accomplished, in accordance with this method, in special equipment for the measurement of total intermodulation distortion by reading the r.m.s. sum of all extraneous frequencies (Refs. B5, B10). For measurement see Chapter 37 Sect. 3(ii).

There is no simple **relationship between harmonic and intermodulation distortion**. For example, it has been shown that in record manufacture the excessive polishing of masters greatly increases intermodulation distortion but does not much affect harmonic distortion (Ref. B6). See also Refs. A45 (correspondence), B7, B11, B19, B20.

If all harmonics are within the frequency range of the amplifier it may be shown that—

1. If only second harmonic is present (a condition which never occurs in practice), the ratio of total intermodulation distortion to second harmonic distortion is 3.2 (Refs. B7, B11).
2. If only third harmonic is present (another condition which never occurs in practice), the ratio of total intermodulation distortion to third harmonic distortion is approximately 3.84 at low values of distortion (Refs. B7, B11).
3. If the distortion is small, the intermodulation sidebands are approximately given by (Ref. B8):

Modulation percentage of first intermodulation sideband	}	$\approx 2 \times$ second harmonic distortion percentage.
Modulation percentage of second intermodulation sideband	}	$\approx 3 \times$ third harmonic distortion percentage.

Thus intermodulation distortion is automatically weighted by the order of the distortion.

As a very rough approximation, the ratio I.M./H.D. may be taken as :

3.2 for single-ended triodes

and 3.8 for push-pull (triodes or pentodes)

where I.M. = total intermodulation distortion (r.m.s. sum)

and H.D. = total harmonic distortion,

*With a-f systems with peaked response in the middle-to-high frequency range, such as high efficiency speech systems and hearing aids, better results are obtained by having the higher input frequency stronger than the lower frequency (Ref. B13). The two methods of measurement will, of course, give different results.

provided that the operation is restricted to the normal low-distortion region (Refs B7, B11). The ratio tends to increase as the distortion increases. These ratios may increase suddenly as the amplifier reaches the overload point. They are also affected if a lower I.M. frequency is selected which gives appreciable attenuation. The ratio is increased if there is any second harmonic cancellation in successive stages in the amplifier or any attenuation of harmonics. In practice therefore, with many disturbing factors, the ratio may vary from less than 1 to more than 6—see summary Ref. B19.

The usual test frequencies are 40, 60, 100, 150 or 400 c/s and 1000, 2000, 4000, 7000 or 12 000 c/s. It is helpful to make tests at two low frequencies—one of these (40 or 60 c/s) should approximate to the low frequency limit of the amplifier; the other may be 100 or 150 c/s. The distortion at the lower of these two frequencies is largely influenced by any iron-cored transformers, while that at the higher of these two frequencies gives a more normal overall value. The upper frequency may approximate to half the upper frequency limit of the amplifier—this does not, however, give a stringent test of the distortion at high frequencies.

Intermodulation distortion may be visually observed with a C.R.O. (Refs. B9, B19)—see also Sect. 3(vi) below.

Reliable intermodulation measurements may be made in the presence of considerable noise since the latter is excluded by filters to a greater degree than with harmonic distortion. It may also be successfully applied in the case of restricted frequency range where the harmonics would be outside the range of the amplifier. In such a case it is important to remember that the distortion is not zero merely because the harmonics are not reproduced.

Permissible intermodulation distortion

The following is an arbitrary grouping which may be useful (Modulation method—r.m.s. sum):

Extremely high fidelity a-f amplifier (40 c/s)	I.M. less than 2%
High fidelity a-f amplifier (40 c/s)	I.M. less than 4%
Good fidelity a-f amplifier (60 c/s)	I.M. less than 8%
Fairly good fidelity a-f amplifier (60 c/s)	I.M. less than 20%
Typical radio receiver—a-f amplifier only (150 c/s)	I.M. less than 40%

The values quoted are only a rough guide, since so many factors are involved. They apply to the equivalent single frequency maximum power output, and the lower test frequency is given in brackets.

See also comments in (vii) below.

Tests with 1 : 1 voltage ratio

More stringent tests at the higher frequencies may be made by the use of a 1 : 1 voltage ratio.

(iii) Difference-frequency intermodulation method

In accordance with this method, two frequencies f_1 and f_2 , of equal amplitude, are applied to the input and the relative amplitude of the intermodulation component at the difference frequency ($f_2 - f_1$) is then considered a measure of the inter-modulation distortion, which may be expressed as a percentage of either output voltage. A wave analyser may be used to measure the difference frequency. Typical lower frequencies are 1000, 5000 and 9000 c/s, while difference frequencies range from 50 to 500 c/s (Ref. A51) or even higher (Ref. B22). For the precise interpretation of results, a fairly low difference frequency is desirable.

Equipment has been designed so that the frequencies of the two input voltages can be varied over the a-f range with a constant difference frequency maintained between them (Refs. B3, B22).

See also comments in (vii) below.

References A51, B3, B12, B13, B22.

(iv) Individual sideband method

In accordance with this method the individual sidebands are measured separately, and some attempt made to select the most important ones (Ref. B1).

If all significant sidebands are measured, the distortion may be recorded in accordance with the peak sum modulation method—see (v) below.

(v) Modulation method of measurement—peak sum

This newer method of defining and measuring intermodulation distortion (Ref. B16) has outstanding advantages over the older method based on the r.m.s. sum. This peak sum method will measure the arithmetical sum of the amplitudes of the modulation products involved, with no discrimination against the weaker modulation products.

In accordance with this method, the percentage intermodulation is defined as the arithmetical sum of the amplitudes of the “in phase” modulation products divided by the amplitude of the high frequency carrier,

$$\text{i.e. percentage intermodulation} = \frac{A_1 + A_{-1} + A_2 + A_{-2} + \dots}{A} \times 100$$

Where A_1 and A_{-1} are the peak amplitudes of the modulation products of frequencies

$$\omega_2 \pm \omega_1,$$

A_2 and A_{-2} are the peak amplitudes of the modulation products of frequencies

$$\omega_2 \pm 2\omega_1, \text{ etc.},$$

A is the peak amplitude of the high frequency carrier,

ω_1 is the angular velocity of the low frequency input,

ω_2 is the angular velocity of the high frequency input.

The input amplitude of ω_2 is 12 db below that of ω_1 .

In order to measure the sum of these voltages accurately, it is necessary to use a peak-reading voltmeter. Ref. B16 describes such an analyser primarily for use with frequencies of 400 and 4000 c/s for testing pickups, but also capable of use with input frequencies less than 400 or greater than 4000 c/s.

See also comments in (vii) below.

(vi) Le Bel's oscillographic method

The use of an oscilloscope to give a qualitative indication of intermodulation distortion is well known—a good description is given in Ref. B9. A quantitative method has subsequently been developed by Le Bel (Ref. B19). The two voltages of different frequencies are applied to the input of the amplifier in the usual way, the output is passed through a high-pass filter to an oscilloscope with the sweep adjusted to cover one cycle of the low frequency. If there is no intermodulation, the high frequency wave has constant peak amplitude and the envelope is rectangular as in Fig. 14.1A.

Fig. 14.1A & B. Envelope of oscilloscope images without intermodulation (A), and with intermodulation (B). Ref. B19.

Fig. 14.1C. Definition of notch depth (Ref. B19).

Intermodulation results in an envelope such as Fig. 14.1B. Normally, the intermodulation causes a “notch” or notches in the envelope and the notch depth is defined by Fig. 14.1C. The experimental relationship which has been determined between notch depth and intermodulation (using the normal modulation method of measurement—r.m.s. sum—as in Ref. B2) is shown in Fig. 14.1D. This curve is practically linear below 50% notch depth (i.e. 10% intermodulation), so that a scale may be used directly on the screen for measuring the value corresponding to each notch. If there is more than one notch, Le Bel defines total notch depth as the arithmetical

Fig. 14.1D. Relation between notch depth and per cent. intermodulation (Ref. B19).

sum of the individual notch depths. Each notch in the low frequency cycle on top and/or bottom of the envelope is counted. Some typical envelope patterns are shown in Figs. 14.1E, F and G. If a peak instead of a notch occurs at any point, this indicates regeneration.

The harmonic and intermodulation* distortion characteristics of a push-pull amplifier are shown in Fig. 14.1H. At low output levels the intermodulation is less than the harmonic distortion, while at high output levels the reverse is true. This

*In accordance with Le Bel's oscillographic method.

indicates that the method is a much more sensitive indication of the approach towards the overload point than is total harmonic distortion.

See also comments in (vii) below.

(vii) Comparison between different methods

In recent years the modulation method of measurement based on the r.m.s. sum has been widely used. However this method has a serious shortcoming in that the lower amplitude modulation products have a negligibly small effect on the reading, which is almost entirely controlled by a few modulation products of high amplitude. It has been clearly demonstrated that this method does not give an indication proportional to the subjective effect on the listener, particularly when discontinuities ("kinks") occur in the valve characteristics as with Class AB or Class B operation, or when running into grid current with a high impedance source.

This defect is at least partially overcome by the use of the peak reading analyser described in (v) above, which is distinctly preferable as giving an indication more in line with the results from listening tests.

It seems that Le Bel's method described in (vi) above is an oscillographic equivalent of the peak sum method, and close correlation would be expected between them.

It remains to be proved whether or not the peak sum method gives readings proportional to the subjective effect on the listener under all conditions. It may be that some "weighting" method is required to give even greater prominence to the higher-order products that arise from sharp kinks in the linearity characteristic.

All modulation methods with the lower frequency at the higher level are primarily tests on low frequency distortion and, as such, fulfil a useful purpose. It is essential, for design purposes, to have separate measurements of distortion both at low and high frequencies. Insufficient investigation has been made into the general use of modulation methods with the higher frequency at the higher level, for testing high frequency distortion (however see Refs. B13, B19).

The difference-frequency method is very suitable for testing distortion at middle frequencies, and also at high frequencies where conventional* modulation methods are deficient. Unfortunately there are no published data to enable a comparison to be made with the peak sum modulation method.

The distortion indicated by the several methods may differ appreciably. For example, consider high-frequency pre-emphasis as used in recording and F-M. If distortion takes place after pre-emphasis and before de-emphasis, and if the distortion is measured after de-emphasis, the percentage harmonic distortion is lowered by the de-emphasis; the modulation method of measuring intermodulation is not significantly altered by de-emphasis; while the difference-frequency method gives a higher value as the result of de-emphasis (Ref. B13).

See also Ref. A43 and Chapter 37 Sect. 3(ii)A.

(viii) Synthetic bass

(A) When two or more input frequencies are applied to a non-linear amplifier the output will include sum and difference frequencies located about each of the higher input frequencies. For example with input frequencies of 50 and 150 c/s, the output will include frequencies of 50, 100, 150 and 200 c/s. Even if the lowest frequency is very much attenuated by the amplifier, the sum and difference frequencies tend to create the acoustical impression of bass. With more than two input frequencies the effect is even greater, so that fairly high distortion has the effect of apparently accentuating the bass.

(B) Owing to the peculiar properties of the ear, a single tone with harmonics may be amplified, the fundamental frequency may be completely suppressed, and yet the listener hears the missing fundamental (Ref. A18).

These two effects assist in producing "synthetic bass"—Chapter 15 Sect. 12(ii)—when the natural bass is weak or entirely lacking. It should be emphasized that this is not the same as true bass, and does not constitute fidelity.

*With the lower frequency having the greater amplitude.

SECTION 4 : FREQUENCY DISTORTION

(i) *Frequency range* (ii) *Tonal balance* (iii) *Minimum audible change in frequency range* (iv) *Sharp peaks.*

(i) Frequency range

Frequency distortion in an amplifier is the variation of amplification with the frequency of the input signal. A high fidelity a-f amplifier should have nearly constant amplification over the whole range audible to the most critical listener—from say 30 to 20 000 c/s (see Sect. 7). There is no serious difficulty in designing such an amplifier, but it can only be usefully applied when it is fed from a wide-range source and excites a wide-range loudspeaker system.

In practice there are limitations imposed by both the source and the loudspeaker, but it is good practice to design the amplifier for full-power-handling capacity with negligible non-linear distortion over a wider frequency range than it will normally be required to handle. The limitation in frequency range (if not inherent in the source) should preferably be applied either by a filter between the source and the input terminals, or in an early stage in the amplifier—see Chapter 15 Sect. 1(iii).

The full frequency range is only audible at very high levels as is demonstrated in Sect. 7. If a particular equipment is to be operated always at comparatively low levels (e.g. dinner music) or in noisy locations, reduction of the frequency range is quite correct and may even be beneficial.

Amplifiers for other than wide-range high-fidelity are usually designed to meet the requirements of the average listener, with a frequency range (at maximum orchestral level) of about 45 to 15 000 c/s, which may be still further reduced to about 70-13 000 c/s at typical levels for home listening—see Sect. 7(ii).

In commercial quantity-produced equipment the frequency range is often restricted to the extreme. By this means non-linear distortion and hum are reduced to a bearable level without expense. Unfortunately, frequency range can only be extended, while remaining free from obvious distortion, at a cost which rises at a rapidly increasing rate—largely due to the loudspeaker. It is important to reduce the distortion before widening the frequency range—see Sect. 12(ii).

(ii) Tonal balance

It has been found that good **tonal balance** between high and low frequencies is obtained when the product of the limiting frequencies is about 500 000* (Refs. A8, A17, A38, C1, C10).

For example :

1. 25-20 000 c/s. Very wide frequency range,
2. 33-15 000 c/s. Wide frequency range,
3. 50-10 000 c/s. Fairly wide frequency range,
4. 60- 8 000 c/s. Medium frequency range,
5. 100- 5 000 c/s. Restricted frequency range,
6. 150- 3 300 c/s. Very restricted frequency range,

but these should not be taken as more than a general guide. (5) is typical of a medium quality console, and (6) a mantel model receiver with "mellow" tone. These frequency ranges should include both amplifier and loudspeaker. Wide frequency range is only comfortable to the listener so long as other forms of distortion are imperceptible.

(iii) Minimum audible change in frequency range

Just as with sound level there is a minimum audible change in level, so there is also a minimum audible change in frequency range. The limen has been proposed (Ref. A25) as being the minimum difference in band width that is detectable by half the observers. Tests were made on a limited number of observers resulting in the following list of frequencies in steps of 1 limen : 15 000, 11 060, 8000, 6400, 5300,

*Various authorities place this figure from 400 000 to 640 000.

4400 c/s. It would therefore be possible to reduce the frequency range of an amplifier from 15 000 c/s (say the limit of hearing in a particular case) to 11 000 c/s without a non-critical listener noticing the restriction. The same principle also holds in reverse, when widening the frequency range. (See also Ref. A9).

(iv) Sharp peaks

One particularly objectionable form of frequency distortion is that due to sharp peaks in the output, as may be caused by loudspeaker cone resonances, especially in the 2000-3500 c/s range. Sharp troughs are relatively unimportant through their direct effects, although they may be accompanied by poor transient response.

The effect of restricted frequency range on articulation is covered in Sect. 11.

SECTION 5 : PHASE DISTORTION

Phase distortion is the alteration by the amplifier of the phase angle between the fundamental and any one of its harmonics or between any two component frequencies of a complex wave. Phase distortion causes the output waveform to differ from the waveform of the input voltage.

A fixed phase shift of 180° (or any multiple of 180°) at all frequencies does not constitute phase distortion. A phase shift which is proportional to the frequency also does not cause phase distortion.

It has been demonstrated in monaural listening (Ref. A23) that the tonal quality of a complex steady-state waveform depends not only upon the component frequencies and their relative amplitudes, but also—over certain ranges of frequency and level—upon the envelope shape, which is controlled by the phase angles. Large changes in aural perception can occur, through changes in phase only, among frequencies which are related harmonically or otherwise. These effects vary from a raucous to a smooth-sounding quality, depending on the relative phases. The frequency range, over which these effects were observed, increases as the acoustical level increases, at least up to 60 phons.

The authors state that “in the case of very complex, but continually varying sounds, such as voice or a musical instrument with many harmonics, phase effects of this type are probably not noticeable under usual listening conditions because the patterns are coming in and out non-simultaneously in various parts of the frequency range.”

Phase shift has a serious effect on transients (see Sect. 6).

In the light of the known effects, and with insufficient data to determine what degree of phase shift is permissible for high fidelity reproduction, it is wise to reduce the phase shift in amplifiers to the lowest practicable value.

With normal circuits, the phase shift is determined by the overall attenuation at the extreme low and high frequencies of the sound system. If the frequency characteristic is practically flat over the whole useful frequency range, the phase shift may normally be neglected. However, when a high-pass or low-pass filter is used to limit the frequency range, or when some form of tone control is used, the phase angle may be quite large over a limited frequency range.

Refs. A15, A23, A28, A40, A42, A57, E11.

SECTION 6 : TRANSIENT DISTORTION

(i) *General survey* (ii) *Testing for transient response.*

(i) General survey

It has been demonstrated by Prof. Richardson that it is the attack and decay times of sounds that largely determine their tonal quality, rather than their harmonic content (Ref. A41).

An amplifier which gives fairly good reproduction of steady tones may give serious distortion with transients. The distortionless reproduction of a short pulse requires

1. Very wide frequency response—possibly higher than the limit of audibility.
2. No phase distortion.
3. No “hang-over.” The duration should not be greater than the original pulse.

“Hang-over” effects are caused by insufficiently damped *LC* circuits such as may occur with a-f transformers, tone correction circuits and filters—see Chapter 15 Sect. 1(ix). Loudspeakers are particularly prone to this effect, and it is desirable for them to have heavy acoustical and electro-magnetic damping, with reduction of mass of moving parts.

Some measurements of the phase shift introduced by microphones and loudspeakers are given in Ref. A40.

References : A40, A41, E1.

(ii) Testing for transient response

Amplifiers and loudspeakers may be tested by applying to the input terminals a waveform with a sharp discontinuity—e.g. square wave or saw-tooth.

One of the most serious problems with certain kinds of music is the occurrence of extremely high transient peaks which may possibly reach a level 20 db above the reading of the volume indicator. This effect has been observed with choral music, orchestral string passages and similar highly complex sounds (Ref. E15—see also A3). These peaks cause overloading and distortion in the amplifier and loudspeaker, but particularly in recording. Some form of peak limiting is usually adopted in recording and broadcasting in order to avoid blasting or “buzz.” However, for true fidelity, these transient peaks should be reproduced in their original form.

One interesting approach is the use of **white-noise** as a test signal. White-noise is random fluctuation noise, but the construction of a white-noise signal generator whose output power is uniformly distributed over the a-f region of the spectrum is difficult. One white-noise generator, which heterodynes a selected portion of the r-f noise spectrum to produce nearly uniform voltage over the a-f range, is described in Ref. D18. A simpler method is described in Ref. D17 which employs a disc recording of white-noise (40 to 20 000 c/s) together with bands having high frequency cut-off at 7000, 9000 and 12 000 c/s and low frequency cut-off at 80 and 150 c/s. This is recorded on a constant velocity basis. A flat noise voltage characteristic may be obtained by playing back with a velocity pickup of the dynamic or magnetic type, without any equalizing network. The recording is corrected for translation loss—4 db at 20 000 c/s. The following comments are based on Ref. D17.

Loudspeakers may be tested for undamped resonances by applying white-noise signal, picking up the sound by a suitable microphone and applying the output to the vertical plates of an oscilloscope. The sweep frequency is then varied to pick up the resonances. Cross modulation may be recognised by a periodic thinning out of the fine-grain high frequency noise. It is stated that a miniature condenser microphone is particularly suitable for this test.

When an amplifier is overloaded, the peaks on the oscilloscope appear beaded.

The elliptical pattern, obtained by applying the white-noise to both pairs of plates with approximately 90° phase difference, may be used as a sensitive indication of overloading. The circuit is arranged to give larger ellipses with higher frequencies.

SECTION 7: DYNAMIC RANGE AND ITS LIMITATIONS

(i) *Volume range and hearing* (ii) *Effect of volume level on frequency range* (iii) *Acoustical power and preferred listening levels* (iv) *Volume range in musical reproduction* (v) *The effect of noise.*

(i) Volume range and hearing

Every source of sound, for example speech or music, has a variation in sound level from its minimum to its maximum. The loudness level is measured in phons (see Chapter 19 Sect. 5) while the maximum variation in level may be expressed in decibels—this is known as the **volume range**, and is measured by a standard sound-level meter or volume indicator. As this instrument does not indicate short sharp peaks, the **peak dynamic range** is usually 10 or occasionally up to 20 db greater than that indicated by the instrument.*

FIG. 14.2

Fig. 14.2. Threshold of audibility curves for average and very critical (5% most acute) listeners in the absence of noise. Reference level 0 db = 0.0002 dyne per sq. cm. Curves by courtesy of Jensen Radio Manufacturing Company, based on Fletcher (Ref. A3).

A symphony orchestra, with a peak dynamic range of up to 70 db provides the most difficult problem for the reproducing equipment. This range is equivalent to a power ratio of 10,000,000 : 1.

Before proceeding further, it is necessary to consider some of the characteristics of hearing. Fig. 14.2 shows the hearing characteristics of average and very critical listeners in the absence of noise—at any one frequency, a listener is only able to hear sound intensity levels above the curve.

Fig. 14.3. Masking levels for noise in average and very quiet residences. Curves by courtesy of Jensen Radio Manufacturing Company, based on Refs. A3, D6, D7, E9.

FIG. 14.3

The masking† effect of room noise is shown by Fig. 14.3 for average and for very quiet residences. These curves may be applied directly to the hearing characteristics of Fig. 14.2. The result is shown in Fig. 14.4 for average conditions and in Fig. 14.5

*The 10 db ratio is given in Ref. A51, quoting Refs. E7, E16. The 20 db ratio is mentioned in Sect. 6(ii), based on Refs. E15 and A3.

†The masking level is the level of pure tones which can just be perceived in the presence of noise. The masking level is higher than the noise (spectrum) level at the same frequency by a margin of 15db up to 1000 c/s, increasing to 28 db at 10 000 c/s (Ref. A53).

for a very critical listener and low room noise level (these latter are the extreme conditions for high fidelity). In each case the room noise reduces the effective hearing over a frequency range from about 150 to 6000 or 9000 c/s.

The effect of noises other than room noise is covered in (v) below.

Fig. 14.4. Effective hearing characteristic for average listener with average noise level. Curves by courtesy of Jensen Manufacturing Company.

FIG. 14.4

FIG. 14.5

Fig. 14.5. Effective hearing characteristic for very critical listener with low room noise level. Curves by courtesy of Jensen Manufacturing Company.

(ii) Frequency range

When listening to the rapidly varying intensity levels which occur with speech or music, the ear appears to integrate these varying sounds over about $1/4$ second intervals. When considering frequency range, the measurements of the sound levels created by the various types of musical instruments should therefore be reduced to their **equivalent sound levels in $1/4$ second intervals**.

If we compare the loudness of a narrow band of thermal noise with that of a pure tone having the same intensity, the two will be judged to have equal loudness if the width of the transmitted frequency band of noise is limited to a critical value called the **critical bandwidth** (Ref. A3). For this reason, measurements on the sound levels of musical instruments should be reduced to intensity levels which would have been obtained if the frequency bandwidths used in the filters had been equal to the critical bandwidths (Ref. A3).

The integrated sound energy in a critical band over a $1/4$ second interval will sound as loud as a pure tone in the same frequency band which produces the same sound energy in each $1/4$ second interval (Ref. A3).

Fig. 14.6 gives the maximum r.m.s. intensity levels in 1/4 second intervals in critical frequency bands for certain musical instruments and an orchestra at a distance of 20 feet from the sound source, together with the threshold of audibility curve for average listeners, indicating that a frequency range from 40 to 15 000 c/s meets all normal requirements for an average listener to an orchestra.*

FIG. 14.6

Fig. 14.6. Maximum r.m.s. intensity levels in 1/4 second intervals in critical frequency bands for whole orchestra and certain instruments. After Fletcher (Ref. A3).

Fig. 14.7 (highest curve) shows the same "orchestra" curve as Fig. 14.6, but combined with the threshold of audibility curve for a very critical listener, indicating that the maximum possible frequency range is from 32 to 21 000 c/s. These are the most extreme conditions to be taken into account for high fidelity reproduction. If this orchestra is reproduced at lower levels as indicated by the lower "orchestra" curves in Fig. 14.7, the frequency range is more restricted, particularly at the lower end. The values for both average and critical listeners are tabulated below :

Peak value	100	90	80	70 db
Average listener				
Lower frequency	45	50	70	100 c/s
Upper frequency	15 000	14 000	13 000	12 000 c/s
Critical listener				
Lower frequency	32	40	50	70 c/s
Upper frequency	21 000	20 000	19 000	18 000 c/s

Fig. 14.7. Maximum r.m.s. intensity levels in 1/4 second intervals in critical frequency bands for whole orchestra, with threshold of audibility curve for very critical listener. Also illustrating effect on frequency range of reproduction at lower levels.

FIG. 14.7

*The bass drum, played solo and very loudly, and the loud organ have frequencies in the vicinity of 30 c/s audible to an average listener.

The curves of Fig. 14.6 and the orchestra curves used in Fig. 14.7 are only suitable for determining the audible frequency ranges of the various sound sources—they cannot be used for calculating the peak power.

(iii) Acoustical power and preferred listening levels

The r.m.s. peak sound level at a desirable seat in a concert hall for “full orchestra” is not likely to exceed a value of 100 db (Refs. A51, E13).

If we accept the value of 100 db as being “maximum orchestral level,” then a maximum r.m.s. peak acoustical power of about 0.4 watt will be required for reproduction at the same level in a fairly large living room—see Chapter 20 Sect. 6(ii). If the loudspeaker is 3% efficient over the frequency band, then the maximum power from the amplifier will need to be 13 watts—with a more efficient loudspeaker, the power from the amplifier would be less.

Peaks above 100 db may occur occasionally with a large orchestra or choir, but they are usually “peak limited” before being broadcast or recorded. However in the design of the amplifier it is desirable to allow a margin to provide for possible peaks above this level.

Since sound levels are normally measured with a sound-level meter, it is necessary—when considering acoustical reproduction—to make allowance for the margin of 10 db or more between this level and the r.m.s. peak level.

Preferred listening levels

Tests conducted by the B.B.C. (Ref. C12) on listeners give the following preferred maximum sound level, as measured with a sound level meter :

	Public		Musicians	Programme Engineers		Engineers
	Men	Women		Men	Women	
Symphonic music	78	78	88	90	87	88 db
Light music	75	74	79	89	84	84 db
Dance music	75	73	79	89	83	84 db
Speech	71	71	74	84	77	80 db

Individual variations varied from 60 to 97 db for symphonic music, but in all cases 50% of the subjects were within ± 4 db of the mean. Increasing age showed a preference for lower listening levels.

The following table gives an approximate guide for home listening :

Loudness	Sound-level meter reading	Normal r.m.s. peak
Very loud	80 db	90 db
Loud (serious listening)	70 db	80 db
Medium (as a background)	55-65 db	65-75 db

(iv) Volume range in musical reproduction

(A) Orchestral reproduction

If the full peak orchestral dynamic range of 70 db is to be reproduced, the receiver (if any) and amplifier must have a peak dynamic range of the same amount. This may be accomplished with the peak sound intensity in the room either equal to that in the concert hall, or at a lower level. However, if the reproduced dynamic range is to be effective it must all be above the noise masking level.

Fig. 14.8 shows the extreme conditions for high fidelity reproduction, with the threshold of audibility curve for a very critical listener, combined with the masking

FIG. 14.8

FREQUENCY, CYCLES PER SECOND

Fig. 14.8. *Effective hearing characteristic for very critical listener with low room noise level, showing 70 db dynamic range for orchestra in a concert hall. Minimum orchestral level based on Ref. E13.*

effect of low room noise. The 70 db dynamic range of an orchestra in a concert hall is shown, with the minimum orchestral level of 30 db well above the masking level of the noise. In this case it would be possible to reproduce the full dynamic range at a level 15 db lower than the level in the concert hall, without loss due to noise. With an average listener and average noise level, however, the reproduction could not be more than 5 db below the level in the concert hall without loss due to noise. Any further reduction in level will result in the masking of the softest passages by the noise.

(B) Volume range broadcast or recorded

The volume range actually broadcast or recorded is frequently less than that of the original.

Source	Volume range
F-M broadcast (direct)	at least 60 db (F.C.C.)
A-M broadcast (direct)	at least 50 db (F.C.C.)
Transmission over telephone lines	40-50 db*
ditto (special lines)	50-75 db*
Lateral-cut disc records :	
shellac	30-45 db*
microgroove, say	40-56 db*
transcription (orthacoustic)	45-58 db*
Vertical-cut (hill and dale)	45-50 db*

To reduce the volume range, it is usual to employ automatic peak limiters together with volume compressors, although some manual adjustment is also made on occasions. To restore the volume range, it is sometimes possible to use volume expansion (see Chapter 16).

(v) The effect of noise

Noise as heard by the listener is contributed by many sources—for example by background noise in the studio, by the microphone and pre-amplifier, the transmitter, the receiver, the a-f amplifier and room noise. If the sound source is a record, there will be additional noise due to the recording. Under conditions for good fidelity, noise due to the transmitter and receiver (if any) can be made negligibly small. The remaining noise sources may be grouped as

*Maximum signal to noise ratio. The maximum dynamic range may be somewhat higher—see Sect. 7(v).

1. Noise from the sound source.
2. Noise from the amplifier.
3. Room noise.

It is assumed here that hum from the amplifier has been made inaudible, and then the total* noise arising from amplifier and room noise may be determined by the nomogram Fig. 19.6A when both component values are expressed in decibels. By following a similar procedure, this value may then be combined with noise from the sound source to give the total noise from all sources.

The value of room noise is 43 db for the average level (Fig. 14.4) and 33 db for the low noise level (Fig. 14.5).

It is usually simpler to combine these noises electrically than acoustically, a convenient point being the primary of the output transformer. The equivalent electrical value of the room noise for a typical living room of 3000 cubic feet is given approximately by†

Room noise	Electrical noise power (milliwatts)
33 db	$0.009/\eta$
43 db	$0.09/\eta$

Where η = loudspeaker efficiency percentage.

If the loudspeaker efficiency is 3%, the equivalent electrical value of the room noise is approximately - 25 dbm for low room noise, or - 15 dbm for average room noise.

The masking value of the total noise can only be determined accurately by calculating or measuring the total noise spectrum and applying the masking curves of Fletcher and Munson (Ref. E9 Fig. 15 ; also reproduced in Olson Ref. E3 Fig. 12.30). However for the simple case where room noise predominates, it may be taken as a reasonable approximation that the curves of Fig. 14.3 may be moved vertically as required and that the masking ordinate at 1000 c/s is 18 db below the total noise level.

Thus the masking effect at 1000 c/s of room noise alone is approximately - 43 dbm for low room noise, or - 33 dbm for average room noise, for 3% loudspeaker efficiency and a room volume of 3000 cubic feet. If the total noise from other sources is equal to the room noise, these values would be increased by 3 db.

For high fidelity reproduction, the amplifier and pre-amplifier noise should be kept below the lowest room noise level. Under the preceding conditions, with room volume 3000 cubic feet and loudspeaker efficiency 3%, a reasonable value for total amplifier noise‡ appears to be about - 30 dbm, giving a masking level 5 db below that of the lower value of room noise. For values of loudspeaker efficiency other than 3%, the value of total amplifier noise is given by

$$\text{amplifier noise power} = 0.003/\eta \text{ mW} \quad (1)$$

$$\text{or amplifier noise in dbm} = 10 \log (0.003/\eta) \quad (2)$$

where η = loudspeaker efficiency percentage.

See also Chapter 18 Sect. 2(ii) pages 782-783 for noise in pre-amplifiers ; Chapter 19 Sect. 6(iii) page 829 for the measurement of noise in amplifiers.

SECTION 8 : SCALE DISTORTION

When music or speech is reproduced in a room with flat frequency response and at a level such that the listener experiences the same sensation of loudness as he would in the concert hall or studio, the tonal balance will be the same as in the original (assuming that his seat occupies the same position as the microphone). If the level of reproduction is less than the original, the bass will be weak in comparison with the middle frequency range from 600 to 1000 c/s, while the frequencies above 1000 c/s will also be attenuated, although only slightly. This is illustrated in Fig. 14.9 for one selected condition with 90 phons average original level, reproduced at an average level of 70 phons ; the loss at 50 c/s is over 10 db.

*It is assumed that the room noise can be treated as random noise. Random noises are additive.

†Based on Chapter 20 Sect. 6(ii)B.

‡For measurement of amplifier noise see Chapter 19 Sect. 6.

Fig. 14.9. Loss of bass and high audio frequencies caused by reproduction at a loudness of 70 phons as compared with the original at 90 phons (based on Fig. 19.7).

On the other hand, if the reproduction is louder than the original, the bass (and to some extent the treble) will be accentuated. This commonly occurs with the human voice when reproduced at a high level, unless some correction is applied in the studio amplifier.

It is for this reason that orchestral or organ music, when reproduced at normal room volume, sounds weak and uninteresting. The application of the correct amount of bass boosting assists considerably in maintaining realism and tonal balance. This application of bass boosting may be made automatically with the adjustment of the volume control, provided that maximum setting of the control corresponds to maximum volume from the loudspeaker on musical peaks (Chapter 15 Fig. 15.59). This provision makes a second (semi-fixed) volume control desirable in reproduction from records—it calls for an exceptionally flat a.v.c. characteristic in a receiver, in addition to the double volume control. If the automatic arrangement is adopted without these precautions being taken, it is only partially effective, and many users prefer a manually operated bass-boost. The automatic arrangement is only satisfactory when the tonal balance is correct at the maximum setting of the volume control; it merely boosts the bass when the setting of the control is lowered.

Refs. A7, A29, A30, A33, A34, A56.

SECTION 9 : OTHER FORMS OF DISTORTION

(i) Frequency-modulation distortion (ii) Variation of frequency response with output level (iii) Listener fatigue.

(i) Frequency-modulation distortion

Frequency-modulation distortion (or “wow”) tends to occur in recording, and is a cyclic variation of a higher frequency by a lower frequency. Frequency-modulation distortion may also occur in loudspeakers—see Chapter 20 Sect. 7(ii).

(ii) Variation of frequency response with output level

The frequency response of an amplifier should be substantially the same at all working levels. Amplifiers should be tested for frequency response at maximum output and at 30 and 60 db below maximum output. Output transformers are a frequent cause of variations in frequency response at different levels.

(iii) Listener fatigue

There is no doubt that listening to reproduced music causes listener fatigue much more rapidly than listening to the original. This listener fatigue is caused by the necessity for mental processes arising from the unnatural effects in the hearing system.

Probably the creation of synthetic bass, intermodulation distortion and transient distortion play important parts in producing this fatigue.

An excessively high background noise level, whether caused by hum, record scratch or any form of extraneous noise, is also an important factor contributing to listener fatigue.

Ref. C7.

SECTION 10 : FREQUENCY RANGE PREFERENCES

(i) *Tests by Chinn and Eisenberg* (ii) *Tests by Olson* (iii) *Single-channel versus dual-channel tests* (iv) *Summing up.*

(i) Tests by Chinn and Eisenberg (Ref. C1)

This was the first large scale series of tests on a number of listeners in order to determine their preferences in the frequency range of reproduced music. The ranges were (3 db attenuation) :

Wide	35 to 10 000 c/s.
Medium	70 to 6 500 c/s.
Narrow	150 to 4 000 c/s.

The equipment included a single channel amplifier and loudspeaker system.

Only 12% of the listeners preferred the wide range on classical music, and 21% on male speech ; the remainder had no preference or were divided between narrow and medium. Tests were made at indicated sound intensities of 50, 60 and 70 db, the preference being between 60 and 70 db, varying with the type of music ; a somewhat higher sound intensity was preferred for speech than for music.

These tests gave rise to considerable discussion—see also (iv) below.

Refs. C1, C2, C3, C4, C5, C6, C7, C8, C9, C14, A12, A34.

(ii) Tests by Olson (Ref. C10)

In this case preferences were made on the frequency range for orchestral music with the listeners in the same room as the orchestra. No amplifying equipment was used ; the restriction of frequency range was accomplished by an acoustical filter. Listeners were given a choice between a high frequency limit of 5 000 c/s and full frequency range.

From 66% to 69% of the listeners preferred the full frequency range on music, and there was a majority preference for the full range on speech in “all acoustical” tests.

Refs. C10, C11, C7.

(iii) Single-channel versus dual-channel tests

Webster and McPeak (A19) carried out tests with single channel and dual channel (audio perspective) transmission of a live programme, compared with transcribed music. The majority preferred the transmission of a live programme to transcribed music. The majority also preferred the dual-channel to the single-channel transmission. The results, however, have been seriously challenged regarding their interpretation (C7, A12). The tests gave no indications of the preferred frequency range.

Hilliard (A27) expressed the opinion that the entertainment value of a two channel system reproducing frequencies up to 3500 c/s is better than a single channel system with 15 000 c/s response.

It seems to be generally agreed that any satisfactory form of stereophonic reproduction is very much preferable to single channel—see Chapter 20 Sect. 6(v).

(iv) Summing up

The tests by Chinn and Eisenberg indicated that, under their conditions of test, the majority preferred a restricted frequency range. The tests by Olson indicated that, under his "all acoustical" listening conditions the majority preferred an unrestricted frequency range. Obviously the conditions of the tests are of vital importance—see discussion (i) above, also summing-up by Olson, C10.

Subsequent amplifier tests by Olson have indicated that an audience was able to perceive a value of 0.7% total harmonic distortion (see Sect. 2 and Ref. E3). A reasonable inference is that the reduction in frequency range preferred by listeners in the Chinn and Eisenberg tests was caused by distortion present in the sound system.

It has been pointed out (Ref. C14) in connection with the Chinn and Eisenberg tests, that the choice between "wide" and "medium" (at 60 and 70 db) and between "medium" and "narrow" (at 50 and 60 db) was complicated by inadequate discriminability.

SECTION 11 : SPEECH REPRODUCTION

- (i) *The characteristics of speech* (ii) *Articulation* (iii) *Masking of speech by noise*
(iv) *Distortion in speech reproduction* (v) *Frequency ranges for speech.*

(i) The characteristics of speech

It has been shown (Ref. A3) that conversational speech audible at 2½ feet occupies a frequency band from 62 to 8000 c/s. The average conversational speech power is about 10† microwatts, loud shouting power is about 5 milliwatts, while the softest conversational level is about 0.01 microwatt (Ref. E5). The peak dynamic range is about 40 db for any one speaker in ordinary conversation, but may reach 56 db as an extreme limit in the general case (Ref. A3).

The peak power in conversational speech may reach 100 or even 200 times the average speech power. The octave with maximum energy in men's voices is from 300 to 600 c/s, and for women's voices from 555 to 1110 c/s, the energy in the octave being 31% of the total for both cases (Ref. E5).

The characteristics of a man's conversational speech at a distance of 2½ feet have been given as (Ref. A3):

Level of speech above threshold (+ 5 db)	63 db
Long root-mean-square intensity level	68 db
Peak level in 1/8 second intervals exceeded 5% of the time	85 db
Root-mean-square level in 1/8 second intervals exceeded only 1% of the time	78 db

Refs. A3, D5, D9, D20, E4, E5, E6.

(ii) Articulation

The articulation of speech is defined as the percentage of syllables interpreted correctly (Ref. D8). The results for an average listener receiving syllables at optimum intensity are given below (Ref. A3):

Articulation	Minimum frequency	or	Maximum frequency
98%	40 c/s		15 000 c/s
98	100		12 000
98	250		7000
96	570		5000
94	720		3900
90	960		3100
80	1500		2300
70	1920		1970
60	2300		1700
50	2600		1500

†A more recent test gave 34 microwatts for men and 18 microwatts for women (Ref. D5).

Columns 2 and 3 are the results of separate tests with a high-pass filter and a low-pass filter respectively. They cannot be combined to give a pass-band with the limiting frequencies as tabulated, except as a rough approximation for high percentages of articulation ($> 90\%$); in this case the two articulation values should be multiplied together (e.g. $96\% \times 96\% = 92\%$ articulation approximately for a pass band from 570 to 5000 c/s).

There is no loss in articulation with a frequency range (pass band) from 250 to 7000 c/s, while the loss is quite small with a range from 570 to 5000 c/s. With continuous speech the loss in articulation is noticeably less than with syllables.

Owing to the unnaturally high-pitched tone and obvious lack of balance, these frequency ranges are extended towards the bass for all communication purposes.

An articulation index has been proposed (Ref. D3) which may be calculated for any known conditions, including noise. A value of 1.0 is the maximum (for perfect articulation) while a value of 0.5 or over is entirely satisfactory.

Those who are interested in the intelligibility of speech either with or without noise interference should read Refs. D10, D11, and D12.

Experiments have shown that intelligibility is impaired surprisingly little by the type of amplitude distortion known as **peak clipping**. Conversation is possible even over a system that introduces "infinite" peak clipping, i.e., that reduces speech to a succession of rectangular waves in which the discontinuities correspond to the crossings of the time axis in the original speech signal. The intelligibility of the rectangular speech waves depends critically upon the frequency-response characteristics of the speech transmission circuits used in conjunction with the "infinite clipper". A word articulation value of 97 was obtained using firstly a filter providing a frequency-response characteristic rising 6 db/octave, followed by the infinite peak clipper, followed in turn by a filter with a characteristic falling at the rate of 6 db/octave (Ref. D13).

References to articulation: A3, D3, D8, D10, D11, D12, D13, D19.

(iii) Masking of speech by noise

Noise has a similar masking effect with both speech and music. If the noise level is reasonably low there is very little effect on the reproduction of speech, since the dynamic range is not excessive. It is sometimes required to operate loudspeakers in very noisy locations, and in such cases it is helpful to provide the amplifier with a bass cut-off at 500 c/s, since the maximum intensity levels of speech (particularly declamatory* speech) occur below this frequency, and the effect of the lower frequencies on the articulation is negligible. This permits the middle frequencies from say 1000 to 3500 c/s to be boosted to the threshold of pain at 120 db, thus bringing them above the noise. An alternative arrangement is to give a treble boost of 6 db per octave over the whole useful frequency band, up to at least 3000 c/s—this will automatically reduce the bass frequencies as desired (D2, D4). This latter method requires much less acoustical power—19% of that of a flat system with 500 c/s cut-off—but the effect sounds unnatural.

Refs. A3, D2, D3, D4, D14, D15, D16, E4.

(iv) Distortion in speech reproduction

A considerable degree of distortion is possible before speech becomes objectionably distorted—about 15% second harmonic with a high frequency cut-off at 3750 c/s. This may be put in the form of about 48% intermodulation distortion (r.m.s. sum) with a similar cut-off frequency.

If the frequencies below 500 c/s are attenuated, the distortion for a given loudness will be much less than for a wide frequency range.

*Very loud public speaking.

(v) Frequency ranges for speech

Application	Articulation	Frequency range
High fidelity reproduction	98%	62-8000 c/s
Good fidelity	98%	150-7000 c/s
Fair fidelity (Public address)	96%	200-5000 c/s
Restricted bass*. Unbalanced	96%	500-5000** c/s
Restricted bass and treble*	95%	500-4000** c/s
Very restricted*	90%	500-3000** c/s
Telephone		300-3400** c/s

*For noisy locations.

**Response may be peaked.

SECTION 12 : HIGH FIDELITY REPRODUCTION

(i) *The target of high fidelity* (ii) *Practicable high fidelity* (iii) *The ear as a judge of fidelity.*

(General references A3, A9.)

(i) The target of high fidelity

High fidelity reproduction is essentially reproduction such that the most critical person can listen intently to it without any apparent distortion and without any appreciable fatigue, other than any effects due to the single point source of sound. With the present limited state of knowledge we have no definite measurable limits which can be set for each form of distortion, to ensure high fidelity.

However, it is generally agreed that a high fidelity amplifier should comply with the following specification. Values in brackets are rather extreme.

Frequency range : 40-15 000 (30-20 000) c/s.

Variation in output ± 1 db (± 0.5 db) at three levels.

Total harmonic distortion not more than 1% (0.7%).

Intermodulation distortion not more than 3% (2%), measured at 40 c/s and, say, 7000 c/s—r.m.s. sum.

Power output sufficient to ensure that overloading does not occur.

Phase angle as small as practicable.

The desired degree of damping on loudspeaker at bass resonant frequency.

Hum inaudible.

Noise* to give specified dynamic range 70 (80) db :

Total noise† 52 (62) db below max. r.m.s. peak signal.

Noise* to be inaudible in low noise room :

For room volume 3000 cubic feet—

Loudspeaker efficiency	3%	10%	30%	45%
Total noise	-30	-35	-40	-42 dbm

Conditions of test—Including microphone (or other source) and loudspeaker.

This specification does not include some very important loudspeaker characteristics, such as frequency-modulation distortion, time delay for specified increase in sound pressure, transient decay characteristics, and sub-harmonics (see Chapter 20 Sect. 7). These have been omitted owing to difficulties in testing and the lack of standardized procedure.

(ii) Practicable high fidelity

There is no great difficulty in meeting the specification given in (i) above so far as a microphone and amplifier are concerned. However, when a loudspeaker is added, to say nothing of the additional distortion contributed by transmission and reception, or reproduction from disc records, it is impossible to meet this specification.

*See Sect. 7(v).

†Based on total noise 18 db above masking level of noise at 1000 c/s. For measurement of noise see Chapter 19 Sect. 6.

This raises the question whether such high standards are essential. The principal characteristics in question are variation in output, distortion, and frequency range.

Variation in output over the frequency range

A tolerance of the order of $\pm 5\%$ appears to be generally acceptable for the overall electro-acoustical performance of a sound system.

Distortion and frequency range

The permissible non-linear distortion in a high fidelity amplifier is dependent on the frequency range, the type of programme, the critical character of the listener and the sound level. It has been observed that the sensitivity of the ear to distortion in music appears to be a maximum for sound levels in the vicinity of 70 to 80 db (Ref. A51). Hence for sound levels of the order of 90 db (sound level meter indication), somewhat higher values of distortion than those specified in (i) above would be permissible—possibly of the order of 2% total harmonic distortion with a cut-off frequency of 10 000 c/s, and 2.5% with a cut-off frequency of 7500 c/s.

Most direct radiator loudspeakers exceed 2% total harmonic distortion over certain frequency bands when operated to give a sound level (meter reading) of 90 db in a fairly large living room. However, the problem is complicated by the fact that many types of music have maximum intensity levels in the 200 to 500 c/s frequency band where loudspeakers often have distortion values well below their maximum values.

When the distortion in any individual case is distressing to a listener, the high cut-off frequency should be reduced until he is relieved from the discomfort. It is better to have freedom from discomfort than to have a wide frequency response, particularly when listening for a sustained period. This leads to the conclusion that "the true measure of the quality of an electro-acoustical system is the maximum bandwidth which the public finds acceptable" (Ref. C7). Thus all high fidelity amplifiers should have a choice of high roll-off* frequencies.

In addition, it is necessary to provide the listener with tone controls on treble and bass, with the choice of boosting or attenuation on each (see Chapter 15). He can then please himself on the choice of tonal balance and frequency range.

In the writer's opinion, nearly distortionless reproduction of bass frequencies up to say 400 c/s is far more important than reproduction of frequencies above 10 000 c/s.

The importance of **improved bass response** in reproduced music is gradually gaining recognition. Various methods are being adopted to produce acceptable extreme bass response without requiring an excessively large loudspeaker. Fortunately the extension of the bass range, with or without bass boosting, does not directly result in any increase in the subjective effects of the distortion such as occurs with extension of the treble range.

High fidelity reproduction with a level frequency response, when compared with a distorting amplifier, seems to lack bass. If a fair comparison is to be made between them, when operating at the same sound levels, the high fidelity amplifier will require bass boosting.

A direct radiator loudspeaker, or a conventional horn type, cannot give high fidelity reproduction at frequencies lower than the bass resonance, because the distortion rises very rapidly. Thus the minimum frequency for high fidelity depends upon the loudspeaker and any extension to lower frequencies will require another, and usually larger and more expensive, loudspeaker.

The output transformer should, for high fidelity, have low distortion at the lowest frequency which the loudspeaker can handle. A transformer to handle high power at very low frequencies and low distortion is both heavy and expensive, but is not otherwise difficult either in design or manufacture.

If the output transformer and loudspeaker are incapable of handling frequencies below a critical value without serious distortion, it is wise to filter out these lower frequencies and so rid the amplifier of their bad effects. It is better to have a clean bass limited to say 80 or 100 c/s, than to have a distorted condition resulting in intermodulation effects over a wide frequency range.

*Sharp cut-off characteristics are undesirable for fidelity. However a roll-off and sharp cut-off may be combined to give an acceptable result.

(iii) The ear as a judge of fidelity

It is common practice to regard the ear as the final judge of fidelity, but this can only give a true judgment when the listener has acute hearing, a keen ear for distortion, and is not in the habit of listening to distorted music. A listener with a keen ear for distortion can only cultivate this faculty by making frequent direct comparisons with the original music in the concert hall.

Non-linear distortion in any good quality **amplifier** should be so low as to be inaudible to the most critical listener. This distortion can therefore only be checked by measurements.

The ear is the only final judge of fidelity with **loudspeakers**, although it should be supplemented by measurements of harmonic distortion, frequency response, frequency-modulation distortion, damping of bass resonance, time delay for 60 db increase in sound pressure, transient decay characteristics (Shorter's method), and sub-harmonics—see Chapter 20 Sect. 7.

The ear is the only judge of **tonal balance**.

In any acoustical test, the **sound level** should be that of normal loudspeaker operation.

SECTION 1 : INTRODUCTION

(i) The purpose of tone compensation (ii) Tone control (iii) General considerations (iv) Distortion due to tone control (v) Calculations involving decibels per octave (vi) Attenuation expressed as a time constant (vii) The elements of tone control filters (viii) Fundamental circuit incorporating R and C (ix) Damping of tuned circuits (x) Tolerances.

(i) The purpose of tone compensation

An "ideal" audio frequency amplifier is one having a response which is linear and level (i.e. "flat") over the whole a-f range. An amplifier which has a drooping characteristic at the extremes of its frequency range may be made practically flat by the incorporation of a suitable degree of bass and treble boosting. This device is adopted in studio amplifiers where rigid tolerances are imposed on the frequency response of each amplifier or unit, and also in video and wide-band amplifiers where the frequency range is so great that conventional a-f designs are unsatisfactory.

(Refs. 35, 38, 53 are typical.)

Studio microphones and pickups are "equalized" by a suitable filter to give a flat response. Thus any input source may be connected to any amplifier or amplifiers, and the overall result will be flat, since each unit in the chain is flat.

A different approach is usually adopted in complete units such as home gramophones where the whole is always used as one unit, and where we are only concerned with the overall performance.

In such a case it is possible to vary the frequency response of the amplifier so as to compensate for certain components such as pickups or loudspeakers which do not have a flat response.

All these are examples of tone compensation, the purpose of which is to give a flat overall frequency characteristic.

(ii) Tone control

A tone control is a variable filter (or one in which at least one element is adjustable) by means of which the user may vary the frequency response of an amplifier to suit his own taste.

Tonal balance is covered in Chapter 14 Sect. 4(ii).

(iii) General considerations

It is usual to regard the middle range of audio frequencies from say 500 to 2000 c/s as the "body" of musical reproduction, with 1000 c/s as the reference frequency.

Thus a lower or higher frequency is said to be attenuated if it is reproduced at a lower level than 1000 c/s or boosted if it is at a higher level than 1000 c/s.

An equalizer for a pickup or microphone is usually placed either between the source and the first amplifier valve or, if this is at a low level, between the first and second amplifier valves.

All sources of input voltage should have a frequency range which is more limited than the range which the amplifier and loudspeaker are capable of handling without noticeable distortion. In other words, no voltage should be applied to the input terminals of the amplifier which has a frequency lower than the low frequency limit of the amplifier and loudspeaker or a frequency higher than the high frequency limit of the amplifier and loudspeaker. If this does not hold, it is highly desirable to limit the frequency range of the input voltage, either at one or both ends of the range as required, by means of a suitable filter (see Sects. 3 and 6 below), inserted before the input terminals of the main amplifier. If there is a pre-amplifier followed by a main amplifier, the filter may be inserted between the two.

If a tone control is to be fitted to an amplifier, its position is of considerable importance, the only exception being when the amplifier has low distortion at all frequencies with a loudspeaker load. In an amplifier using a pentode or beam power amplifier without negative feedback, it is desirable to fit a r.c. filter across the primary of the output transformer. This may be fixed, with a supplementary tone control elsewhere, or it may form the tone control itself. In most amplifiers it is desirable to connect a small capacitance (say 0.001 μ F for a 5000 ohm load) directly from the plate of the output valve to earth, or from the plate of each output valve in the case of push-pull operation. This assists in by-passing any radio or ultrasonic audio-frequencies which may be present, without having much effect on the frequency response. Its capacitance might be increased with advantage if some attenuation of the highest frequencies is permissible.

In a typical radio receiver without negative feedback, the tone control may be in the plate circuit of the power valve, in the coupling circuit between the first a-f amplifier valve and the power valve, or in the grid circuit of the first a-f valve.

If an amplifier incorporates negative feedback, the tone control may be incorporated in the feedback network (see Sect. 9 below) or else should be connected to a part of the amplifier which is external to the feedback loop.

Tone controls may be continuously variable or stepped. The more complicated types are stepped but, like a studio attenuator, the steps may be made barely perceptible.

(iv) Distortion due to tone control

Tone control frequently has a pronounced effect on the effective distortion due to stages in the amplifier preceding the tone control filter. **Treble attenuation results**

in a reduction in the amplitude of harmonics compared with that of the fundamental—that is a reduction in the harmonic distortion—provided that the predominant harmonics are within the attenuation range. In general, intermodulation distortion is also reduced by treble attenuation, subject to the same limitation.

On the other hand, any form of **treble boosting** will increase the effective distortion at any frequency so long as the harmonics are accentuated by the treble boosting with respect to the fundamental; the same also applies to intermodulation distortion. This is one of the reasons why treble boosting is not widely used, or is limited to a very slight rate of boosting.

If an amplifier naturally has some treble attenuation, and is equalized by the correct amount of treble boosting, the distortion will be the same as though the amplifier had a naturally flat characteristic. However, in the case of a radio receiver, effectively having a treble attenuation through side-band cutting, the distortion at the output terminals will be greater than that at the second detector if treble boosting is used, even if the a-f amplifier distortion could be zero.

Bass boosting gives a reduction in harmonic distortion provided that the fundamental frequency is amplified more than the harmonics, which condition holds over a limited frequency range.

Bass attenuation gives increased distortion over a limited frequency range where the harmonics are amplified more than the fundamental.

References to distortion : 3, 61.

(v) Calculations involving decibels per octave

The rate of attenuation, or of boosting, is usually given in the form of so many decibels per octave. For example, a simple shunt condenser across a resistive network produces an ultimate treble attenuation of 6 db/octave—see Chapter 4 Sect. 8(ii) and Fig. 4.38. Ultimate attenuation is normally in multiples of 6 db/octave—e.g. 6, 12, 18 and 24 db/octave. Actual values of attenuation may differ from the ultimate values, particularly in the range from 0 to 7 db.

In some cases the frequencies at which readings are taken do not conveniently cover an exact number of octaves. In such a case the following procedure may be adopted.

(A) To convert db/specified frequency ratio to db/octave

Frequency ratio	Multiply db/specified frequency ratio by factor
1.2 : 1	6.02 to give db/octave
1.25 : 1	3.10 " " "
1.33 : 1	2.43 " " "
1.5 : 1	1.71 " " "
2 : 1	1.00 " " "
3 : 1	0.63 " " "
4 : 1	0.50 " " "
5 : 1	0.43 " " "
6 : 1	0.39 " " "
7 : 1	0.36 " " "
8 : 1	0.33 " " "
10 : 1	0.30 " " "

Example—A change of 0.7 db occurs with an increase of frequency from 1000 to 1250 c/s. What is the rate of change in db/octave?

Rate of change = $0.7 \times 3.10 = 2.17$ db/octave.

Note. A table relating frequency ratio, octaves and decades is given on page 368.

(B) To convert db/octave to db/specified frequency ratio

Frequency ratio	Multiply db/octave by factor	to give db/specified frequency ratio			
1.2 : 1	0.263	"	"	"	"
1.25 : 1	0.322	"	"	"	"
1.33 : 1	0.412	"	"	"	"
1.5 : 1	0.585	"	"	"	"
2 : 1	1.00	"	"	"	"
3 : 1	1.59	"	"	"	"
4 : 1	2.00	"	"	"	"
5 : 1	2.33	"	"	"	"
6 : 1	2.59	"	"	"	"
7 : 1	2.81	"	"	"	"
8 : 1	3.00	"	"	"	"
10 : 1	3.33	"	"	"	"

Example—What is the change in level for a frequency ratio of 1.5 to 1 when the rate of change is 6 db per octave?

Change in level = $0.585 \times 6 = 3.51$ db.

(vi) Attenuation expressed as a time constant

In F-M receiver design it is common practice to express the degree of pre-emphasis (treble boosting) in the transmitter as a time constant of so many microseconds, and the degree of de-emphasis (treble attenuation) in the receiver in the same form. The two methods are fundamentally related because the time constant in seconds is equal to RC where R is the resistance in ohms and C is the capacitance in farads. In the general case

$$\text{attenuation in db} = -10 \log_{10} (1 + \omega^2 T^2)$$

where $\omega = 2\pi f$

$T = CR =$ time constant in seconds

and $R =$ total effective resistance of supply network.

In the particular case where $T = 75$ microseconds and f is expressed in Kc/s, this becomes

$$\text{attenuation in db} = -10 \log_{10} (1 + 0.222f^2).$$

A de-emphasis curve for a time constant of 75 microseconds is given in Fig. 15.1. This curve, like all other curves of this class, has an ultimate rate of attenuation of 6 db/octave.

Fig. 15.1. De-emphasis curve with time constant of 75 microseconds, as used in F-M receivers.

(vii) The elements of tone control filters

Tone control filters are networks including at least two of the basic elements—resistance, capacitance and inductance. In adjustable tone controls it is simplest to use the resistance as the variable element, since continuously variable resistors are available. To vary capacitance or inductance values, it is necessary to use separate components or tapplings, with a step switch.

In radio receivers and home amplifiers it is usual, wherever possible, to avoid using inductors for tone control purposes. This is firstly because inductors are generally more expensive than condensers, and secondly inductors are very prone to pick up hum unless elaborate and often expensive precautions are taken. An additional reason is that inductors with the desired values of inductance and tolerances are not usually stock lines.

The inductance of an inductor with any form of iron core is not constant, but is affected by the applied alternating voltage, the frequency, and by any direct current.

When a composition “potentiometer” is used with the moving arm in the grid return circuit of a valve, there will be additional noise caused by the movement of the arm. In such a case, the subsequent amplifier gain should be low.

(viii) Fundamental circuit incorporating R and C

The circuit shown in Fig. 15.2 may be used for the purpose of obtaining many forms of tone compensation. The values of the six components may be varied as desired to provide bass boosting or attenuation as well as treble boosting or attenuation. It is to be understood that the choice of values extends from zero to infinity, this being equivalent to the optional short-circuiting or open-circuiting of any one or more resistors or condensers. This form of filter is intended for use with a constant input voltage (E_i). This holds approximately when a triode valve is used.

Fig. 15.2. Fundamental circuit incorporating R and C for use with a constant input voltage.

(ix) Damping of tuned circuits

When tuned circuits are used for purposes of tone control, the damping should be sufficient to reduce the “overshoot” to a small value when a unit step (pulse) input is applied to the amplifier. This overshoot may be reduced to a small value if Q does not exceed 0.7. Under no circumstances should Q exceed 1.0 by more than a small margin. Insufficient damping results in distortion of transients.

(x) Tolerances

In all cases where a tone control, tone compensating network or filter is required to have specified frequency response characteristics, the elements of the network must be specified within narrow tolerances, and should preferably also be tested after delivery by the component manufacturer. Even in cases where the response characteristic is not specified, the effect of normal tolerances with capacitors, resistors and inductors is to cause a wide “spread” of response characteristics since the tolerances are sometimes cumulative.

When a single item of equipment is being built, it is important to check either the values of the critical components or the overall response characteristic, or preferably both.

SECTION 2: BASS BOOSTING

(i) *General remarks* (ii) *Circuits not involving resonance or negative feedback*
 (iii) *Methods incorporating resonant circuits* (iv) *Circuits involving feedback* (v) *Regeneration due to negative resistance characteristic.*

(i) General remarks

Bass boosting, either for tone compensation or tone control, implies that the gain of the amplifier at 1000 c/s must be reduced sufficiently to permit the full gain to be available for amplifying bass frequencies. For example, if the maximum amplifier gain is 56 times (35 dbvg*), and a maximum bass boost of 15 db is required, then the gain at 1000 c/s cannot be more than 20 dbvg*.

Bass boosting for tone control purposes may be used to provide better tonal balance at acoustical levels lower than the original sound, and is generally controlled manually—for automatic control see Section 10. Bass boosting increases the power output from the power valve and loudspeaker at low audio frequencies, and therefore tends to cause overloading if used at maximum volume; this effect does not occur at lower volume levels. When using bass boosting, the apparent loudness at which overloading occurs is less than that without bass boosting. For this reason, bass boosting should be used with discretion except in amplifiers having ample reserve of power.

For general tone control purposes in typical radio receivers and amplifiers, a bass boost variable from zero to +6 db is a good compromise. This involves, at maximum bass boosting, four times the power without bass boosting. Any increase beyond 6 db would involve a careful analysis of the whole design.

The bass boost should reach its maximum value at some suitable frequency, say 75 c/s, and should fall fairly rapidly below this frequency. There should be zero boost or even attenuation at the minimum frequency which the amplifier and loudspeaker are capable of handling without distortion.

Bass boosting should not extend appreciably above a frequency of 250 c/s at maximum volume, or the male voice will sound unnatural. When the boosting is only used at lower levels this limitation does not hold.

Some of these limitations are removed by the use of automatic frequency-compensated tone control (Sect. 10).

Fig. 15.3. Conventional bass boosting circuit (plate shunt compensation).

(ii) Circuits not involving resonance or negative feedback

(A) Conventional bass boosting circuit (Fig. 15.3)

(also known as plate shunt compensation)

The bass boosting is due to the increasing impedance of C_2 as the frequency is lowered. It is assumed here that the reactance of C is negligibly small compared with R_1 ; in practice the value of C may be selected to give attenuation below a specified frequency. R_2 should be at least 20 times R_1 and preferably higher. The top limit is the maximum grid circuit resistance permitted for V_2 ; if V_2 is a resistance coupled stage, see Chapter 12 Sect. 2(iii)E and Sect. 2(iv) for triodes, or Sect. 3(iv) and Sect. 3(v) for pentodes. If V_2 is a power valve, R_2 will usually be limited to 0.5 megohm for cathode bias.

*Decibels of voltage gain—see Chapter 19 Sect. 1(vi)A.

The resistor R_1 is intended to reduce distortion through low a.c. load impedances connected to the plate circuit of V_1 ; it may be omitted if the stage is operating at a low level or if R_4 is not less than twice the plate resistance of V_1 . A suitable value is not less than $2r_p$ in the case of a triode or not less than $2R_L$ in the case of a pentode. The resistor R_1 also has the effect of decreasing the gain at high frequencies more than at low frequencies, thereby increasing the ratio of gains at low and high frequencies.

It may be shown that

$$\text{Gain at high frequencies} = \frac{\mu}{(1 + r_p/R_L)(1 + R_1/R') + r_p/R'} \quad (1)$$

where $R' = R_2 R_4 / (R_2 + R_4)$

$$\text{Gain at zero frequency} = \frac{\mu}{(1 + r_p/R_L)(1 + R_1/R_2) + r_p/R_2} \quad (2)$$

$$B = \text{ratio of gains} = 1 + \frac{R_2}{R_4} \left\{ \frac{(1/r_p + 1/R_L)R_1 + 1 - R_4/R_2}{(1/r_p + 1/R_L)(R_1 + R_2) + 1} \right\} \quad (3)$$

As a sufficiently close approximation, R_4/R_2 may be taken to have a value as indicated below :

Boost	6	10	15	20	db
R_4/R_2	0.1	0.05	0.02	0.01	approx.

Using this approximation, we may determine the value of R_4 to provide any desired ratio of gains, that is the bass boost expressed as a ratio (B) :

$$R_4 \approx \frac{R_2}{B - 1} \left\{ \frac{(1/r_p + 1/R_L)R_1 + 1 - R_4/R_2}{(1/r_p + 1/R_L)(R_1 + R_2) + 1} \right\} \quad (4)$$

where B = ratio of amplification at zero frequency to amplification at high frequencies.

Typical values of resistors are given below :

	General case	Valve type 6J5	Valve type 6AV6
Plate resistance	r_p	7 700*	62 500*ohms
R_L	$5 r_p$	50 000	220 000 ohms
R_1	$2 r_p$	20 000	120 000 ohms
R_2	$20 r_p$	500 000	1 000 000 ohms
R_4 for 6 db boost	$2.4 r_p$	25 000	140 000 ohms
R_4 for 10 db boost	$1.1 r_p$	11 600	67 000 ohms
R_4 for 15 db boost	$0.53 r_p$	5 500	30 000 ohms
Gain at high frequencies :			
6 db boost	0.36μ	7.6	30 times
10 db boost	0.22μ	4.7	19 times
15 db boost	0.13μ	2.6	10 times

A typical example incorporating a pentode is Fig. 15.37A (Sect. 8).

The procedure in design is

- (1) to determine the desired total bass boost in db from high frequencies to zero frequency.
- (2) to select a suitable valve type.
- (3) to assume suitable values for R_L , R_1 and R_2 .
- (4) to calculate the value of R_4 to give the desired boost, using eqn. (4).
- (5) to determine a suitable value for C (this may be done by following Chapter 12 Sect. 2(ii), assuming $R_1 + R_2$ to be the effective value of R_{22}).
- (6) to determine the value of C_2 to give the required position of the boosting curve on the frequency characteristic, as described below.

Frequency characteristics

The shape of the frequency characteristic is determined solely by the amount of the total boost in db (Fig. 15.4). It is convenient to consider the frequency at which each characteristic reaches half the total boost in decibels, and to call this the "half-

*As normal Class A₁ amplifier. Higher values are to be anticipated for resistance-coupled conditions.

FIG. 15.4

Fig. 15.4. Bass boosting frequency characteristics. These are quite general and may be applied to any r.c. boosting provided that the value of the total boost in db is known. See text for value R/X (Ref. 10).

boost point." It will be seen that the frequency of the "half boost point" (f_0) increases as the total boost increases.

Total boost	20	15	10	6	3	db
Half-boost	10	7.5	5	3	1.5	db
Boost ratio (B)	10	5.62	3.16	2.0	1.41	
R/X for half-boost*	3.16	2.37	1.78	1.41	1.19	
C_2^\dagger	$3.16/\omega R$	$2.37/\omega R$	$1.78/\omega R$	$1.41/\omega R$	$1.19/\omega R$	F

* $(R/X) = \sqrt{B}$ at half-boost point.

† $C_2 = 1/(\omega X) = (R/X)/(\omega R)$ and $\omega = 2\pi f_0$

where $R = [r_p R_L / (r_p + R_L)] + R_1 + R_4$

and f_0 = frequency at half-boost point.

(Fig. 15.3)

The slope of the frequency characteristic at the half-boost point, which is very nearly the point of maximum slope, is approximately:

Total boost	20	15	10	6	3	db
Slope at half-boost point	4.9	4.1	3.0	2.0	1.0	db/octave

If a tangent is drawn to the curve at the half-boost point, it will be seen that the slope of the frequency characteristic does not fall off to any appreciable extent from the half-boost point to the three-quarters boost point (i.e. 75% of the total boost in db). The falling off in slope does not cause a difference of more than 1 db between the curve and the tangent up to 90% of the total boost in db, the reading of 90% being taken on the tangent.

This circuit may be applied to continuously variable bass boosting by using a variable resistor in place of R_4 , but this has the effect of varying the amplifier gain at the middle audio frequencies and hence varying the apparent loudness. One possible alternative which avoids this defect, is to put a high variable resistor (say 0.5 megohm logarithmic taper) across C_2 . This method gives a variation in total boost without much change in level of the middle frequencies, but the shapes of the frequency characteristics are not the most desirable for tone control purposes—Fig. 15.5; see also (D) below.

Several values of C_2 may be selected by means of a tapping switch, leaving the total boost unchanged, but this merely moves the frequency characteristic horizontally and is not satisfactory, on its own, for tone control purposes.

Fig. 15.5. Frequency characteristics with conventional bass boosting circuit, having variable resistor across C_2 (Ref. 9).

A modification which has some advantages is shown in Fig. 15.6. Here R_2 has been moved from the grid circuit of V_2 to reduce the shunting effect on R_4 and C_2 . The total grid circuit resistance of V_2 is $(R_1 + R_2)$. Ref. 11.

References to conventional bass boosting circuit—9, 10, 11, 20, 23, 38, 51, 55.

(B) Plate series compensation (Fig. 15.7)

This is a simple method of providing a fixed amount of bass boosting which uses the plate decoupling circuit. It is generally limited to use with r.c.c. pentodes. With the values of components shown, the frequency response curves for two values of C are given in Fig. 15.8.

References to plate series compensation : 38, 52, 53.

Fig. 15.6. Modified form of Fig. 15.3.

Fig. 15.7. Bass boosting—plate series compensation.

(C) Grid series compensation

This is the same in principle as plate series compensation (Fig. 15.7) except that C_1 is taken to a tapping point on R_p instead of on R_L . This is often preferred in wide-band amplifiers as C_1 will be smaller for the same frequency characteristic than with plate series compensation.

Reference to grid series compensation : 38.

Fig. 15.8. Frequency characteristics with the circuit of Fig. 15.7, $V_1 = 6J7$, $R_L = 0.05 M\Omega$, $R_1 = 0.2 M\Omega$, $R_k = 2000 \Omega$, $C_k = 25 \mu F$, $R_s = 1.5 M\Omega$, $C_s = 0.1 \mu F$, $C = 0.02 \mu F$, $R_v = 1 M\Omega$.

(D) Improved variable bass boost

A method for obtaining continuously variable bass boost having improved shape of the frequency characteristics, is incorporated in the bass and treble boost circuit of Sect. 8(x)K and Figs. 15.55 and 15.56A.

(iii) Methods incorporating resonant circuits

Resonant circuits give greater flexibility than those incorporating only capacitance and resistance. They are limited, however, to values of Q not greater than 1 (Ref. 54) and preferably not greater than 0.7—see Sect. 1(ix).

(A) Parallel resonant circuits

A parallel resonant circuit, which may be connected in the plate circuit of a r.c.c. pentode (Fig. 15.9) provides boosting in the vicinity of its resonant frequency, with maximum boost at its resonant frequency. For bass boosting the resonant frequency is often between 50 and 120 c/s, although higher and lower frequencies are sometimes adopted.

The inductor L_1 has to carry the greater part of the plate current of V_1 (several milliamperes in a typical case) and should have a butt joint or air-gap to reduce the effect of the plate current on the inductance.

Fig. 15.9. Bass boosting with parallel resonant tuned circuit in plate circuit.

Fig. 15.10. Bass boosting with parallel resonant tuned circuit in grid circuit.

In all circuits of this type, it is advisable to select a high L/C ratio in order to give the highest gain for a fixed amount of boosting.

$$Q = \omega_0 CR_s$$

For the limiting value of $Q = 1$,

(5)

$$R_s \gg 1/\omega_0 C \quad (6)$$

where R_s = equivalent total shunt resistance in ohms

$$\omega_0 = 2\pi f_0$$

f_0 = frequency of resonance in c/s

$$LC\omega_0^2 = 1$$

L = inductance in henrys

and C = capacitance in farads.

Typical values for a resonant frequency of 70 c/s are : $L_1 = 51.5$ H, $C_1 = 0.1$ μ F, $R_1 = 22\,000$ Ω , $R_{L1} = 3\,900$ Ω , $R_s = 0.47$ M Ω , total bass boost 15 db at 70 c/s, $Q = 0.93$. The exact value of R_s will be influenced by the winding resistance of L_1 —the value given above is on the assumption that the winding resistance is zero.

An alternative arrangement which has the advantage of avoiding direct current flow through the inductor is Fig. 15.10—this has the resonant circuit in the grid circuit of V_2 . As a result, it is possible to use a higher value of L and to shunt the tuned circuit by a variable resistor as a control. Typical values for $f_0 = 70$ c/s are : $R_L = 0.1$ M Ω , $R_1 = 50\,000$ Ω , $R_4 = 50\,000$ Ω , $L_2 = 250$ H, $C_2 = 0.02$ μ F, and $R_3 = 0.5$ M Ω maximum. In this case the winding resistance of L_2 must be taken into account.

Let r_2 = winding (series) resistance of L_2

R_s = equivalent shunt resistance corresponding to r_2

$$\text{then } R_s = L_2 / C_2 r_2 \quad (7)$$

The total shunting on the tuned circuit is therefore R_s in parallel with R_s in parallel with $(R_L + R_1 + R_4)$.

If r_2 is 10 000 ohms*, then

$$R_s = 250 / (0.02 \times 10^{-6} \times 10\,000) = 1.25 \text{ megohms}$$

$$R_s = 0.5 \text{ megohm (max.)}$$

$$(R_L + R_1 + R_4) = 100\,000 + 50\,000 + 50\,000 = 0.2 \text{ megohm.}$$

$$\text{Then } \frac{1}{R} = \frac{1}{1.25 \text{ M}\Omega} + \frac{1}{0.5 \text{ M}\Omega} + \frac{1}{0.2 \text{ M}\Omega}$$

Thus $R = 0.13$ megohm = total shunting resistance

and $Q = 1.15$ at maximum setting of R_s and would normally be below 1.0.

(B) Series resonant circuits

A series resonant circuit has a low impedance at the resonant frequency and a gradually increasing impedance at frequencies off resonance. These are used in combined bass and treble controls (Sect. 8) and in circuits incorporating negative feedback (Sect. 9).

(C) Transformer primary resonance

When parallel feed is used with an a-f transformer, the coupling capacitance C may be made to resonate with the primary inductance of the transformer. By this means a limited degree of bass boosting is provided. See Chapter 12 Sect. 4(xii) and Fig. 12.24. The Q should not exceed unity.

The same principle holds when an inductor (choke) is used in the grid circuit, with parallel feed.

References to methods incorporating resonant circuits : 51, 54.

(iv) Circuits involving feedback

(A) Amplifiers with feedback over several stages

This is dealt with in Section 9.

(B) Negative current feedback

Negative current feedback may be applied by omitting the cathode capacitor on the power amplifier valve. This increases the output resistance and provides a close approach to a constant current source for the loudspeaker. It has the effects of peaking the loudspeaker at the bass resonant frequency, reducing the damping on the

* This value is typical for a silicon steel core. Very much lower values are typical for mu-metal cores.

loudspeaker, and decreasing the stage gain. This device is usually avoided on account of its short-comings.

(C) Conventional circuits with decreased negative feedback at bass frequencies

One very popular circuit is Fig. 7.33 [Chapter 7 Sect. 2(vi)] which gives feedback over two stages—this has been adapted to provide bass boosting in Fig. 15.11 (Ref. 58). As explained in Chapter 7, this circuit inherently tends to give a slight degree of bass boosting—the boosting is continuously variable from 1.3 db to 12 db using 1000 c/s as the reference frequency, Fig. 15.12. As a modification, the feedback may be taken from the secondary of the transformer—it is advisable to check experimentally to see that the phase rotation due to the transformer does not adversely affect the frequency characteristics.

FIG. 15.11

Fig. 15.11. Two stage amplifier with negative feedback over both stages providing bass-boost tone control (typical application).

Fig. 15.12. Frequency characteristics of amplifier in Fig. 15.11. Condition (1) tone control max. resistance (2) three quarters max. (3) half max. (4) one quarter max. resistance. The curves have been superimposed to coincide at 1000 c/s.

Another possible circuit is Fig. 15.13 (Ref. 36) in which the feedback is taken from the plate to the grid through C and R_2 . The response is given by

$$(1 - \alpha)(1 + j\omega_0/\omega) \quad (8)$$

where $\omega_0 = \alpha/[CR_2(1 - \alpha)]$

and α = proportion added to the original signal by the setting of VR_1 .

Typical values are: $R_1 = R_2 = 1 \text{ M}\Omega$, $R = 0.22 \text{ M}\Omega$, $C = 200 \mu\text{F}$, giving $\omega_0/2\pi = 250 \text{ c/s}$ when $\alpha = 0.25$. The resistance of VR_1 and VR_2 should be high, preferably with VR_2 greater than VR_1 and $R_3 = VR_1$.

Still another possible circuit is Fig. 15.14A in which feedback is taken from the cathode of the second stage to a resistor at the earthy end of the volume control feeding the grid of the first stage (Ref. 65). It is stated that this gives 10 db of negative feedback at middle and high frequencies and 3 db of positive feedback at low frequencies, equivalent to 13 db bass boost.

Fig. 15.13. Single stage amplifier giving bass boosting with adjustable frequency characteristic (Ref. 36).

Fig. 15.14A. Two stage amplifier giving 13 db effective bass boost (Ref. 65).

In Fig. 15.14B a capacitance is inserted in the feedback network from the plate of V_2 to the plate of V_1 , with r.c. coupling between the stages. This capacitance provides a fixed amount of bass boosting which is generally limited to about 6 db maximum (Ref. 68).

Fig. 15.14B. Amplifier with $0.005 \mu\text{F}$ condenser in feedback network to provide bass boosting. V_2 is a power amplifier valve (Ref. 68).

A circuit using an inductor in the feedback network is Fig. 15.54—this may be used for bass boosting only by omitting C_2 and R_4 .

A particularly interesting circuit is Fig. 15.15 which incorporates a parallel-T network in the feedback loop (Ref. 57). In the figure the parallel-T network is tuned to 80 c/s, but it may be tuned to any other desired frequency. The frequency characteristic is shown in Fig. 15.16.

There have been many other applications of negative feedback to provide bass boosting which have appeared in articles and patents, too numerous to give in detail. Some are given in the References (Sect. 15).

See also Sects. 4, 8, 9, 10 of this chapter, and Chapter 17, Sect. 5.

FIG. 15.15

Fig. 15.15. Single stage amplifier incorporating a parallel-T network in the feedback loop (Ref. 57).

SECTION 3 : BASS ATTENUATION

(i) *General remarks* (ii) *Bass attenuation by grid coupling condensers* (iii) *Bass attenuation by cathode resistor by-passing* (iv) *Bass attenuation by screen by-passing* (v) *Bass attenuation by reactance shunting* (vi) *Bass attenuation by negative feedback* (vii) *Bass attenuation by Parallel-T network* (viii) *Bass attenuation using Constant k filters* (ix) *Bass attenuation using M -derived filters.*

(i) General remarks

It is desirable for any amplifier to have bass attenuation, although the frequency at which attenuation commences, and the rate of attenuation, should be carefully determined during the design.

Shortwave receivers are often fitted with about 6 db/octave attenuation below about 150 c/s. In multi-band receivers the attenuation may be incorporated only on the bands where it is desired. A preferable arrangement is to incorporate a choice of two or three bass cut-off frequencies, say 150, 250 and 400 c/s—this is usually only practicable in communication type receivers. This extreme attenuation is only usable under bad conditions for barely intelligible speech. A slight degree of attenuation is helpful in eliminating acoustical feedback to gang condensers and valves and other minor receiver troubles, as well as giving better listening under average shortwave conditions.

Conventional table and mantel model receivers may have an ultimate attenuation of 12 db/octave below say 100 and 150 c/s respectively. Conventional consoles may have a similar attenuation below 80 c/s, but this may be extended down to say 60 c/s in the case of those having loud-speakers capable of handling the lower frequencies. Fidelity amplifiers should have an ultimate attenuation of 18 db/octave below the lowest frequency which the loudspeaker and output transformer can handle at maximum power output without distortion. Fidelity amplifiers incorporating negative feedback should connect the filter prior to the main amplifier input terminals.

(ii) Bass attenuation by grid coupling condensers

Every grid coupling condenser introduces some bass attenuation, and it is a matter of good design to select a value to provide the best overall performance of the equipment. The choice of a capacitance to give a known attenuation at a certain frequency is covered in Chapter 12 Sect. 2(ii) and Fig. 12.9A. Each coupling condenser gives an ultimate 6 db/octave attenuation. If it is desired to eliminate low frequency interference or to reduce hum, the coupling condensers may be designed to have identical frequency characteristics, thus giving 12 or 18 db/octave attenuation for 2 or 3 stages respectively. Even if the grid resistors differ in resistance, the frequency characteristics may be made the same by maintaining the same value of time constant RC . This method does not apply to the design of feedback amplifiers (see Chapter 7 Sect. 3).

Communication receivers are usually fitted with a switch giving the choice of 2 or 3 bass attenuation characteristics—this may operate by changing the value of grid coupling condenser, or by any other convenient means.

Typical attenuation/frequency characteristics for 1, 2, and 3 stages having identical time constants are given by curves 1, 2 and 3 in Fig. 15.19.

(iii) Bass attenuation by cathode resistor by-passing

The attenuation/frequency characteristics of a resistance-coupled triode with by-passed cathode resistor are given in Chapter 12 Sect. 2(iii) and Fig. 12.3A for a typical case. These frequency characteristics differ from those for grid coupling condensers in that they are limited to a maximum attenuation which is usually less than 10 db, typical values for r.c. triodes being from 3.7 to 8 db (Chapter 12). Frequency characteristics for a typical r.c.c. pentode with by-passed cathode resistor are given in Fig. 12.12, the total attenuation being nearly 8 db in this example.

The shape of a typical attenuation/frequency characteristic is illustrated by Curve 4 in Fig. 15.19.

Fig. 15.19. Bass attenuation versus frequency characteristics : (1) Single grid coupling condenser ($R = 1$ megohm, $C = 0.005 \mu F$) ; (2) Two stages each with identical values of time constant RC ; (3) Three stages each with identical values of time constant ; (4) R.c.c. pentode with by-passed cathode resistor (6J7, $R_L = 0.25 M\Omega$, $R_k = 2000 \Omega$, $C_k = 0.5 \mu F$) and screen adequately by-passed.

(iv) Bass attenuation by screen by-passing

The attenuation/frequency characteristics of a r.c.c. pentode with a by-passed screen are given in Chapter 12 Sect. 3(iii) and Fig. 12.11A. These characteristics have the same general form as those for cathode resistor by-passing, with a maximum attenuation which is a function of the series screen resistor—with a high resistance series resistor a typical maximum attenuation is 24 db (see Chapter 12). Although the screen by-pass condenser could be used as a step type tone-control, the use of a low capacitance by-pass generally necessitates additional screen filtering for the elimination of hum.

It is possible to design an amplifier so that all grid coupling condensers, cathode and screen by-pass condensers have the same attenuation (say 2 db each) at the same frequency. In such a case, particularly if there are two or more stages, the rate of change of attenuation becomes quite high, although the cathode and screen by-passing tends to introduce steps in the characteristic. However, care is necessary with tolerances—see Sect. 1(x).

(v) Reactance shunting

Any inductance, whether a-f transformer or output transformer, causes ultimate 6 db/octave attenuation below a certain frequency. If the amplifier is to provide good fidelity, it is advisable to design so that this frequency is below the lower frequency limit of the whole amplifier. In other cases, the cut-off frequencies may be made to coincide for more rapid attenuation—however see Sect. 1(x).

If a transformer primary is resonated with the coupling capacitance, in the case of parallel-feed, the ultimate rate of attenuation below the resonant frequency is 12 db/octave.

Owing to the wide tolerances in inductance normally occurring in quantity production, and to the variation caused by the d.c. and signal currents, it is not considered good practice to use the transformer primary resonance for tone control purposes ; a further contributory factor is the increased valve distortion caused by a low impedance load—see Chapter 12 Sect. 4(xii).

If it is desired to vary the cut-off frequency of an a-f transformer with parallel feed, a variable resistor may be inserted to adjust the equivalent source impedance (R_1 in Fig. 15.20). The low frequency attenuation (Ref. 51) is

$$\text{attenuation in db} = 10 \log_{10} [1 + (R/X_1)^2] \quad (1)$$

where $R = R_1 + [r_p R_L / (r_p + R_L)]$

$$X_1 = \omega L_1$$

and L_1 = primary inductance in henrys.

(vi) Bass attenuation by negative feedback

A network may be inserted in the feedback loop which reduces the feedback voltage at middle and high audio frequencies, thus effectively giving bass attenuation (Fig. 15.21, Ref. 23). Condenser C_2 is merely for blocking the d.c. path, while R_1 , R_2 and C_1 form a voltage divider across the output voltage of V_2 . The voltage drop across R_2 and C_1 is applied across R_3 , thus applying the feedback voltage between V_1 cathode and earth.

FIG. 15.20

FIG. 15.21

Fig. 15.20. Amplifier, giving variable low-frequency cut-off using a-f transformer and parallel feed.

Fig. 15.21. Amplifier providing bass attenuation by negative feedback (Ref. 23).

(vii) Bass attenuation by Parallel-T network

The parallel-T network—Chapter 4 Sect. 8(iii)—may be used to provide infinite attenuation at one frequency. An example of its application is Fig. 15.22 and the frequency characteristic is given in Fig. 15.23. In its simple form the attenuation is severe even at frequencies five times the frequency giving infinite attenuation. One suggested way of providing a more level characteristic is to incorporate bass boosting around 200 c/s (Ref. 59).

FIG. 15.22

Fig. 15.22. Amplifier providing bass attenuation by Parallel-T network (Ref. 59).
Fig. 15.23. Frequency characteristics of amplifier Fig. 15.22 when V_1 = typical r.c.c. pentode, $C_1 = 0.001 \mu F$, $C_2 = 0.004 \mu F$, $C_3 = 0.02 \mu F$, $R_1 = R_2 = 2 M\Omega$, $R_L = 0.2 M\Omega$, $R_v = 0.5 M\Omega$. The frequency for infinite attenuation is 56 c/s.
Switch position (1) Fidelity (2) Bass attenuation (Ref. 59).

(viii) Bass attenuation using Constant k filters

If it is desired to achieve a rapid rate of attenuation and a sharp cut-off, it is necessary to use some form of correctly designed filter incorporating both inductors and capacitors. The constant k filter [Chapter 4 Sect. 8(vii)] in its simplest form only incorporates 2 condensers and 1 inductor. An example of its incorporation in an amplifier is Fig. 15.24 (Ref. 60). This filter is fairly non-critical as regards the inductance of L , a 2:1 variation still giving a reasonable characteristic with, of course, a change in cut-off frequency. The frequency characteristic obtained with balanced loading is Fig. 15.25 Curve 1; when the source impedance is 50 000 ohms and load 0.5 megohm the frequency characteristic is curve 2, showing the typical rise above 0 db due to unbalanced conditions; curve 3 shows the effect of increasing the resistance of the inductor L .

If sharper attenuation is required, two or more filter sections may be incorporated.

Fig. 15.24. Amplifier providing bass attenuation by constant k filter (Ref. 60).
 Fig. 15.25. Frequency characteristics of amplifier Fig. 15.24 when V_1 = typical r.c.c. pentode, $C_1 = C_2 = 0.002 \mu\text{F} \pm 5\%$, $C_3 = 1 \mu\text{F}$, $L = 70 \text{ H}$ with $Q = 6$; Curve (1) $R_1 = R_2 = 0.25 \text{ M}\Omega$; Curve (2) $R_1 = 50\,000 \Omega$, $R_2 = 0.5 \text{ M}\Omega$ (unbalanced); Curve (3) as Curve 2 with additional resistance in inductor to give $Q = 3$ (Ref. 60).

(ix) Bass attenuation using M-derived filters

One T section of an M-derived filter may be used to provide a more rapid attenuation than that of a Constant k filter—see Chapter 4 Sect. 8(viii). The filter itself is shown in Fig. 15.26 and the frequency characteristics for balanced and unbalanced impedances in Fig. 15.27. Here, also, a considerable tolerance is permissible with the value of L and in the degree of mismatching. With mismatching, the value of R may be taken as $\sqrt{R_1 R_2}$ (Ref. 60).

Fig. 15.26. One T section of a series M-derived filter.

Fig. 15.27. Frequency characteristics of filter Fig. 15.26; Curve (1) $R_1 = R_2 = 0.25 \text{ M}\Omega$, $C_1 = 0.0023 \mu\text{F}$, $C_2 = 0.024 \mu\text{F}$, $L = 74 \text{ H}$; Curve (2) $R_1 = 50\,000 \Omega$, $R_2 = 0.5 \text{ M}\Omega$ (unbalanced), $C_1 = 0.0058 \mu\text{F}$, $C_2 = 0.035 \mu\text{F}$, $L = 73 \text{ H}$ (Ref. 60).

SECTION 4: COMBINED BASS TONE CONTROLS

(i) *Stepped controls* (ii) *Continuously variable controls.*

(i) Stepped controls

A typical stepped control (Fig. 15.28) has 2 positions giving bass boost, 1 giving "flat" response, and 2 giving bass attenuation. The values of capacitance may be selected to give the desired frequency characteristics.

See also Sect. 8 for combined bass and treble tone controls, particularly Figs. 15.37A, 15.37B, 15.39, 15.40.

References 17, 50, 54, 55, 64.

Fig. 15.28. Step-control giving bass boosting and bass attenuation.

(ii) Continuously variable controls

Circuits providing only bass boosting or attenuation with a single continuously variable control are not widely used.

SECTION 5: TREBLE BOOSTING

(i) *General remarks* (ii) *Circuits not involving resonance or negative feedback*
(iii) *Methods incorporating resonant circuits* (iv) *Circuits involving feedback.*

(i) General remarks

Treble boosting, mainly on account of the increased distortion which it causes, is usually avoided altogether or else used only for the purpose of equalizing an unavoidable attenuation in the amplifier at the maximum frequency limit.

The subject of distortion has been covered in Section 1(iv).

(ii) Circuits not involving resonance or negative feedback

(A) Conventional treble boosting circuit (Fig. 15.29)

This is an adaptation of the fundamental circuit Fig. 15.2. It may be shown that

$$\text{Gain at low frequencies} = \frac{\mu R R_2}{(R_1 + R_2)(R + r_p) + R r_p} \quad (1)$$

$$\text{Gain at very high frequencies} = \frac{\mu R'}{R' + r_p} \quad (2)$$

where $R = R_L(R_1 + R_2)/(R_L + R_1 + R_2)$

and $R' = R_2 R_L/(R_2 + R_L)$.

Then B = ratio of amplification at very high frequencies to amplification at low frequencies

$$= 1 + \frac{R_1}{R_2 + R''} \quad (3)$$

where $R'' = r_p R_L/(r_p + R_L)$.

We may determine the value of R_1 for any desired value of B from the equation

$$R_1 = (B - 1)(R_2 + R'') \quad (4)$$

In the case of pentodes, R'' approximates to R_L .

The frequency characteristics for treble boosting have been plotted (Ref. 51 Fig. 9.18; also Refs. 9,55) but for most purposes it is sufficient to work on the "half-boost" points as for bass boosting, the curves being approximately symmetrical S curves about these points. The values of R/X for the half-boost point are identical to those for bass boosting, and not the inverse as might be expected.

Total boost	20	15	10	6	3	db
Half boost	10	7.5	5	3	1.5	db
Boost ratio (B)	10	5.62	3.16	2.0	1.41	
(R_1/X_1) for half boost*	3.16	2.37	1.78	1.41	1.19	
C_1 †	$3.16/\omega R_1$	$2.37/\omega R_1$	$1.78/\omega R_1$	$1.41/\omega R_1$	$1.19/\omega R_1$	F

* $(R_1/X_1) = \sqrt{B}$ at half boost point.

$X_1 = 1/\omega C_1$

† $C_1 = 1/\omega X_1 = (R_1/X_1)/\omega R_1$

$\omega = 2\pi f_0$

where R_1 and C_1 are as shown in Fig. 15.29

and f_0 = frequency at half-boost point.

A variable control may be achieved in various ways (Ref. 9):

(a) Varying C_1 —This can only be done in steps. The result is to change the frequency of the half-boost point (see table).

(b) Varying R_1 —This varies the amplification for middle frequencies, and is unsatisfactory for tone control purposes.

(c) Adding a variable resistor in series with C_1 —This is fairly effective but the shapes of the frequency characteristics are not ideal for tone control. It is used in a slightly modified form in the combined bass and treble boost circuit of Fig. 15.46.

References to conventional treble boosting circuit: 9, 17, 48, 51, 55.

Fig. 15.29. Conventional treble boosting circuit.

Fig. 15.30. Treble boosting with inductance in grid circuit.

(B) Using inductance in grid circuit (Fig. 15.30)

This gives the same shape of frequency characteristics as the conventional treble boosting circuit. The same expressions may be used except that in this case

$$X_1 = \omega L_1 \text{ and } B = R_1/R_2$$

where $R = [r_p R_L / (r_p + R_L)] + R_1$.

If R_1 is made variable, it has a very pronounced effect on the gain at middle frequencies. A preferred method of tone control is to use a step switch and tappings on the inductance (see Sect. 8 and Fig. 15.40).

References 17, 51.

(C) Correction for side-band cutting

The methods which may be used for the equalization of side-band cutting in a receiver are described in Refs. 3 and 62.

(iii) Methods incorporating resonant circuits

Resonant circuits are rarely used for treble boosting tone control since there are other preferable methods which give the required performance (Ref. 17).

(iv) Circuits involving feedback

(A) Cathode resistor by-passing

If a suitable small capacitance is used as a by-pass condenser across any cathode resistor, a limited degree of treble boosting will be achieved. In the case of resistance-coupled amplifiers the maximum boost is not more than 6 or 8 db. Greater boosting may be achieved by increasing the cathode resistor and returning the grid resistor to a suitable tapping point in the cathode circuit.

(B) Network in feedback loop

The same method may be used as for bass attenuation—see Sect. 3(vi) and Fig. 15.21.

SECTION 6 : TREBLE ATTENUATION

(i) *General remarks* (ii) *Attenuation by shunt capacitance* (iii) *Treble attenuation by filter networks* (iv) *Treble attenuation in negative feedback amplifiers.*

(i) General remarks

Every amplifier should have a maximum frequency of response, beyond which attenuation should be at a rate of not less than a nominal 12 db per octave for conventional amplifiers or 18 db per octave for fidelity amplifiers. This attenuation may be partly prior to the input terminals of the main amplifier or in the early stages of the amplifier, and partly (at least 6 db/octave) at the output end.

Because the simplest methods of treble attenuation have a gradual commencement, there tends to occur a rounding of the response curve which may be appreciable at the maximum frequency of response. It is suggested that 2 db attenuation at this frequency is a reasonable compromise, or even higher attenuation for other than fidelity amplifiers, but where an amplifier must be designed within narrow tolerances it is generally necessary to use one of the more elaborate methods of attenuation.

In the case of amplifiers incorporating negative feedback, the filter to provide the attenuation must be outside the feedback loop.

(ii) Attenuation by shunt capacitance

The theory has been covered in Chapter 4 Sect. 8(ii) under the heading “r.c. low-pass filter” with the circuit of Fig. 4.37; the attenuation characteristic is given in Chapter 4 eqn. (4) and plotted in Fig. 4.38.

FIG. 15.31

Fig. 15.31. Typical “tone control” used in radio receivers. In a typical case $C_1 = 0.05 \mu F$, $R_1 = 50\,000 \Omega$ (max.), $V_1 =$ power pentode with load resistance about 5000 ohms.

This forms part of the usual “tone-control” in many radio receivers of the less expensive class, as illustrated in Fig. 15.31. The control is in the form of a variable resistance in series with the capacitance which limits its attenuation. A suitable

maximum value for the resistance is 10 times the load resistance. In some cases a fixed capacitance only is used—typical values are from 0.005 to 0.02 μF for a loud-speaker load resistance of 5000 ohms. In this application the “effective resistance” for the calculation of the attenuation will be the loudspeaker impedance in parallel with the output resistance (R_o) of the amplifier.

Tone control by shunt capacitance, when used with discrimination, is fairly satisfactory with a flat amplifier operating from an equalized source. It is far from satisfactory in selective radio receivers in which the high audio frequencies are already heavily attenuated; this effect is minimized when variable selectivity i-f amplifiers are used. One reason for the popularity of shunt capacitance tone control is that the intermodulation frequencies produced by the distortion in the pentode or beam power amplifier valve are much reduced, and listening thereby made less fatiguing. If methods are taken to reduce the distortion, e.g. by negative feedback, the tone control may preferably take the form of bass boosting.

In order to achieve the desired treble attenuation, a shunt capacitance may be placed across the source (radio receiver, pickup or microphone), from any grid to earth, from any plate to earth or across the output terminals of the amplifier. In each case the effective resistance (R in eqn. 4 of Chapter 4 and Fig. 4.38) is the resultant a.c. resistance between the points across which the shunt capacitance is connected. In the case of a r.c.c. pentode it is approximately the load resistance in parallel with the following grid resistor, and it does not make any appreciable difference whether the capacitance is shunted across the plate load resistor or the following grid resistor, owing to the coupling through the grid coupling condenser. Even if no shunt condenser is added, the output capacitance of the valve plus the dynamic* input capacitance of the following valve plus wiring capacitances provide appreciable treble attenuation—see Chapter 12 Sect. 2(xi). The effect on treble attenuation may be reduced by reducing the plate load resistance; it may be increased by increasing the plate load resistance or by adding shunt capacitance. A typical r.c.c. pentode followed by a similar stage has only slight attenuation at 10 000 c/s when the load resistance is less than 0.25 megohm. In the case of a r.c.c. triode the effective resistance is the plate resistance of the valve (under r.c.c. conditions) in parallel with the load resistance and the following grid resistance.

In the general case the effective resistance is given by

$$R = R_s + R_L' r_p / (R_L' + r_p) \quad (1)$$

where R_s = resistance in series with C as part of the tone control,

$$R_L' = R_L R_g / (R_L + R_g)$$

R_L = load resistance

R_g = following grid resistance

and r_p = plate resistance of valve.

With a high- μ triode such as type 6SQ7 the effective input capacitance is of the order of 100 μF . If this capacitance is shunted across an effective resistance of 0.5 megohm, the attenuation is about 10 db at 10 000 c/s.

The **total attenuation** at any frequency will be the attenuation at that frequency prior to the amplifier plus the sum of the attenuations of the stages in the amplifier at that frequency plus the attenuation by the shunt capacitance at that frequency, all expressed in db. It is not sufficient to assume an attenuation of 6 db/octave from each stage in the amplifier unless all the stages have the same cut-off frequency. In the general case it is necessary, for design purposes, to calculate the attenuation of each stage or filter for convenient frequencies, e.g. 10 000, 14 000, 20 000, 28 000, 40 000 c/s and then to add the values in db to determine the overall attenuation characteristic. The latter will, eventually, almost reach a slope of 6 db/octave per stage or per shunt capacitance, but the knee of the curve will be very rounded unless the cut-off frequencies are identical.

*Under operating conditions, including the “Miller Effect” capacitance from the plate.

(iii) Treble attenuation by filter networks**(A) Constant k low-pass filter**

An approximate Constant k low-pass Π section filter to provide a nominal treble attenuation of 24 db/octave with the choice of several cut-off frequencies is shown in Fig. 15.32. This is intended to be connected between a pickup or microphone pre-amplifier and the main amplifier. For theory see Chapter 4 Sect. 8(vii) and Fig. 4.49. In reality only C_2 has been calculated to give a constant k filter for the correct terminating impedances, and C_1 and C_3 have been calculated merely to give the desired cut-off frequencies leaving L unchanged. Thus it is only a constant k filter on tapping 3 and a sufficiently close approximation on the other tappings. A considerable degree of mismatching is permissible between R_1 and R_2 provided that $\sqrt{R_1 R_2} = 0.1$ megohm.

The calculation of the constant k filter is based on the expressions :

$$L/C = R^2 \text{ (see Fig. 4.49C for symbols)}$$

$$f_0 = 1/\pi\sqrt{LC} \text{ where } f_0 = \text{cut-off frequency.}$$

FIG. 15.32

Fig. 15.32. Approximate constant k low-pass Π section filter. $R_1 =$ source impedance. When $R_1 = R_2 = 0.1 \text{ M}\Omega$, $L = 5 \text{ H}$, $C_1 = 0.0001$, $C_2 = 0.0002$ and $C_3 = 0.0004 \text{ }\mu\text{F}$, the cut-off frequencies will be (1) none (2) 10 000 c/s (3) 7000 c/s (4) 5000 c/s.

(B) M-derived filters

One T section of an M-derived filter may also be used for treble attenuation. See remarks for bass attenuation.

(C) Parallel-T network

The parallel-T network—Chapter 4 Sect. 8(iii)—may be used to provide infinite attenuation at one frequency but the rate of attenuation begins very gradually. One improvement is described in Chapter 17 Sect. 5(iv) Figs. 17.24B and 24C (Ref. 57). See also Sect. 11(iv).

(iv) Treble attenuation in negative feedback amplifiers

A network may be inserted in the feedback loop to reduce the feedback voltage at low and middle audio frequencies, thus effectively giving treble attenuation. The circuit is effectively the same as for bass boosting (Fig. 15.11) except that the capacitance is selected to give the required frequency characteristics. See also Ref. 23, Fig. 9.

There have been many negative feedback circuits which give a measure of tone control among which are—

(A) Fig. 15.33. This circuit incorporates a very small condenser C (of the order of 10 to 100 μF) to provide some negative feedback at the higher audio frequencies without seriously affecting the gain at 400 c/s. This is only fully effective when no plate by-pass capacitor is used.

Fig. 15.33. Power amplifier valve with small condenser C giving negative feedback at high audio frequencies (treble attenuation).

Fig. 15.34. Power amplifier valve with variable negative feedback at high audio frequencies (treble attenuation).

(B) Fig. 15.34 is a development of Fig. 15.33 to provide continuously variable tone control. The feedback condenser is larger and a potentiometer is used in the grid circuit to control the tone. At maximum treble cut it gives an attenuation of 28 db at 20 000 c/s (Ref. 39).
